

GENERAL QUESTIONS OF ANESTHESIOLOGY

Fundamentals of anesthesia

1.1. Historical information

People always wanted to overcome the sufferings caused by pain. The history of civilization left numerous documented evidences of permanent search for ways and methods of anaesthesia. The first written mention of the pain relieving medicines was found in Egypt (described in Ebers papyrus 4 - 5 thousand years ago). Much attention was paid to this problem by the doctors of ancient Greece and Rome. They used wine, mandrake root, opium, Indian hemp, henbane and thorn-apple. In the East, in the mountains of Tibet, acupuncture and massage were widely used with anaesthetic aim.

However, until the eighteenth century there was no radical ways of pain relieving. At this time, because of the fundamental discoveries in natural sciences the preconditions of new medical possibilities appeared. In 1776 chemist Priestley synthesized nitrous oxide - an anaesthetic, which is still widely used in anaesthesiology. Another chemist, Davy, on April 9, 1779 for the first time tested the effect of nitrous oxide on himself. Later he wrote: "Nitrous oxide, along with other properties, has the ability to relieve pain and thus can be successfully used in surgical operations". And only 25 years later, an English surgeon Hickman began to use the "laughing gas" in medical practice. However, this method of anaesthesia had not received adequate acceptance in Europe. At the same time in America dentist Wells began to apply nitrous oxide anaesthesia. In April 1842 his compatriot surgeon Long first used ether anaesthesia in practice. (It should be noted, that diethyl ether was synthesized by well-known chemist Paracelsus a few centuries before). With ether anaesthesia Long performed eight operations, and his observations were never published.

However, priority in the use of ether narcosis belongs to another American researcher - Morton. On October 16, 1846 at Boston University clinic he successfully administered ether narcosis during surgical removing of hemangioma in public. The operation was performed by surgeon Warren. A special Morton's contribution was a preliminary study of ether narcosis effect on animals, which was the beginning of the experimental study of general anaesthesia techniques.

Therefore, the 16th of October, 1846 is considered to be the birthday of anaesthesiology.

In few months enthusiastic followers of ether narcosis appeared in all civilized countries. At the beginning of February 1847 this type of narcosis was performed by professor F.I. Inozemtsev in Moscow clinic, two weeks later it was performed in St. Petersburg by our compatriot, surgeon Mykola Ivanovych Pirogov. This outstanding surgeon and the first anaesthesiologist played prominent role in the history of ether narcosis. He was the first to argument theoretical basis for the action mechanism of ether on the central nervous system; he proposed alternative ways of administration of ether (into the trachea, in the blood, into the gastrointestinal tract). Invaluable experience of ether narcosis M. I. Pirogov described in his monograph “On the application of sulphuric ether vapours in operational medicine” published in 1847.

In the Crimean-Turkish war (1853 – 1856) our compatriot performed hundreds of successful ether anaesthesias during surgeries on gunshot injuries.

In 1937 Guedel determined the clinical stages of ether narcosis, which are still considered to be classic.

In 1847 a prominent scientist Simpson introduced into clinical practice another preparation for narcosis - chloroform.

Since that time anaesthesiology has begun its scientific development.

For 150 years of anaesthesiology history scientists proposed and implemented in clinical practice dozens of anaesthetic preparations, both inhalation and non-inhalation, as long as various types and methods of pain relief. This stimulated development of operative surgery and allowed various range of surgical interventions in all organs and systems of the body.

Anaesthesiology is a science that studies how to protect the organism from operating injuries. It improves the well-known and develops new methods of preparing patients for surgeries, providing anaesthesia, controlling the body functions during the operation and in postoperative period.

1.2. Preparing of the patients for the surgery

During the preoperative period an anaesthesiologist should evaluate the patient's condition (main disease and comorbidities, degrees of their compensation), provide correction of health disorders, prevent complications that may occur during the operation, etc. In another words anaesthesiologist should create perfect conditions to perform anaesthesia with the largest adequacy and the least harm to the patient.

The tasks of an anaesthesiologist are:

1. Evaluation of somatic and mental condition of the patient:
 - determine the severity of main disease, concerning operation, which is planned;
 - identify comorbidities (of the cardiovascular, respiratory, digestive, nervous and endocrine systems, etc.);
 - define the psychological and emotional state of the patient (his/her attitude to future operations, anaesthesia, etc.).
2. Preoperative preparation of the patients.
3. Determination of the anaesthetic risk level.
4. Choice of the best anaesthesia method.
5. Postoperative treatment.

In the preoperative period it is essential to clarify the nature of operation: planned, urgent or emergency:

- a) in case of planned surgeries with decompensated comorbidities there should be an adequate therapy performed at first; If necessary ask other specialists to take part in the treatment;
- b) if an operation is urgent the main vital parameters should be stabilized in short term, further correction should be made during the operation;
- c) in case of emergency the patient is transferred to the operating room as soon as possible, as anaesthesia and surgery are critical factors in saving his/her life. Stabilization of vital functions is achieved on the operating table.

During the examination of the patient special attention should be paid to the condition of

the central and peripheral nervous system (mental and emotional lability, sleep disorders, the presence of anxiety and fear, paresis and paralysis). Constitution of the body, anthropometric data (weight and height) should be determined. The attention is paid to the subcutaneous fat and its distribution, peripheral veins.

While examination should be assessed: the skin and its colour, temperature, humidity and turgor of tissues (particular attention is paid to the capillary refill - press the nail of the patient for 5 seconds and if the white spot after pressing will not disappear in 2 seconds microcirculation is violated); anatomical features of the upper respiratory tract: the width of mouth opening, the size of oral cavity, presence of dentures, caries teeth, type of bite, the size of the tongue, size of tonsils, size of the nasal passages; shape of the neck and its size, the size of the thyroid gland.

Reserves of respiratory system are determined by spirometry tests (breath-holding after maximal inspiration and expiration – tests of Stange and Hensch). Normally they are 50 - 60 sec. and 35 - 45 sec., respectively. If necessary, more detailed study called spirometry is made.

The breathing rate should be determined and the chest should be examined (palpation, percussion and auscultation).

While assessing the state of the cardiovascular system, it is necessary to auscultate the heart, measure blood pressure and evaluate the pulse. In case of cardiac rhythm disorders, it is necessary to measure pulse deficit (the difference between the heart rate and the pulse rate on the radial artery per minute). An electrocardiogram should be made in order to make a detailed study of the disorder.

Examination of the digestive system should start from the tongue, which gives information about the degree of organism dehydration (dry tongue, marked buds, available longitudinal grooves), the severity of stomach inflammation (the tongue is coated), convulsions in anamnesis (scars on the tongue from biting), manifestations of avitaminosis and fungal diseases ("geographic", raspberry tongue). Also the inspection, palpation, percussion and auscultation of the abdomen should be made. Always check the symptoms of peritoneal irritation and muscular defence of the anterior abdominal wall. Ask the patient about the distension of the abdomen, nature, and frequency of defecations.

The urinary system should be assessed by palpation of the kidneys and lower abdomen (projection areas of the bladder), check of Pasternacki symptom. The frequency, volume and nature of urination, colour and odour of the urine should be determined. In urgent and emergency surgery with suspicion of renal insufficiency the bladder should be always catheterized in order to control the urination during surgery.

Don't forget to assess the probability of thrombosis: identify peripheral veins of lower extremities, swelling and pain of the ankles. Laboratory tests and instrumental examinations are also very important. The required minimum of these examinations depends on the urgency of an operation.

In emergency surgery as soon as possible (often right during the operation) the following

analyses are made:

1. Clinical blood test.
2. Clinical urine analysis.
3. Blood group and Rh identification
4. ECG .
5. Glucose control.

Urgent operational interventions allow to perform the listed above diagnostic minimum is necessary in the preoperative period and also require:

6. X-ray examination of the chest.
7. Examination of the patient by a therapist (paediatrician) or a required specialist.

In preparing patients for planned operational interventions the functions of other organs and systems are examined in a more detailed way:

8. Biochemical analysis of the blood (bilirubin, urea, creatinine, protein and its fractions, electrolytes, coagulogram, transaminase, cholinesterase, etc.).

9. Functional tests to determine the degree of compensation of the respiratory, cardiovascular, central nervous systems, organs of detoxification and secretion (according to the indications).

10. Special instrumental investigations (endoscopy, angiography, ultrasound examination, scanning, etc.).

After you found a disease, which requires preoperative correction, treat it together with other leading experts and a responsible doctor. Duration of the therapy is limited on the one hand, by the nature and degree of compensation of this disease, on the other hand – by emergency of planned surgery.

2. Preoperative preparation of the patients (premedication) is divided into previous and immediate.

Previous premedication is a treatment given to the patients hours before the surgery (usually in the evening before the invasive procedure). It includes therapy of different dysfunctions as well as sedative treatment.

One of the obligations of the anaesthesiologist is to provide psychological and emotional comfort to the patient before the surgery. To achieve this aim use the following:

- psychological effect of medical personnel - soothing, honest conversation of an anaesthesiologist with the patient, including explanation of the basic stages of future operation and anaesthesia, provides the sense of a confidence and develops belief in favourable outcome of the treatment;

- sedative and analgesic therapy (therapeutic doses of benzodiazepines and sleeping pills for example).

A full, deep sleep and psycho-emotional balance of the patients before the surgery are very important for prevention of undesirable reactions of the vegetative and endocrine systems. They allow to create the best background for the uncomplicated introduction and providing of anaesthesia with quick end of narcosis.

Preparation of the gastrointestinal tract includes one obligatory condition - "empty stomach" (in order to prevent aspiration of gastric contents into the lungs). The patients should:

- follow the light diet during 2 – 3 days before the operation;
- not to eat at least 6-8 hours before the surgery;
- take H₂blockers (ranitidine, cimetidin, etc.) before an operation to reduce gastric juice production and decrease its acidity;
- undergo cleansing enemas (in the evening and in the morning before an operation, however not before all surgeries; this method plays an important role in detoxification of the organism and soon restoration of the intestinal peristalsis in the early postoperative period;

In cases of urgent surgical interventions stomach should be clean with inserted gastric probe 1 hour before the operation; give 200 mg of cimetidine solution intravenously and 15 - 20 min. before the anaesthetic introduction ask the patient to drink 15 ml of 0.3 M sodium citrate solution.

Those steps will minimize the risk of vomiting, regurgitation and aspiration of the gastric

contents into the airways (one of the most common and severe complications of anaesthesia).

Immediate premedication in planned surgery is performed 30-40 minutes before the intervention. The classical scheme includes such medicines (given i/m):

- a) peripheral M-cholinolytics (0.1% atropine sulphate solution or 0.1%, metacin solution, dose: 0.01 mg / kg);
- b) antihistaminic drug (1% dimedrol solution or 2.5%, pipolfen solution, 1-2 ml of 2% suprastin solution);
- c) narcotic analgesics (1ml of 2% promedol solution or morphine hydrochloride, dose: 0.4 mg / kg).

In urgent operations premedication medicines are often used intravenously (right before induction). If there are special indication you can include into the typical premedication other medicines, such as: tranquilizers (2-4 ml of 0.5% Diazepam solution, 0.25% droperidol solution, etc.), non-narcotic analgesics (2 ml of 50% analgin solution, 5 ml of baralginum solution, etc.), steroids (60-90 mg of prednisolone solution), etc.

You should avoid rapid intravenous administration of antihistamine preparations, tranquilizers and narcotic analgesics in patients with deficiency of circulating blood volume due to the high probability of hypotension!

With properly chosen and performed premedication the patient is calm and a bit sleepy before the operation and to the operating-room he/she is transported on a trolley.

3. Evaluate the anaesthetic risk before each surgery. In Ukraine we traditionally used the classification of risk degrees proposed by V. Holohorskyi in 1982. It includes:

I. Somatic condition of the patients:

1. The patients without organic pathology or with local disease without systemic disorders.
2. The patients with light or moderate systemic disorders associated or not associated with surgical pathology, which moderately violate general condition.
3. The patients with severe systemic disorders, associated or not associated with surgical pathology that significantly violate vital functions.
4. The patients with the most severe systemic disorders associated or not associated with surgical pathology, which are life-threatening.
5. The patients in critical condition who can die within 24 hours with or without the surgery.

II. The severity of operative intervention.

- A. Small operations on the body surface and hollow organs (uncomplicated appendectomy

and hernial plastic, haemorrhoidal surgeries, amputation of fingers, etc.).

B. Operations of average size (amputation of the limb segments, complicated appendectomy and hernial plastic, peripheral vascular surgery).

C. Large operations (radical operations on the organs of the chest and abdomen, enlarged limb amputations).

D. Operations on the heart and main vessels.

E. Emergency surgery.

For example: a young patient without comorbidities is prepared for planned biliary tract surgery (calculous cholecystitis). The degree of operational risk is 1C. However, biochemical examination has revealed high level of glucose, and diabetes mellitus was diagnosed. Thus the degree of operational risk is 2C. In case of emergency operations of the same patient, the risk degree will be 2CE.

Now ASA (American Society of Anaesthesiologists) classification is widely used.

The tasks of medical staff in preparing of the patient to the surgery are:

- to create best conditions for psychological comfort of the patient. The appearance of the medical personnel should reassure the patient. Neat uniforms, accurate fulfilment of various manipulations, calm voice, encouraging smile and soothing conversation of a nurse or doctor are very important for the patient and develop confidence in a successful outcome of the treatment;

- to monitor changes of the patient's state (colour of the skin, consciousness, body temperature, character of the respiration, blood pressure and pulse, urination volume, etc.);

- to perform clearly, professionally and skilfully the necessary manipulations (getting of i/v access; taking of blood samples for laboratory tests; intravenous, intramuscular and subcutaneous injections; insertion of gastric and urinary probes, etc.);

- to follow the rules of asepsis and antisepsis in the department;

- to perform premedication in a ward or in the operating room.

Remember, that some medicines must not be mixed in one syringe, like narcotics and atropine. After effective premedication patients can feel sleepy, so as it was mentioned above they are transported on a trolley to the operating room (don't forget to control their condition during the transportation).

1.3 Anaesthesia and its preparations.

Anaesthesia is a set of methods applied to patients during operations and painful manipulations in order to protect their life and health.

Anaesthesia includes the following components:

- drug-induced sleep;

- pain relieve;
- neuro-vegetative protection;
- muscle relaxation;
- adequate ventilation;
- optimal level of blood circulation;
- normalization of metabolic processes in tissues.

Narcosis (from 'narkosis' - get torpid) is the process of temporary reversible depression of the central nervous system caused by pharmacological agents.

Analgesia (from Greek 'analgesio' - no pain) – absence of pain sensitivity.

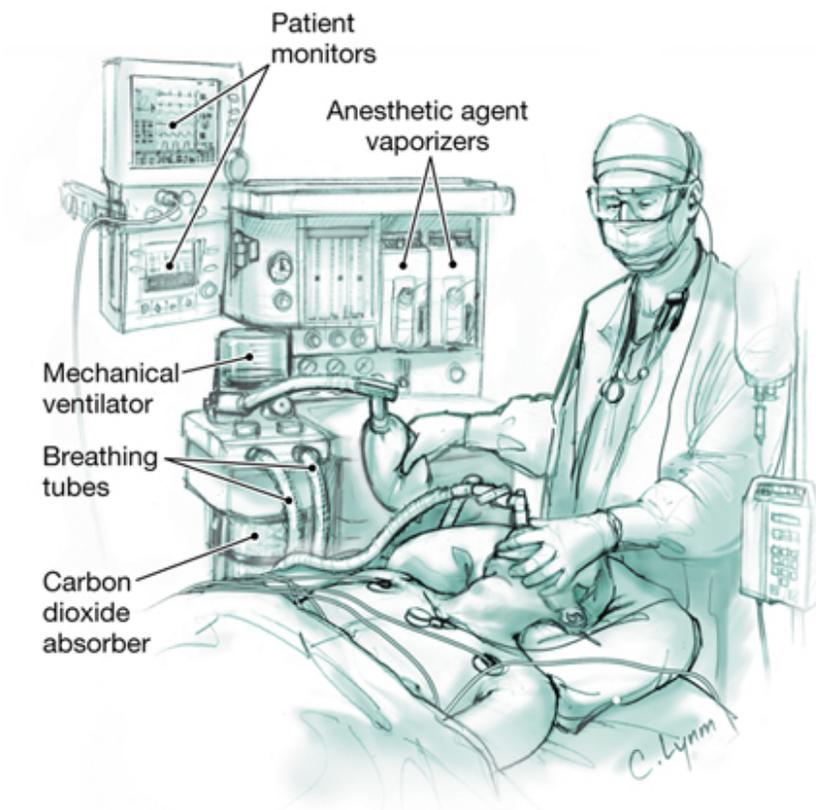

Anaesthesia (from Greek 'anaestasio' – loss of sensation) - a set of methods used to remove all kinds of sensitivity.

Anaesthetics - pharmacological agents, which eliminate sensitivity.

Anaesthetics can have general (agents for narcosis) or local action (medicines for regional anaesthesia).

Depending on the way of admission anaesthetics are divided into inhalational and non-inhalational (mostly intravenous).

During inhalation anaesthesia gases or vapour of anaesthetics enter the patient's through the airways and lungs (anaesthesia machines are connected with the mask, endotracheal tube, tracheostomy tube, etc.) This type of anaesthesia is characterized by the simplicity of the method and high degree of control. The most common anaesthetics are: nitrous oxide, sevoflurane, isoflurane, xenon. Ether and phtorotan have now historical meaning.

Non-inhalational anaesthesia can be delivered through intramuscular injection, orally or per rectum, but the most common way is intravenous administration.

Those first ways are less popular in adult anaesthesiology, however still popular in paediatric anaesthesiology.

Characteristic feature of intravenous total anaesthesia is its difficult control: the anaesthesia becomes dependable on the biological transformation (neutralization and excretion) of anaesthetic in the body.

Intravenous anaesthetics include barbiturates (hexenal, thiopental sodium) sodium oxybate, propofol, ketamine, etc. In the past viadril, propanidid, altezin were also used. There are combined methods of general anaesthesia, like: neuroleptanalgesia, ataralgesia, central analgesia and others.

Unlike general anaesthesia (narcosis), during regional anaesthesia patients are conscious.

Depending on the site of local anaesthetic administration (dicaine, novocain, lidocaine, bupivacaine, etc.), regional anaesthesia is divided into:

topical (surface); infiltrative; plexus and single nerves blockades; neuroaxial blockades - epidural, spinal anaesthesia.

Inhalation anaesthesia implies respiratory introduction of anaesthetics into the body. It can be performed through open, semi-open, semi-closed and closed circuits.

In the open circuit the patients inhale and exhale into the atmosphere; in semi-open they inhale oxygen or oxygen-air mixture, and exhale into the atmosphere. In closed and semi-closed circuits the patients inhale oxygen only from gas cylinders, and exhale completely (in closed circuits) or partially (in semi-closed circuits) into the chemical absorber (absorbs carbon dioxide). Respiratory mixture with eliminated carbon dioxide can be used for breathing again.

1. Nitrous oxide (N₂O) is a gas stored in liquefied state under the pressure of 50 atmospheres in the cylinders of grey colour (in French-speaking countries, these tanks are painted blue!). From 1 kg of liquid N₂O about 500 litres of colourless inflammable stable gas are formed. To prevent gas freezing at the outlet of the container it is necessary to use a special type of reductors (ribbed). Gas supply of the anaesthetic machine is performed through a high-pressure hose. Dosage control is made with special flow measurement devices (rotameters).

Nitrous oxide should be always combined with oxygen in the anaesthetic mix, otherwise patient can die; usually a ratio of 1:1, 2:1, 3:1 are used.

Note that false connection of nitrous oxide supply hose to the oxygen supply inlet is dangerous for the patient!

This gas does not cause unconsciousness, has a weak anaesthetic and mild analgesic (pain-relieving) properties. It is not toxic for the patient and it can be combined with other inhalation and intravenous anaesthetics.

Harmful effects of nitrous oxide are noticeable when its concentrations in the respiratory mixture is over 75 - 80% (in these cases, the oxygen content in the mixture is lower than 20%, which is life-threatening).

Nitrous oxide is used in combination with other anaesthetics to enhance their effects during various anaesthesias, in the form of oxide-oxygen mixture - for pain relief during attacks of angina pectoris, myocardial infarction, complicated and uncomplicated childbirth.

2. Anaesthetic ether was widely used in anaesthesiology for about 150 years. Although currently ether is not used it is a classic of anaesthesiology.

Ether is a colourless volatile liquid with a specific odour. It is produced in orange bottles of 100 and 150 ml. Boiling point of ether is 37°. It is explosive!

Ether is a potent anaesthetic, which causes unconsciousness, analgesia and muscle relaxation. It has sympathomimetic effects (causes tachycardia, increases blood pressure, stimulates the activity of the salivary and bronchial glands, increases level of sugar in the blood, stimulates the respiratory centre).

In toxic doses, ether depresses the activity of the heart, liver and kidneys. It irritates the respiratory tract. Therefore, rapid increase of its concentration in the breathing mix can cause

laryngeal or bronchial spasm.

Ether is an universal anaesthetic. It can be used in open, semi-open, semi-closed and closed circuits, in combination with other anaesthetics, during mask and intubation anaesthesia. Ether became popular as an anaesthetic because of its large therapeutic range and safety.

Ether as an anaesthetic is contra-indicated for patients with hypertension, diabetes mellitus, acute and chronic inflammation of the respiratory system. During ether narcosis, it is strongly contraindicated to use an open flame and it is dangerous to use diathermy!

During the surgery we usually evaluate the course of general anaesthesia according to the classic scheme of 4 ether narcosis stages.

Clinical course of ether narcosis (by Guedel).

I. Analgesia stage lasts from the start of vapour inhalation up to the loss of consciousness. It is characterized by the gradual loss of pain sensitivity (temperature and tactile are preserved) and depression of consciousness. During this stage you can do short-time surgery and painful manipulations.

II. Excitement stage. The patient loses consciousness. Motor and verbal excitement appear. Skin is hyperaemic, breathing is deep and noisy, the teeth are clenched, the eyeballs make floating movements, the pupils are dilated, all kinds of reflexes are increased. Blood pressure is increased, as well as heart rate; even ventricular fibrillation can occur.

During this stage various surgical interventions and manipulations are contraindicated! Just control the vital parameters and wait.

With the deepening of narcosis exciting symptoms fade, cross-striated muscles relax and breathing normalizes.

III. Surgical stage (stage "of narcotic sleep") is divided into three levels:

III.1. It is characterized by quiet sleep, deep and rhythmic breathing. The pupils are narrow, their reaction to light is preserved, the eyeballs are "floating." Ciliary, swallowing reflexes and reaction to weak pain stimuli disappear.

III.2. Corneal reflex is absent, the eyeballs are fixed in the central position, the pupils are narrow, and do not react to the light, breathing is rhythmic, blood pressure and heart rate are stable. The majority of surgical interventions are performed during this stage.

III.3. It is characterized by progressive depression of reflexes and vital functions. There may be signs of toxic ether effects: the dilated pupils, lack photoreaction, depression of respiration (with predominant diaphragmatic type of breathing) and cardiovascular activity, total lack of reaction to painful stimulation.

IV. Agonal stage is extremely dangerous, so you never intentionally deepen anaesthesia this much! In case of ether overdose there is a progressive depression of respiration and cardiac activity followed by cardiac arrest.

Pre-agonal signs of ether overdose: clammy cold sweat, grey skin colour, the sphincter relaxation and spontaneous urination and defecation.

During the recovering of the patient the same stages are observed, however in reverse order.

3. Fluothane (halothane) was widely used at the end of the 20th century, however now it is not popular. It was discovered by Raventos in 1956. It is a clear liquid with a sweet odour, not explosive. It is produced in bottles of dark glass (capacity 50, 150, 250 ml).

Fluothane is characterized by severe anaesthetic and weak analgesic effect. It depresses the secretion of the salivary and the bronchial glands, extends the bronchi. The drug depresses the larynx and throat reflexes, the respiratory centre and relaxes the cross-striated muscles. It also causes myocardial depression.

Fluothane has a short therapeutic range, its overdose is characterised by hypotension and bradycardia.

During fluothane narcosis it is contraindicated to use sympathomimetics! Fluothane increases catecholamine sensitivity of the myocardium. Adrenaline, noradrenaline and other drugs of this group during fluothane anaesthesia can cause myocardial fibrillation, followed by cardiac arrest.

For the narcosis fluothane should be filled in special evaporators of anaesthetic machines, which are situated beyond the circulation circuits. This is the way of overdose prevention.

Mask fluothane-oxygen narcosis was widely used in paediatric anaesthesiology, during short-term and small traumatic surgery. As medical narcosis - (manipulation of despair) - it is used for the immediate spasm relief when there is no venous access (epileptic state, seizures in case of eclampsia, meningitis, tetanus) for the treatment of bronchial spasm in patients with asthmatic conditions.

Fluothane anaesthesia is contraindicated for the patients with low blood pressure, deficiency of circulating blood volume (massive haemorrhage), heart failure, insufficiencies of parenchymal organs (liver-kidney failure).

4. Sevoflurane (Sevoran) was first synthesized in 1969 in the USA, now it is leading among the inhalational anaesthetics. It is a clear, colourless, mobile liquid with floral odour. It is produced in bottles of 100 and 200 ml.

Sevoran can be applied for initial anaesthesia, and for its maintaining. Sevoran is easily controlled: rapid induction of patients and quick recovery after termination of anaesthetic supply are its known benefits.

Initial narcosis is characterized by minimal excitement and absence of upper respiratory tract irritation. Sevoran causes dose-dependent inhibition of respiratory function and decrease of blood pressure. Therefore, its dose should be selected individually to achieve the desired effect, taking into account age and state of the patient.

Sevoflurane is administered by inhalation in a mixture of oxygen and nitrous oxide at a concentration of 0.5-3%, using the minimum-flow anaesthesia (0,5-2 litres of oxygen per minute). It also works with barbiturates, benzodiazepines and opioid analgesics.

Easiness of control, as well as minor side effects of sevoflurane (sleepiness after a general anaesthesia, dizziness, depression of respiratory and cardiac activity, rarely - nausea, vomiting) contributed to its wide introduction in anaesthesiology.

5. Isoflurane (forane) is a colourless inflammable liquid. It has high resistance to different agents, so it can be saved without special safety measures.

The main features of isoflurane anaesthesia are rapid falling asleep of the patient without excitement phenomena and the presence of analgesic effect after waking from anaesthesia. Isoflurane does not have toxic effects on respiration and cardiovascular system, however it has quite noticeable muscle relaxant effect. During forane anaesthesia tachycardia and increased tissue bleeding can occur.

6. Enflurane (Ethrane) was first described in 1968. It is a clear inflammable liquid with a sweetish odour. It does not cause excitement, has potent anaesthetic and weak analgesic effect (two times weaker than fluothane). During anaesthesia heart rate and respiratory rate increase, blood pressure decreases. It slightly depresses reflexes of the larynx and throat. According to the safety of its use it is placed between anaesthetic ether and fluothane. It can be combined with intravenous anaesthetics.

7. Xenon.

Xenon has been allowed for medical use as a preparation for inhalation general anaesthesia since 1999. This drug belongs to inert gases, that is why it does not enter into any chemical reaction in the body and it is not subjected to biological transformation. However, it has significant analgesic and anaesthetic effects (1.5-2 times more potent than nitrous oxide).

Clinical course of Xenon narcosis: after 5-6 inhalations of narcotic concentration of xenon the first stage occurs – peripheral paraesthesia and hypalgesia. Numbness and heaviness in the legs gradually rises upwards, spreading onto the skin of the abdomen, chest, neck and the head. In 2-3 minutes appears the second stage of euphoria and psychomotor activity, that is rapidly changing into the third stage of complete analgesia and partial amnesia. With the loss of consciousness, there is the fourth stage of complete analgesia and anaesthesia (corresponding to the first surgical stage of ether narcosis). At this stage, in conditions of mono-narcosis and spontaneous respiration, it is possible to perform surgery without the narcotic analgesics. Cardiovascular and respiratory systems (gas exchange) are stable.

Analgesia occurs in case of inhalation of 30-40% mixture with oxygen, the loss of consciousness occurs during inhalation of 65-70% of mixture. Muscle relaxation is quite significant. Recovery fast: in 2-3 minutes after gas supply is turned off, the patient is entirely conscious with pleasant subjective sensations.

Xenon can be used as an anaesthetic for various surgical operations, childbirth, painful manipulations; for relieving of pain attacks and treatment of pain syndromes and depression states in all fields of medicine, especially in patients of high risk groups. It is not toxic, that is why xenon should become an anaesthetic of choice, "gold reserve" during operations of patients with high anaesthesiology risk.

Xenon is used as a single component of anaesthesia (mask and endotracheal option) or in combination with various intravenous preparations: sedatives, narcotic and non-narcotic analgesics, neuroplegics, tranquilizers, gangliolytics etc.

Xenon can also be used for treatment at pre-hospital stage (emergency and urgent medical care to relieve pain in case of myocardial infarction, angina pectoris, burn or skeletal injuries, asthma attacks with the usage a special devices (mixture of Xe: O₂ - 50:50). It can be used as an antidepressant in neurotic and stress-anxiety disorders and other neurological conditions, to relieve abstinent syndrome, in treatment of motor aphasia, dysarthria.

Non-inhalational anaesthesia occurs in case of the parenteral injection of anaesthetics. The most common way of administration is intravenous route.

1. Derivatives of barbituric acid.

	R_1	R_2	
4-218 Thiopental	$-C_2H_5$	$-\underset{\text{CH}_3}{\text{CH}}-(CH_2)_2CH_3$	(2-S)
4-219 Hexobarbital	$-CH_3$		(1-CH ₃)
4-220 Pentobarbital	$-C_2H_5$	$-\underset{\text{CH}_3}{\text{CH}}-(CH_2)_2CH_3$	
4-221 Amobarbital	$-C_2H_5$	$-CH_2CH_2CH(CH_3)$	
4-222 Phenobarbital	$-C_2H_5$		
4-223 Barbitol	$-C_2H_5$	$-C_2H_5$	

Sodium thiopental (hexenal) was first described by Lundy in 1934. It is a powder of green (sodium thiopental) or white (hexenal) colour. It is produced in bottles of 0.5 and 1 gram. Immediately prior to anesthesia, this powder is dissolved with distilled water (isotonic solution of sodium chloride) up to 1% concentration.

Barbiturates have narcotic effect (cause unconsciousness) with minor pain relief effect. Therefore, they are used for initial narcosis, during the painless manipulations. For anaesthesia during barbituric narcosis it is necessary to introduce additional narcotic analgesics (morphine hydrochloride, phentanyl).

Easy, pleasant for the patient falling asleep and lack of excitement at the same time led to widespread use of sodium thiopental and hexenal in the practice of an anaesthesiologist.

In addition, due to strong anticonvulsant effect barbiturates are used for removal of cramps in patients with epilepsy, tetanus, meningitis, eclampsia etc.

Derivatives of barbituric acid have parasympathomimetic properties. Therefore, at the use of them the following complications are possible: cough, bronchial spasm, laryngeal spasm. They inhibit the activity of the respiratory centre, with fast intravenous administration of large doses of sodium thiopental or hexenal respiratory arrest is possible.

Barbiturates may be used only when the apparatus for artificial ventilation of the lungs is available!

A nurse – anaesthetist should prepare anaesthetic for anaesthesia and give it to the patient by the anaesthesiologist's instruction. She should dissolve in aseptic conditions 1 gram of sodium thiopental in 100 ml of 0.9% solution of sodium chloride (up to 1% concentration). After venous puncture and managing system for infusion therapy (only by the anaesthesiologist's instruction)

she should introduce 1-2 ml of anaesthetic intravenously. Waiting for 1 - 2 minutes, she should determine if the patient has sensitivity to thiopental sodium, if the solution is not under the skin. Then she should introduce the rest of the drug. The dose of anaesthetic is especially individual (from 4 to 8 mg / kg of body weight). Barbituric narcosis lasts 15 - 30 minutes. To continue narcotic sleeping the patient should be administered 10 - 20 ml of 1% solution or use other anaesthetics.

2. Sodium oxybutyrate (GOBA).

Sodium salt of gamma-oxybutyric acid (GOBA) was first described by H. Laborit in 1960. It is produced in ampoules of 10 ml of 20% solution. It has sedative and narcotic effect. Anaesthetic effect is not significant.

Sodium oxybutyrate - derivative of gamma-aminobutyric acid - a natural metabolite of the organism. Therefore, its use does not cause toxic effects in patients. Involving in metabolic processes, GOBA normalizes cellular respiration, transmembrane potential, moving potassium from blood plasma into the cells, due to that excitation processes of cells of the heart, brain, etc. decrease.

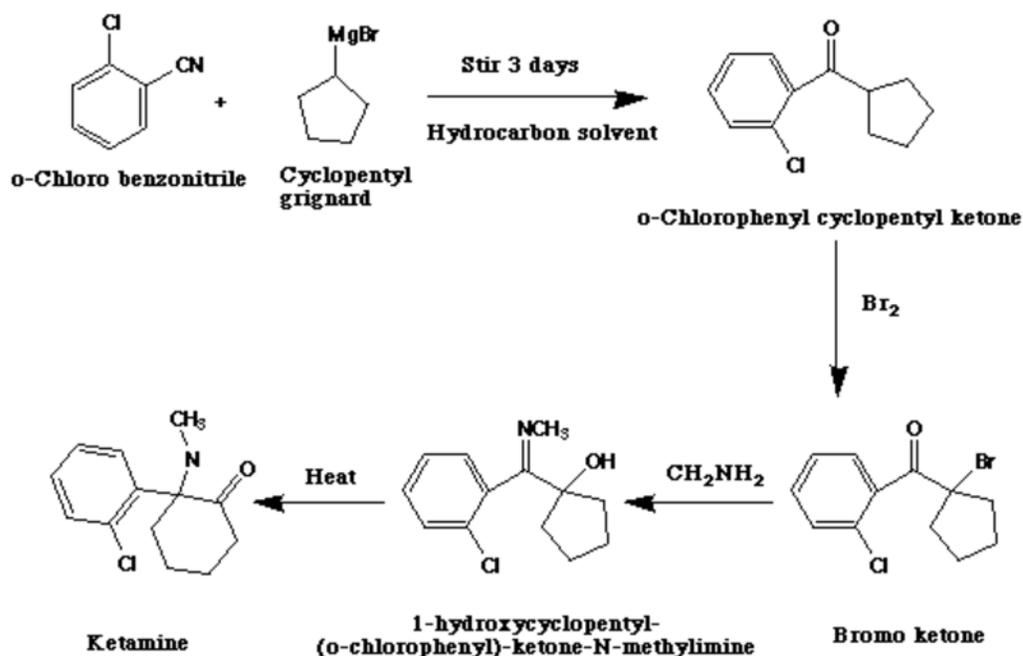

Sodium oxybutyrate also belongs to the group of anti-hypoxants, so it is widely used in intensive care of patients with disabilities of the cardiovascular system (in shock), with severe hypoxic conditions (after having survived clinical death, brain damage, in obstetrics). Anti-hypoxic dose (20-40mg/kg body weight) effectively affects tissue respiration, optimizing it. GOBA at this dose does not influence on consciousness of the patient.

As a means of anaesthesia, it is a method of choice in accompanying diseases of the cardiovascular system, the liver, the kidneys, diseases of the endocrine organs, in neurosurgical operations and in the pathology of pregnancy. In the intravenous method, it can be used intramuscularly, orally, rectally.

For anaesthesia GOBA is used at a dose of 70 - 120 mg / kg of body weight. A nurse - anaesthetist introduces it, following doctor's instructions, intravenously slowly by 10 ml. In order to prevent spasms, GOBA should be introduced together with barbiturates. For this 20-milliliter syringe should be filled with sodium oxybutyrate (10 ml) and sodium thiopental (10 ml). This mixture can be administered quickly. After repeated (3-5 times) injection of the mixture in 5 - 10 minutes the patient falls asleep, which resembles the physiological sleep. A rare, deep breathing, muscle relaxation, inhibition of reflexes are observed. Haemodynamics is not disturbed. Narcotic sleep lasts for 1 - 1,5 hours, its after-effect - up to 5 hours. At this time the patient needs to be looked after because retraction of the tongue, disorder of the lung ventilation may occur.

3. Ketamine.

Synthesis of Ketamine

Ketamine (ketanest, kalipsol, ketalar, velonarkon, petar) was described by Karsen and Domino in 1965. This group of drugs, has the ability to depress the function of some parts of the central nervous system and increase the activity of others, causing a so-called dissociative narcosis. Ketamine is a clear liquid, unstable to light, produced as 1 or 5% solution in bottles of darkened glass (10 ml), or in ampoules (2 ml). Ketamine is a strong anaesthetic, causing a deep sleep with moderate anesthesia. Due to selective stimulation of certain parts of the brain (limbic structures), during ketamine mono-narcosis patients may have visual hallucinations. In addition, ketamine causes a slight neuro-vegetative inhibition, relaxation of the cross - striated muscles with preserved tendon reflexes. It increases blood pressure, heart rate, slightly depresses respiration and stimulates the production of cerebrospinal fluid (liquor).

According to its characteristics ketamine is a tool of choice in patients with deficiency of circulating blood volume (hypohydration, hypotension, and various types of shock, collapse), in the need of anaesthesia with preserved spontaneous breathing. Due to its universal administration (intravenous, intramuscular and rectal) this anaesthetic is widely used in paediatric anaesthesiology.

Ketamine can be administered intravenously at doses of 2 - 3 mg / kg or intramuscularly at doses of 7-15 mg / kg. To avoid unwanted hallucinatory effect it is used with tranquilizer solution (1 - 2 ml of 0.5% sibazon solution).

Ketamine can be combined with various inhalation and non-inhalation preparations in the combined narcosis.

Ketamine anaesthesia is contraindicated for patients with hypertension, liquor hypertension (traumatic brain injury, epilepsy), with mental disorders.

4 Propofol (diprofil, diprivan, isoprivan).

The anaesthetic is produced in the form of white fat emulsion in 20 ml ampoules or bottles of 50 and 100 ml. 1 ml of preparation contains 10 mg of active substance. It can be administered intravenously with different infusion means (optimally - 5% glucose solution), except for blood and plasma (danger of deemulgation).

Propofol has a strong hypnotic and sedative effect, slight anaesthetic effect. Therefore, it should be used in combination with analgesics.

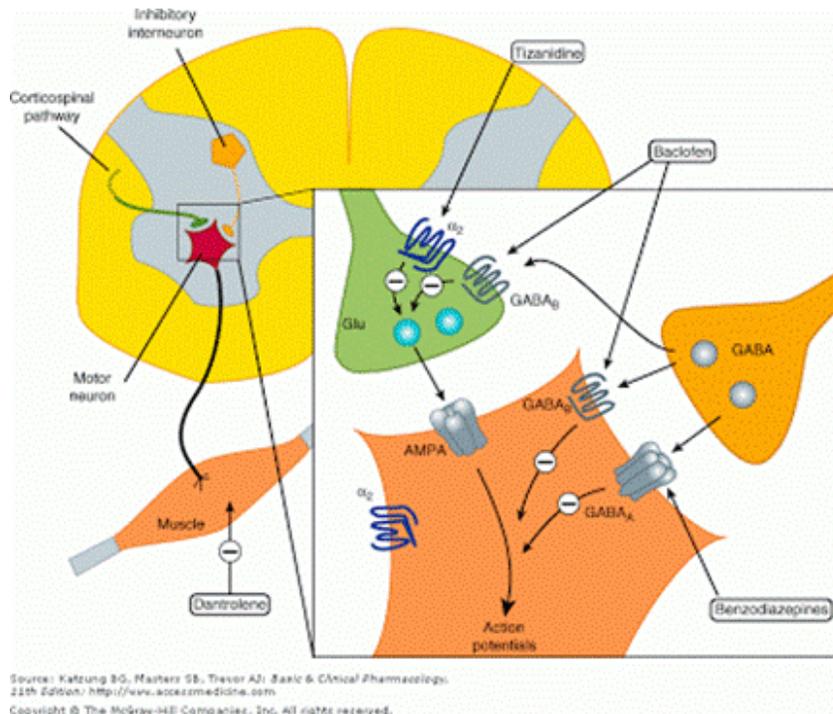

Intravenous injection at a dose of 2-2.5 mg / kg (15-20 ml) causes sleeping in 40 seconds (disappearance of the ciliary reflex). The duration of narcotic sleep is 20 - 30 minutes. Diprivan does not cause excitement, somewhat weakens the breathing, has a weak hypotensive effect without tachycardia. Inhibition of laryngeal reflexes and throat allows to apply laryngeal mask (a means of maintaining airway of the respiratory passages in self breathing and performing artificial ventilation of the lungs).

Diprivan is used for initial narcosis and as a component of balanced anaesthesia during long-term operations. This anaesthetic is injected again in 20 - 30 minutes at a dose of 100 mkg / (kg. min) - (fractional, by 2 ml, followed by a decrease at dose of $\frac{1}{4}$ each time of next administration or continuously, using a dispenser).

After diprivan narcosis (even long-term) the patients wake up fast during 10 minutes. This feature, as well as normalization of haemodynamics during laparoscopic surgery, the minimum number of complications and contraindications make propofol a drug of choice in modern anaesthesiology.

Combined general anaesthesia with muscle relaxants.

To achieve general anaesthesia most effectively use a combination of several anaesthetics should be. In these cases, the dose of each anaesthetic is reduced (and, respectively, their toxicity), therapeutic effect is increased. The use of muscle relaxants and muscle relaxation by themselves still reduce the need for anaesthetic, facilitating optimal performance of surgeons in the depth of the wound.

Muscle relaxants are divided into depolarizing and anti-depolarizing. The first are short-term, causing febrile twitching of the facial muscles, muscles of the trunk, the limbs, the diaphragm, followed by relaxation of the muscles and vocal cords up to 4-6 minutes. Ditylin (succinylcholine) is produced in ampoules of 5 ml of 2% solution, usually used for tracheal intubation at a dose of 2 mg / kg (7 - 10 ml) intravenously.

Anti-depolarizing muscle relaxants cause long-term (from 25 min. to 1,5 hours) muscle relaxation in patients without prior fibrillation, so they are used during prolonged operation on the organs of the abdominal cavity, the chest, etc. They include tubocurarine chloride, pavulon, arduan, tracrium. Arduan is produced in bottles, 4 mg of dry substance. Before the administration muscle relaxant should be dissolved in 2 ml of isotonic solution of sodium chloride, applied at a dose of 0.04 mg / kg (1.5-2 ml) intravenously, every 40 - 45 minutes the drug is re-administered in the half dose.

As a multi component intravenous narcosis with muscle relaxation and artificial

ventilation of the lungs neuroleptanalgesia, ataralgesia, central analgesia are often used.

Neuroleptanalgesia (NLA). For NLA neuroleptic droperidolum and narcotic analgesics phentanyl are used either alone or in combination with other inhalation or non-inhalation anaesthetics.

Droperidolum is produced in bottles: of 10 ml transparent colourless liquid, which contains 25 mg of preparation (0.25% solution). The drug has a marked antishock effect: it blocks extra excitement of the sympathetic-adrenal system, normalizes the activity of the reticular formation, relieves spasm of arterioles (alpha adrenergic influence on the system of microcirculation), does not cause unconsciousness. Duration of the drug action is up to 3-4 hours.

Phentanyl is produced in ampoules of 2 ml of 0.005% solution. It has short-term analgesic effect (up to 30 minutes), which allows to manage anaesthesia by minimizing the risk of drug inhibition of the respiratory centre in patients in the postoperative period.

When using the classic technique of NLA is administered intravenously 0,25-0,5 mg/kg of droperidolum and 0.005 mg/kg of phentanyl (6-8 ml of droperidolum solution and 6-8 ml of phentanyl solution for 1 hour anaesthesia). To cause unconsciousness the respiratory mixture of dinitrogen oxide and oxygen in the ratio 70%: 30% is used. After the introduction of muscle relaxants the patient is intubated, artificial ventilation of the lungs is performed. To maintain narcosis 1-2 ml of droperidolum and phentanyl should be administered every 20-30 minutes. Tachycardia is indication for re-administration of phentanyl, hypertension for re-administration of droperidolum.

Neuroleptanalgesia is used for very weak patients with high operational risk, in disorder of haemodynamics and the need of artificial ventilation of the lungs in the postoperative period.

Ataralgesia is the way of general anaesthesia with sedation preparations (ataractics) and narcotic analgesics.

Ataractic seduxen (diazepam, relanium, sibazon) is produced in ampoules of 2 ml of 0.5% solution. It cannot be dissolved or mixed with other drugs (white precipitate is formed!).

For narcosis seduxen is administered at a dose of 0.3-0.5 mg/kg and intravenously mixture of dinitrogen oxide with oxygen (2:1) is used. Anaesthetic effect is obtained by introducing phentanyl fractionally or other narcotic analgesic (morphine hydrochloride, dipidolor, pentazocine) at doses as for NLA. To achieve muscle relaxation muscle relaxants are used, and to ensure adequate breathing - artificial ventilation of the lungs is used. During the surgery by indications (tachycardia, increased blood pressure) seduxen is re-administered (usually in 1,5 hour) and phentanyl (in 20-30 min.)

The advantage of this narcosis is its minimal adverse effects on various organs and systems so that ATA is used in patients with accompanying pathology of the heart, the liver, the kidneys etc.

Central analgesia is the way of narcosis in which anaesthesia, hyporeflexia and neuro-

vegetative protection in patients is reached by administration of large doses of narcotic analgesics (1% morphine hydrochloride solution up to 20-30 ml, 0.005% of phentanyl solution - up to 100 ml). Other components (relaxation, unconsciousness, support of gas exchange and blood circulation) are used by general rules.

Central analgesia is indicated for patients with severe heart failure, combined heart defects, in case of prolonged artificial ventilation of the lungs in the postoperative period.

1.4 The work of anaesthetic team in the operating room

The success of anaesthesia and of surgery largely depends on accurate and coordinated actions of anaesthesiological team (a doctor-anaesthesiologist and nurses anaesthetists), their experience, concentration, knowledge, skills and available medical equipment.

Necessary medical equipment and instruments:

- system of centralized oxygen and nitrous oxide supply;
- anesthetic machine or artificial ventilation apparatus ("Phase", "Leon", etc.);
- equipment to monitor the functional state of the organism (cardiomonitor - for continuous ECG registration, pulse oximeter - for continuous measurement of oxygen saturation of the blood, volumeter - to monitor the volumes of inspiration and exhalation of the patient, tonometer, phonendoscope, stopwatch, etc.).
- electric pumps, laryngoscopes with a set of blades, set of intubation tubes;
- tools and details of devices: high pressure hose (to supply oxygen and dinitrogen oxide), masks for breathing apparatus, hose pipes, connectors, adapters, system of removal of exhaled gases.
- additional instruments: anaesthesiologist's forceps, clamps, mouth dilator, syringe for inflating cuff endotracheal tubes, flexible conductors for tubes, a tray for bottles, a set of probes and catheters;
- an anaesthetist's table, completed with preparations for narcosis, infusion therapy and others; system for infusion therapy, syringes, sterile rubber gloves, tourniquet, bandages.

An anaesthesiologist personally is responsible for the availability and serviceability of narcosis and respiratory apparatus and accessories, an anaesthetist –c for its asepsis and antisepsis, a table equipment and its management.

Before anaesthesia an anaesthesiologist must check:

- availability of oxygen in the system;
- working condition of narcosis and respiratory apparatus. He personally connects hoses of oxygen and dinitrogen oxide supply to the corresponding connecting pipes of dosimeters, turns on breathing apparatus, and having connected breathing circuit, checks it for hermetic. For this

purpose, he closes by his finger adapter of breathing circuit of working apparatus, following the manometer. In its indications of 300 mm. of water column dehermetisation valve must operate;

-efficiency work of electric suction machine (having closed a rubber hose by finger, follows the vacuum manometer deflection);

-working condition of laryngoscopes. After its turning on the lamp must light;

-state of cardiomonitor, pulse oximeter.

Preparing an anaesthetist's working place

While preparing the anaesthetist's table to work one should follow the order of setting instruments and medical preparation for narcosis and intensive care.

First, a table is covered with a sterile cloth. Then successively disposable syringes are put: in the lower left corner - two of 20-milliliter for 1% thiopental sodium solution (hexenal, propofol) in the lower right corner - syringes for muscle relaxants: 10 ml of capacity for 2% Dithylin solution (listenon, myorelaxant) and 2 ml for 0.2% for arduan solution. Behind them 5-milliliter syringe is located for narcotic analgesics (0.005% phentanyl solution). In the upper right corner there should be 5 ml syringe for solutions of sibazon, droperidolum, ketamine. In the upper left corner - syringes of 5 and 10 ml capacity for other drugs (ganglioblockers, clopheline, dalargin, etc.). Among them there are placed two glass vessels (of 100 ml of capacity) filled with 0.9% sodium chloride solution. In the left bowl the powder of sodium thiopental is dissolved up to 1% concentration; 0.9% sodium chloride solution in the right bowl is used for dissolving other drugs just before their intravenous introduction.

In a separate tray must be sterile gauze wipes and forceps, next to a bottle with antiseptic solution (70% of ethyl alcohol).

The desk drawer is designed to store pharmacological preparations needed during surgery, intravenous catheters, disposable system for transfusions, adhesive plaster, etc.

On the shelf under the box an anaesthetist places the bottles of infusion-transfusion preparations.

In a separate tray a set for tracheal intubation is formed: laryngoscopes with a set of blades (large, medium, small), intubation tubes of various sizes and throat mask, air-way, mouth dilator, a connector of the intubation tube, syringe for cuff blow of the intubation tube, Kocher clamp, napkins.

1.5. Complications of general anaesthesia, their prevention and treatment

Complications may occur at different stages of anaesthesia: during premedication, initial narcosis, during maintenance of narcosis and after narcosis period.

The most responsible for an anaesthesiologist stages are: giving anaesthesia, awakening

and early after narcosis period.

The complications may be associated with:

- a) the specific influence of anaesthetic;
- b) the type and method of anaesthesia;
- c) main or accompanying disease;
- d) the nature of surgery.

The basis of prevention of complications is adequate preparation of the patient for surgery and anaesthesia, and careful monitoring of patients at all stages of anaesthesia.

Complications concerning the respiratory system are with the following disorders:

- a) of airway of the air passages (accumulation of phlegm, tongue retraction, aspiration of vomit, laryngospasm, bronchospasm, etc.)
- b) of the regulation of respiration (respiratory centre depression drugs, hypoxia, etc.)
- c) of neuromuscular conduction (influence of muscle relaxants, antibiotics, disorder of electrolyte metabolism),
- g) of the lungs (pneumonia, atelectasis, pulmonary oedema, etc.).

Any disorder of respiration leads to oxygen starvation (hypoxia) and accumulation of carbon dioxide (hypercapnia).

Hypoxia. Respiratory, or hypoxic hypoxia occurs during hypoventilation, respiratory passage disorders, reducing the oxygen volume in the inhaled mixture, pulmonary pathology. Characteristic feature is decreasing PaO₂ <80 mmHg

Clinical characteristics of hypoxia. I stage of compensation (anaesthetic); II stage decrease of compensatory reactions (narcotic), III stage of decompensation (toxic).

At the first signs of hypoxia one should primarily:

- a) to listen to the respiration of the patient of both lungs,
- b) to ensure airway of the respiratory passages,
- c) to check the narcosis apparatus and oxygen supply.

Hypercapnia occurs in hypoventilation of the lungs due to respiratory depression by anaesthetics or drugs, in case of non-physiologic operating position of the patient, absence or ineffectiveness of adsorbent, large amounts of "dead space"; in the postoperative period - with inadequate anaesthesia.

Hypercapnia stimulates the sympathetic-adrenal system. The increase of blood pressure, increased salivation, bright red colour of the skin and mucous membranes, extra-systoles are observed. Dilatation of the capillary vessels leads to increased capillary bleeding, which is one of the reasons of delayed waking from narcosis and can lead to cerebral oedema.

In case of hypercapnia it is necessary to normalize pulmonary ventilation (auxiliary artificial ventilation or mechanical ventilation), to replace chemical absorber in narcosis apparatus.

Complications concerning the cardiovascular system may be caused by inadequate gas exchange, changes in circulation blood volume, weakening of cardiac activity, disturbance of peripheral circulation, changes in rheological properties, clotting and fibrinolytic systems of the blood. Changing blood pressure, cardiac arrhythmia, cardiac arrest, embolism and thrombosis are observed:

Disorder of normal rhythm and beat of heart activity. Tachycardia occurs in abnormal gas exchange and transport of blood gas, blood loss, inadequate anaesthesia, reflex stimulation of the heart, administration of atropine sulphate, ether. Manifested tachycardia may be the precursor of fibrillation of the heart ventricles. Bradycardia. Its cause is severe hypoxia, stimulation of the vagus nerve, overdose of fluothane or methoxyflurane, administration of dithylin. It may precede cardiac arrest. Arrhythmia is the result of hypercapnia, stimulation of the vegetative nervous system receptors.

Treatment – adequate ventilation, neuro-vegetative blockade, in brady-arrhythmia – the introduction of atropine.

Arterial hypertension may occur due to hypercapnia, hypoxia, painful stress, effects of anaesthetics (ketamine) and adrenomymetics.

Arterial hypotension: a) with tachycardia is developed in hypovolemia of any origin. Treatment is to restore blood circulation volume. In cases of suspected acute adrenal insufficiency hormones are prescribed. In acute heart failure that is due to myocardial infarction or lack of blood and fluids transfusion cardio-tonics are administered;

b) with normocardia - occurs in decrease of vascular tone on a background of moderate vagotonia (sodium-thiopental narcosis). Vasopressors are prescribed;

c) with bradycardia – occurs in severe hypoxia, fluothane and narcotic analgesics overdose, vagotonia.

Having determined decrease of BP, an anaesthesiologist should stop giving anaesthetic and define the cause of hypotension!

Complications concerning the digestive system.

Vomiting is caused by hypoxia, hydration, the influence of anaesthetics (on the vomiting centre and the mucous membrane of the stomach), stimulation of reflexogenic zones (root of the tongue, pharynx).

Regurgitation occurs during mechanical ventilation of the lungs in patients with "full" stomach, lowering the head end during operation at the time of fibrillation of the muscles while administering dithylin for intubation. Lack of symptoms is dangerous prior to aspiration

Complications concerning the nervous system.

Slow awakening from general anaesthesia is caused by prolonged hypoxemia and hypercapnia, anaesthetics overdose, in children – on the basis of hypothermia.

Hypoxia of the brain can be complicated by brain oedema, focal lesions, decerebration. Spasms, mental disorders are possible. Normalization of gas exchange and adequate anaesthesia provide prevention of the complication of the CNS.

As the result of compression or dilatation of the peripheral nerves (brachial plexus, fibular nerve etc.) neuritis, paresis, paralysis can be observed.

To prevent the occurrence of this pathology you should put the limbs properly and control their position during surgery and in postoperative period.

Disorders of thermoregulation. Hypothermia (spontaneous) occurs on the basis of increased heat loss and blockade of thermoregulation centres. To prevent the development of this disease, you should maintain normal body temperature.

Malignant hyperthermia occurs most often in young people and in children in postoperative period. During the operation use of muscle relaxants, fluothane and other drugs should be made with particular caution.

Anaesthesia is meant to protect the body from operating injuries, but it can also be a cause of serious reactions and complications by itself. Therefore, an anaesthesiologist should inform the patient before surgery about possible complications, side effects and consequences of anaesthesia.

Complications of anaesthesia and the effects of narcosis are divided into:

1. Common: nausea, sore throat, tremor, dizziness and disturbance of consciousness, headache, itching, pain in the back and lumbar, muscle pain, confused consciousness.
2. Uncommon: postoperative pulmonary infection, injury of the teeth, the lips, the tongue, awakening during general anaesthesia.
3. Rare and very rare: nerve damage associated with general anaesthesia, nerve injury associated with regional anaesthesia, allergic reaction (anaphylaxis), injury of the eyes during general anaesthesia, death or brain injury.

Common side effects and complications of anaesthesia.

Nausea is a frequent result of anaesthesia, which occurs in about 30% of cases in the postoperative period. Nausea is often typical to the general, than regional anaesthesia. For its prevention it is necessary to provide a patient with adequate pain relief, he/she should not be active during the first hours after surgery – to sit and get up, to drink water and to eat. Deep breath with slow inhalation of the air can decrease nausea.

Sore throat. It can vary from discomfort to severe constant pain during talking or swallowing. The mouth can be dry. These symptoms may be a few hours after surgery, and may remain for two more days.

Tremor, as the result of anaesthesia is a frequent problem because it causes great discomfort, although it is not a danger to the organism and lasts about 20-30 minutes. Tremor may occur after general anaesthesia and be a complication of epidural and spinal anaesthesia. The thermal comfort of the patient before and during surgery decreases the probability of tremor occurrence.

Dizziness and loss of consciousness. The residual effect of anaesthetics may cause decrease of blood pressure, in addition dehydration can cause the same effect, which is not so rare after surgery. Decreased blood pressure may cause dizziness, weakness, loss of consciousness.

Headache. It can be caused by a drug used for anaesthesia, the operation itself, dehydration and the patient's anxiety. Often headache disappears in a few hours after anaesthesia and is treated with analgesics easily. A severe headache may be a complication of spinal or epidural anaesthesia.

Itching. Usually it is adverse reaction to anaesthesia medication (e.g. morphine), but itching may be a manifestation of an allergic reaction.

Backache and pain in the lumbar. During the operation the patient is in a constant position on a firm operating table for a long time, which may cause "tired" back and lead to backache after surgery.

Pain in the muscles. Most often this pain occurs in young males, it is often associated with the use of muscle relaxants during anaesthesia, particularly dithylin. Pain in the muscles is the result of narcosis (general anaesthesia), it is symmetrical, often localized in the neck, the shoulders, the upper abdomen and lasts until 2-3 days after surgery.

Confused consciousness. Some patients, usually elderly, suffer from confused consciousness after surgery and anaesthesia. Their memory may deteriorate, and their behaviour may differ from typical for them usual state.

Uncommon side effects and complications of anaesthesia.

Postoperative pulmonary infection. This problem is the most common consequence of narcosis (general anaesthesia). A few simple measures will significantly reduce the risk of this complication:

- Smokers should quit smoking for about 6 weeks before surgery;
- The patients with chronic lung disease should be operated in a state of remission;
- Adequate pain relief after surgery is the key to effective breathing and ability to cough, and, consequently, to reduce the risk of pulmonary infection.

Injuries of the teeth, the lips, the tongue. General anaesthesia is a risk for teeth injury, which occurs in about 1 case in 45,000 anaesthesias. Minor injuries of the lips or the tongue are common in about 5% of cases of general anaesthesia.

Awakening during anaesthesia. Some of the patients during surgery may come to

consciousness, they can remember some episodes of the operation. It is very unpleasant complications of anaesthesia, however, it is quite a rare event, since the modern system of monitoring can prevent the development of such complication.

Rare and very rare side effects and complications of anaesthesia.

Nerve injury, as a complication of anaesthesia. This type of complication is characterized by a sense of numbness, tingling or pain. There may be a disorder of heat or cold sensitivity. Additionally, there may be a feeling of weakness or paralysis. Typically, all complaints disappear in a few days or months. Complete recovery can sometimes be delayed up to a year. The most common is ulnar nerve injury in the ulna nerve area and fibular nerve in the knee.

Nerves may be injured during epidural and spinal anaesthesia. This complication is rare and usually disappears within a few weeks or months. Cases of temporary immobilization (paralysis) of one or two extremities are very rare (1:50 000).

Reasons that may cause nerve injury:

- Nerve may be injured by a surgeon during some operations (it is sometimes difficult and unavoidable);
- The position in which the patient lies on the operating table can lead to nerve compression or tension, damaging it;
- The use of tourniquets by a surgeon to reduce the amount of blood loss during surgery puts pressure on the nerve, also contributing to its injury;
- The cause of nerve compression may be post-operative swelling of the tissues.

Allergic reaction (anaphylaxis). During anaesthesia, as well as, during the patient's stay in hospital medications may cause severe allergic reaction - anaphylaxis. The frequency of development is 1:15000 of anaesthesia. Usually, an anaesthesiologist successfully diagnoses and treats this terrible complication, however, statistically one of twenty of such severe reactions can lead to death.

Injury of the eyes during general anaesthesia. This is a rare complication of narcosis. The most frequent type of eye injury during and after general anaesthesia is damage of the cornea (1:2000 anaesthesias). This condition does not affect visual acuity, but may cause a dark point in the damaged eye. Most corneal injury is due to the fact, that during anaesthesia the patient's eyelids are not always completely closed. Consequently, the cornea becomes dry and the eyelid "sticks" to it from inside. Then, when the patient opens the eyes and corneal injury occurs.

Death or brain injury.

1.6. Postoperative care of surgical patients

After complex operations the patients are transferred to the department of intensive therapy. Medical personnel of the department should continuously look after the patients

(monitor vital functions) and provide intensive care.

During the postoperative period of patients after long hours of surgery under general anaesthesia combined with the use of muscle relaxants, a special attention should be paid to the respiratory function and the cardiovascular system activity.

The patients, who underwent complicated surgery, particularly on the digestive organs of the gastrointestinal tract, should be provided with a balanced intensive care for a long period of time until the restoration of the physiological processes of digestion.

Planned postoperative prescriptions (general regulations):

1) administration of adequate analgesia (with the use of narcotic and non-narcotic analgesics);

2) prescribing infusion therapy (at a rate of 40 ml per 1 kg of body weight per 24 hours - the regime of moderate haemodilution)

3) providing the organism with the most important electrolytes (daily need: Na⁺ – 2 mmol / kg, Cl⁻ – 2 mmol / kg, K⁺ – 1 mmol / kg, Mg⁺⁺ – 0.2 mmol / kg, Ca⁺⁺ – 0,3 mmol / kg)

4) prescribing parenteral nutrition to the patient, based on

- The necessary energy providing - 25 kcal / kg per 24 hours;

- The daily need of proteins should be 1.4 g/kg;

- The ratio of ingredients for parenteral nutrition:

proteins: carbohydrates: fat = 2: 7: 1,

- It is necessary to prescribe vitamins (at the therapeutic dose);

5) by indications, with a prophylactic or therapeutic purpose, the administration of antibiotics;

6) maintaining therapy, aimed at preventing decompensation of the main and probable accompanying pathology;

7) symptomatic therapy;

8) physiotherapy treatment and exercise therapy;

9) providing different laboratory and instrumental investigations.

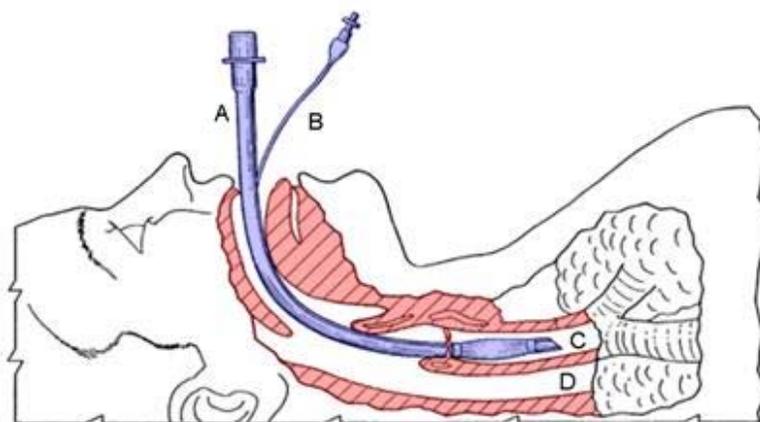

Example. A 47-year-old patient K., 72 kg, survived operation on stomach cancer. Surgery - gastrectomy. Accompanying pathology: chronic bronchitis of a smoker.

The patient was prescribed:

1) for pain - 1% promedol solution, 1 ml intramuscular;

- 2) 0.9% sodium chloride solution - 800 ml, drip intravenously;
- 3) 10% solution of glucose - 400 ml
 - 7.5% potassium chloride solution - 20 ml
 - 25% magnesium sulphate solution - 3 ml
 - insulin solution - 12 units;to administer intravenously, drip, 3 bottles (1270 ml) during 4 hours;
- 4) 8% polyamines solution - 400 ml;
- 5) 20% intralipid solution - 500 ml, drip intravenously during 3 hours;
- 6) 20% glucose solution - 400 ml
 - insulin solution 24 units;to administer intravenously, drip slowly during 2 hours;
- 7) Vitamin C, 5% solution, 5 ml intravenously, 3 times (at 8.00, 16.00, 24.00)
 - vitamins B1, B6 - 1 ml intramuscular;
- 8) ceftriaxone 1g intravenously twice a day (at 10.00 and at 22.00);
- 9) Steam inhalation with sodium hydrocarbonate solution, coltsfoot infusion;
- 10) exercise therapy, breathing exercises with the creation of positive pressure on exhalation;
- 11) Laboratory tests: blood analysis, hematocrit, biochemical blood analysis (glucose, proteinogram, coagulogram, amylase, bilirubin, Na, K, Cl, options of acid-base state, the toxicity of blood serum), urinalysis.

1.7. Medical manipulations and operations

Tracheal intubation

Indications: the necessity of artificial ventilation of the lungs in patients with combined anaesthesia using muscle relaxants, providing respiratory care to patients with acute and chronic respiratory failure, making manipulation (bronchoscopy) in tracheal-bronchial tree, performing cardiopulmonary-cerebral resuscitation.

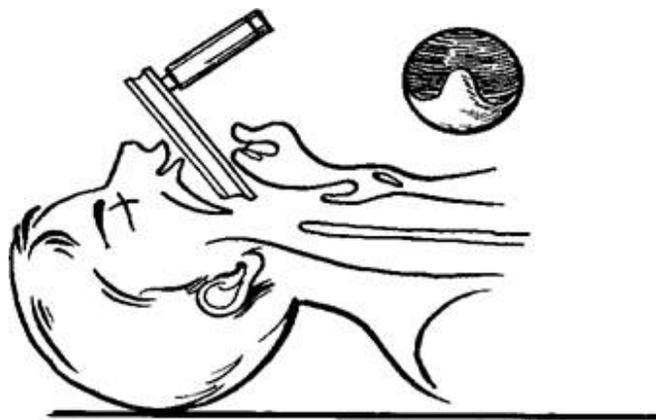

Necessary equipment: A laryngoscope with a set of blades, intubation tubes of different sizes, electrical or mechanical suction machine, apparatus for artificial ventilation of the lungs, atropine sulphate solution, preparations for anaesthesia and muscle relaxants, gauze napkins, phonendoscope.

Methods of intubation. The trachea is often intubated by mouth with laryngoscope in direct laryngoscopy.

For prevention of pathological reflexes the patient is previously injected intravenous 0.1% atropine sulphate solution (0.4 - 0.5 ml) and anaesthetic (e.g. sodium thiopental) for narcosis.

Mask way is used for additional artificial ventilation of the lungs with oxygen, along with administration of muscle relaxation solution.

After full muscle relaxation an anaesthesiologist opens the patient's mouth by his right hand fingers (grasps the incisors of the upper jaw with the second finger tip and moves the chin down with the third finger), he takes the working laryngoscope by his left hand and gently introduces its blade into the mouth cavity.

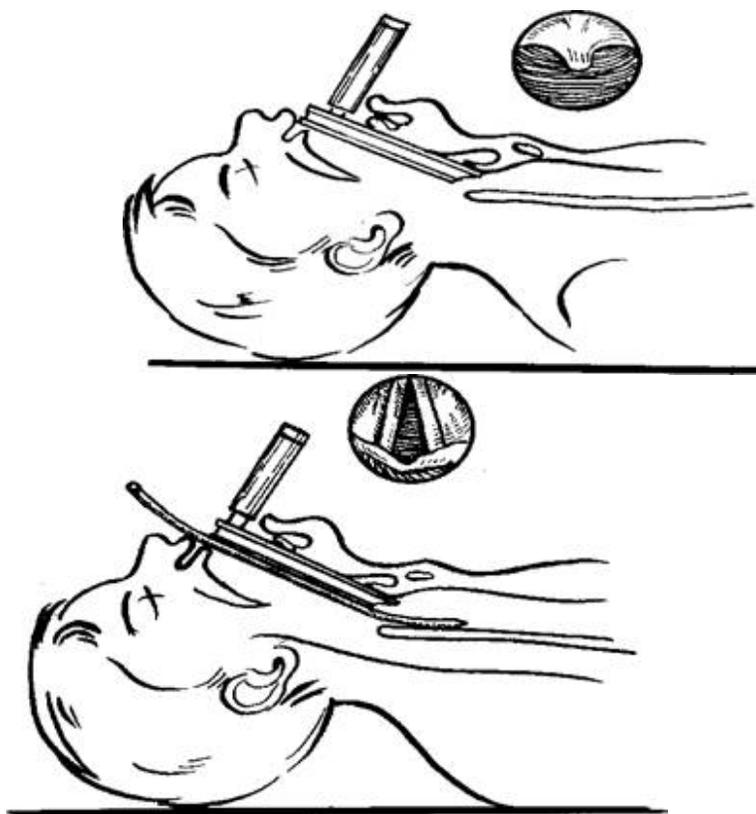

Pic. 1.1 A laryngoscope is putted into the oral cavity.

The root of the tongue is pulled up, the soft palate and the tonsils are visible

Without efforts, carefully in order not to injure soft tissues, he moves the blade deep and medially into, pushing the tongue to the left. The entrance in the throat in and back wall of the throat are visible. With further introduction of the blade the larynx-throat opens with overhanging layer of its epiglottis. An anaesthesiologist displaces it upwards (when using direct blade takes the epiglottis free end and raises it up; while using indirect laryngoscope puts it under the basis of the epiglottis and pressing shifts it upwards). The entrance to the trachea opens, formed by the glottis of inverted trapezoid form. Its side walls are the vocal

cords.

Pic. 1.2-3 The epiglottis is raised by the laryngoscope's blade.

The glottis is visible

By his right hand an anaesthesiologist gently introduces the intubation tube of appropriate size into the glottis, so that its blowing cuff was hidden immediately behind the vocal chords.

The intubation tube is connected to the triple connector of respiration circuit of the apparatus of artificial ventilation of the lungs. Tube cuff of the tube is blown with air, due to that it obturates free lumen of the trachea and seals system "the lungs - apparatus of artificial ventilation of the lungs".

He checks accuracy of the intubation tube position in the trachea, listening to the breathing with phonendoscope on both sides of the chest. In all regions of the lungs vesicular breathing the same sonority should be available (without abnormal noise).

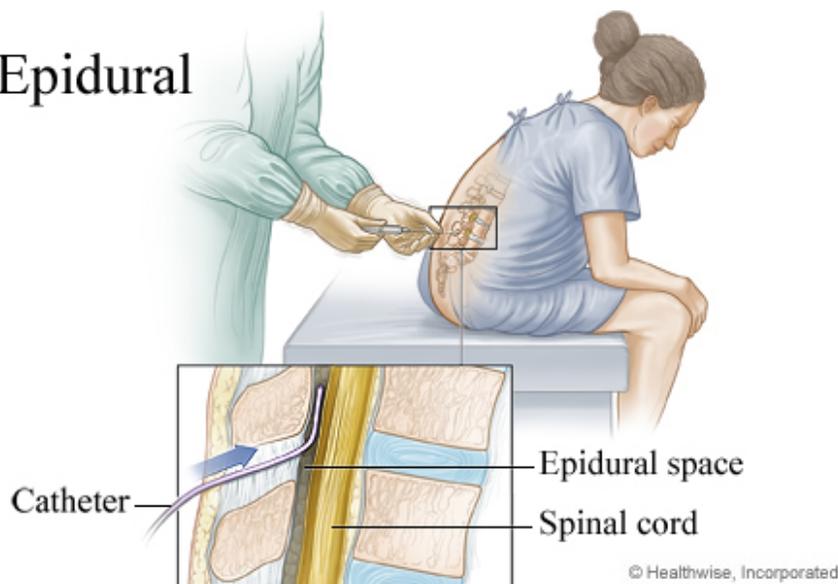

The intubation tube is fixed by adhesive plaster or a bandage, around the patient's head.

In the case of clinical death for effective ventilation of the lungs the trachea should be immediately intubated, without prior administration of anaesthetics. At presence of the mucus, the blood, the gastric contents or foreign bodies in the mouth and the throat an anaesthesiologist performs sanitation of the respiratory passages before the intubation, using

electrical or mechanical suction machine or a gauze tampon at the clips.

Epidural anaesthesia.

Epidural

Indications: anaesthesia in surgery on the abdomen, the pelvis and the lower extremities; intensive therapy of pathological conditions in which a temporary medication denervation of appropriate segments of the body is necessary (asthmatic status, myocardial infarction, pulmonary oedema, acute pancreatitis, paralytic intestinal obstruction, frostbite of the lower limbs etc.).

Picture 1.4 Choice of the place for puncture in epidural anaesthesia, depending on the required level of anaesthesia

Necessary equipment: a needle with a stylet for puncture of epidural space (Tyoxi), Dyufo needle, a needle for intramuscular injections, syringes of 2 ml of capacity with a light piston moving and of 10 ml with the adapter to the catheter, epidural catheter, Kocher clamp, sterile gauze tampons, a solution of ethanol, adhesive plaster, the solution of local anaesthetic.

Methods of administration

The equipment is placed on the sterile surface (a nappy) of the manipulation table.

The patient is placed on the operating table lying on his side or sitting, bending his body maximum (moving the head to the knees).

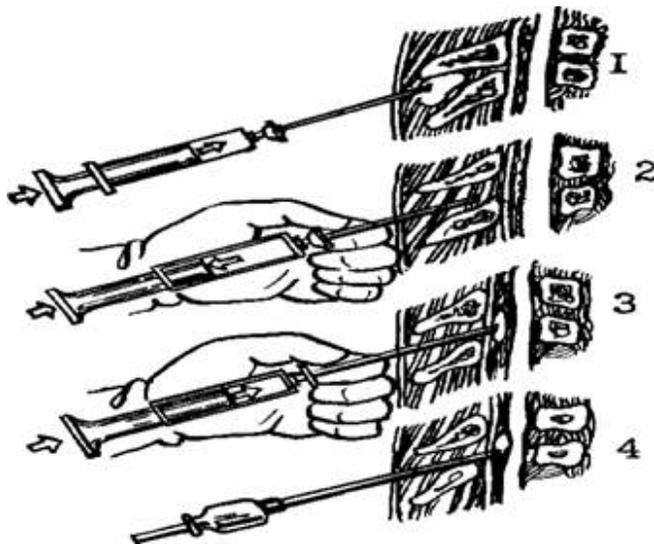

A place for puncture is chosen, according to the indications (the required level of anaesthesia).

The operating field and the anaesthesiologist's hands are washed according to the rules of asepsis and antisepsis.

Infiltration anaesthesia of soft tissues from the puncture along the needle (introducing it in the sagittal direction, in the middle between the osseous processes of the spine) is administered.

Piercing the skin and subcutaneous fat tissue with Dyuflo needle, creating a channel of 2 - 2.5 cm in depth.

Along the channel in the sagittal direction Tyoxi needle with a stylet is introduced in a depth of 3 - 4 cm, piercing upper osseous and intra-osseous ligaments.

Picture. 1.5 Sequence in which needle penetrates the tissues

moving it into the epidural space.

1 - the introduction of anaesthetic into the subcutaneous tissue;

2 – the needle - between osseous ligaments;

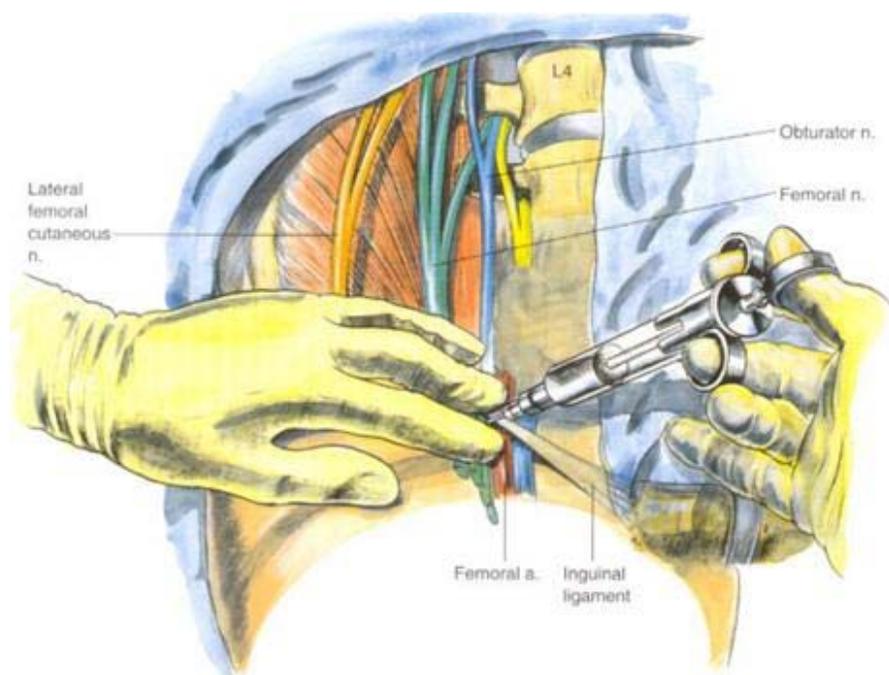

3.4 - the tip of the needle is in the epidural canal, the anaesthetic is injected easily (3), and it does not flow (4).

A 2 ml syringe is filled with isotonic sodium chloride solution, so that it contained a small air bubble. A stylet is removed from the Tyoxi needle and the syringe should be attached to its cannula. Continue to push gently the needle, while easily pressing the syringe piston. Monitor the air bubble. After passing the yellow ligament with the needle "a downfall" is felt: the syringe piston moves freely forward with the slightest effort of the anaesthesiologist, an air bubble is not deformed. The syringe should be carefully disconnected, leaving in the cannula a hanging drop of isotonic solution. The patient is asked to take a deep breath. Drawing of the drops into the cannula confirms that the tip of the needle is in the epidural space.

If one-stage anaesthesia is expected, the patient is injected into the epidural space a test-dose of anaesthetic first (3 - 5 ml 2% lidocaine solution), and in the absence of symptoms of spinal anaesthesia – in 5 minutes - a full dose of anaesthetic.

In case of a long-term anaesthesia the epidural space is catherized, moving the catheter through the Tyoxi needle to a depth of 7 - 8 cm. The needle is carefully removed, an aseptic bandage is put on the place of the puncture, and the catheter is fixed to the skin by adhesive plaster. A syringe with adapter is attached to the outer end of the catheter. First a test dose is administered and then, in the absence of symptoms of spinal anaesthesia - the rest of the required dose of anaesthetic.

Conductive anaesthesia.

In large traumatic operations (femur amputation, under-knee leg amputation) the most reasonable is the use of methods of conductive anaesthesia by blocking the sciatic and femoral nerve in the proximal regions.

The rear (proximal) blockade of the sciatic nerve (according to Rai).

Indications: In case of large operations (usually amputation of the lower third of the thigh), especially when the patient in some reason cannot be placed on the side or on the abdomen.

Necessary equipment: a 10-centimeter needle type UP 20G cut on 15-30 degrees; an anaesthetic - 20-30 ml of 1% xylonest solution (or mepivacaine, or lidocaine).

Anatomical orientation: a large trochanter of the femur, a sciatic tuber.

Methods of administration. The patient's position: on the back, the assistant lifts up the patient's leg, bending it at 90 degrees in the hip and knee joints. An anaesthesiologist marks the line between the large trochanter and the sciatic tuber, strictly in the middle of which, perpendicular to the skin introduces the needle, pushing it into the cranial direction.

At a depth of 5-10 cm during electrical stimulation (0.3 mA / 0.1 ms) foot bending appears (fibular nerve stimulation) or its extension (tibial nerve stimulation);

Blockade of the femoral nerve in the inguinal region (by Vinnie Rosenblatt).

Indications: In case of large operations (amputation of the lower limb).

Necessary equipment: a 5-centimeter needle type UP 18G; an anaesthetic - 20-30 ml of 1% xyloest solution (or mepivacaine, or lidocaine).

Anatomical orientation: the inguinal fold, the femoral artery.

Methods of administration. The patient's position on his/her back, the lower limb is slightly drawn aside and rotated outward. The place of injection: 2 cm below the inguinal fold and 1.5 cm outside of the artery. A needle with electric stimulator is injected at an angle of 30 degrees into the skin in cranial direction to the sense of a double downfall on the passage of two fascias. Motor response is proved by contraction of the quadratus femoris muscle and the patella tingling during electrical stimulation 0.3 mA / 0.1 ms

The distal sciatic nerve blockade (by Meyer).

Indications:

- Anaesthesia during operations on the foot and the ankle joint;
- Treatment of chronic pain, postoperative analgesia of the tissues located distal to the knee joint;
- Sympathicolise in diabetic gangrene, disorder of the peripheral circulation and in treatment of wounds of the legs and the feet, which do not heal for along time.

Necessary equipment: a 5-10 centimeter needle type UP 22G; an anaesthetic - 20-30 ml of 1% xyloest solution (or mepivacaine, or lidocaine).

Anatomical orientation: the popliteal fold, fossa poplitea, arteria poplitea.

Methods of administration. The patient should be placed on the side of a healthy limb, which is bent in the knee and thigh joints. The injured limb should be straightened out; between the legs a small pillow is placed. Side protuberances of the knee are fixed by a thumb and middle finger (two bottom corners of the triangle), and by the index finger - top of an equilateral triangle, which limits the upper half of the popliteal fossa. The point of injection should be determined, which is 1-2 cm outside of the top of the triangle, near the medial edge of the tendon of the thigh biceps muscle. A needle is introduced at an angle of 30-45 degrees into the skin in the cranial and slightly medial direction to a depth of 4-6 cm. In response to electrical stimulation dorsal or plantar flexion of the foot occurs, indicating close to the sciatic nerve location of the needle.

Remarks.

The sciatic nerve is always outside of the popliteal artery.

The distal sciatic nerve blockade is particularly effective for prolonged anaesthesia. For

this purpose the needle 19,5 G and catheter 20G should be used, which is injected to a depth of 4-5 cm cranially from needle cut. The anaesthetic is administered at a speed of 6 ml/hour, with optimum use of continuous administration of anesthetic by infusion pump.

1.8. Control tests and tasks

1. Preparations of sodium thiopental are produced

A - in ampoules (10 ml of 20% solution);

B - in bottles (1 g, 0.5 g);

C - in ampoules (10 ml of 1% solution);

D - in ampoules (10ml of 20% solution);

E - in bottles of 4 mg.

2. Arduan - is

A – a non-inhalation anaesthetic;

B – a depolarizing muscle relaxant;

C – anti-depolarizing muscle relaxant;

D -a narcotic analgesic;

E - an inhalation anaesthetic.

3. In administering neuroleptanalgesia are used:

A- droperidolum and seduxen;

B - phentanyl and seduxen;

C - phentanyl and droperidolum;

D - morphine and sodium thiopental;

E - phentanyl and ketamine.

4. In administering ataralgesia are used:

A - droperidolum and seduxen;

B - phentanyl and seduxen;

C - phentanyl and droperidolum;

D - morphine and sodium thiopental;

E - phentanyl and ketamine.

5. Diprivan is produced

A - in ampoules (10 ml of 20% solution);

B - in bottles (1 g, 0.5 g);

C - in ampoules (10 ml of 1% solution);

D - in ampoules (10ml of 20% solution);

E - in bottles of 4 mg.

6. Signs of fluothane overdose:

A - tachycardia;

B - hypertension;

C - hypotension and bradycardia;

D – comma, asystolia;

E - maximum constriction of the pupils.

7. At what stage of ether narcosis the pupils' reaction to the light disappears:

A - I

B - II

C - III1

D - III2

E - IV

8. Ether is expedient to be administered to patients with:

A - hypotension due to blood loss;

B - acute liver failure;

C - bronchitis;

D - acute renal failure;

E – diabetes mellitus.

Task 1

A 45-year-old patient G., is prepared for planned surgery on the stomach ulcer. Case history: diabetes mellitus, daily receives 28 units of insulin. At the time of examination glycaemia has been compensated. Objectively: the respiratory and the cardiovascular systems are in the normal state. Increased indices of urea (9,6 mmol / l) and creatinine (0,12 mmol / l).

Determine the degree of operating and anaesthesiological risk.

Task 2

During administering mask narcosis an anaesthesiologist noted the patient's sudden inspiration dyspnoea with inability to make an active inspiration. The patient's face became

cyanotic, the neck veins became swollen, the pupils became dilated.

Specify the complication, its probable causes and sequence of nurse (anaesthetist) actions.

Task 3

What preoperative preparation does a 73-year-old patient S. need? He has been admitted to the surgical department with clinical signs of adhesive intestinal obstruction. On examination of the patient hypotension (BP -90 and 60 mm Hg.), tachycardia (heart rate - 112 per minute) have been revealed

Task 4

During intravenous anaesthesia the patient's breathing became discontinuous, noisy, "gurgling": from the mouth gastric content appeared. What has happened? Determine the sequence of emergency aid.

Task 5

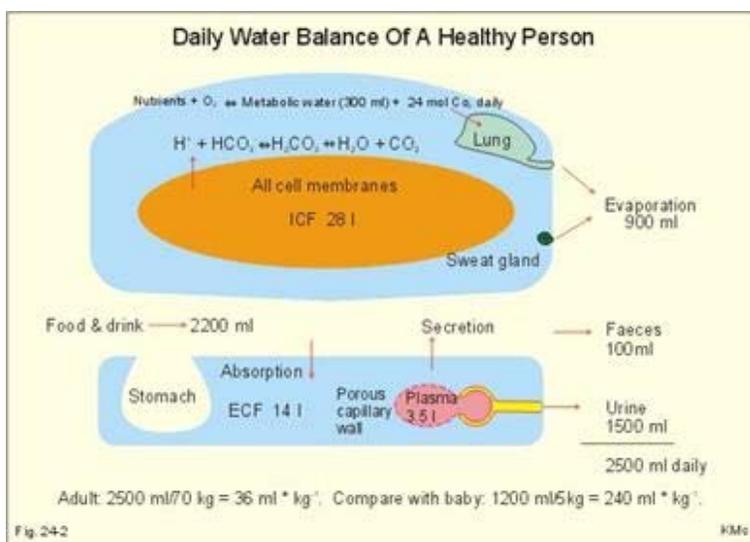

While performing tracheal intubation, an anaesthesiologist observed stomach contents in the mouth of the patient, which slowly moved between the vocal chords into the trachea.

Determine the type of complication, its cause and probable course of the disease, and emergency aid that is necessary for the patient.

Task 6

An anaesthesiologist performed intubation to the patient and connected the intubation tube to the breathing apparatus. With air supply there appeared typical "gurgling" sound. Simultaneously, in the patient began to project epigastric area of the abdomen, breathing in the chest was not available.

Determine the type of complication and urgent aid.

Fluid imbalance and principles of its intensive treatment.

Water imbalance is divided into dehydration and overhydration.

Dehydration is caused by:

- excessive perspiration in conditions of high temperature;
- rapid breathing (dyspnea, tachypnea) or artificial ventilation without humidification of the air;
- vomiting, diarrhoea, fistulas;
- blood loss, burns;
- diuretics overdose;
- excessive urine output;
- inadequate enteral and parenteral nutrition or infusion therapy (comatose patients, postoperative care);
- pathological water distribution (“third space” in case of inflammation or injury).

Dehydration signs: weight loss, decrease of skin turgor and eyeballs tone, dry skin and mucous membranes; low central venous pressure, cardiac output and blood pressure (collapse is possible); decreased urine output and peripheral veins tone; capillary refill over 2 seconds (microcirculation disorders) and low skin temperature; intracellular dehydration is characterized with thirst and consciousness disorders. Laboratory tests show blood concentration: hematocrit, hemoglobin concentration, protein level and red blood cells concentration increase.

Overhydration appears in case of:

- excessive water consumption, inadequate infusion therapy;
- acute and chronic renal failure, hepatic and cardiac insufficiency;
- disorders of fluid balance regulation;
- low protein edema.

Clinical findings in case of overhydration are: weight gain, peripheral oedema, transudation of the plasma into the body cavities (pleural, abdominal), high blood pressure and central venous pressure. In case of intracellular overhydration appear additional symptoms: nausea, vomiting, signs of cerebral edema (spoor, coma). Laboratory tests prove hemodilution.

According to the osmotic concentration of plasma dehydration and overhydration are divided into hypotonic, isotonic and hypertonic.

Isotonic dehydration is caused by equal loss of electrolytes and fluid from the extracellular space (without cellular disorders). Blood tests show hemoconcentration; sodium level and osmotic concentration are normal.

To treat this type of water imbalance use normal saline solution, Ringer solution, glucose-saline solutions, etc.. The volumes of infusions can be calculated according to the formula:

$$V_{H_2O} = 0,2 * BW * (H_{tp} - 0,4) / 0,4 ,$$

V_{H_2O} – volume of infusion, l

H_{tp} – patient's hematocrit, l/l,

BW – body weight, $0,2 * BW$ – volume of extracellular fluid,

0,4- normal hematocrit, l/l,

Hypertonic dehydration is caused by mostly water loss: first it appears in the vascular bed, than in the cells. Laboratory tests show hemoconcentration: elevated levels of proteins, red blood cells, hematocrit. Plasma sodium is over 155 mmol/l and osmotic concentration increases over 310 mOsm/l.

Intensive treatment: if there is no vomiting allow patients to drink. Intravenously give 0,45% saline solution and 2,5 % glucose solution, mixed with insulin. The volume of infusions is calculated according to the formula:

$$V_{H_2O} = 0,6 * BW * (Na_p - 140) / 140 ,$$

V_{H_2O} – water deficiency, l

Na_p – plasma sodium, mmol/l

BW – body weight, $0,6 * BW$ volume of general body fluid

140 – physiological plasma sodium concentration

Hypotonic dehydration is characterized with clinical features of extracellular dehydration. Laboratory tests show decrease of sodium and chlorine ions. Those changes cause intracellular movement of the water (intracellular overhydration). Hemoglobin, hematocrit and protein levels are increased. Sodium is lower than 136 mmol/l, osmolarity is lower than 280 mOsm/l.

To treat this type of water imbalance use normal or hypertonic saline and sodium bicarbonate solution (depends on blood pH). Do not use glucose solutions!

The deficiency of electrolytes is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

Na_d – sodium deficiency, mmol

Na_p – plasma sodium, mmol/l

BW – body weight, 0,2 BW – volume of extracellular fluid

Isotonic overhydration is caused by excess of the water in the vascular bed and extracellular space; however intracellular homeostasis is not violated. Hemoglobin is less than 120 g/l, protein level is less than 60 g/l, plasma sodium is 136-144 mmol/l, osmotic concentration is 285-310 mOsm/l.

Treat the reason of imbalance: cardiac failure, liver insufficiency, etc. Prescribe cardiac glycosides, limit salt and water consumption. Give osmotic diuretics (mannitol solution 1,5 g/kg), saluretics (furosemide solution 2 mg/kg), aldosterone antagonists (triamterene – 200 mg), steroids (prednisolone solution 1-2 mg/kg) albumin solution if necessary (0,2-0,3 g/kg).

Hypertonic overhydration is a state of extracellular electrolytes and water excess combined with intracellular dehydration. Blood tests show decrease of hemoglobin, hematocrit, protein level, however sodium concentration is increased over 144 mmol/l, osmotic concentration is over 310 mOsm/l.

To treat this condition use solutions without electrolytes: glucose with insulin, albumin solutions and prescribe saluretics (furosemide solution), aldosterone antagonists (spironolactone). If it is necessary perform dialysis and peritoneal dialysis. Do not use crystalloids!

Hypotonic overhydration is a state of extracellular and intracellular water excess. Blood tests show decrease of haemoglobin, hematocrit, proteins, sodium and osmotic concentration. Intensive therapy of this condition includes osmotic diuretics (200-400 ml of 20% mannitol solution), hypertonic solutions (50 ml of 10% saline intravenously), steroids. When it is required use ultrafiltration to remove water excess.

9.4 Electrolytes disorders and their treatment

Potassium is a main intracellular cation. Its normal plasma concentration is 3,8-5,1 mmol/l. Daily required amount of potassium is 1 mmol/kg of body weight.

Potassium level less than 3,8 mmol/l is known as kaliopenia. Potassium deficiency is calculated according to the formula:

$$K_d = (4,5 - K_p) * 0,6 BW$$

K- potassium deficiency, mmol;

K_p – potassium level of the patient mmol/l;

$0,6 \cdot BW$ – total body water, l.

To treat this state use 7,5% solution of potassium chloride (1ml of this solution contains 1 mmol of potassium). Give it intravenously slowly with glucose and insulin (20-25 ml/hour). You can also prescribe magnesium preparations. Standard solution for kaliopenia treatment is:

10% glucose solution 400 ml

7,5% potassium chloride solution 20 ml

25% magnesium sulphate solution 3 ml

insulin 12 units

Give it intravenously slowly, during one hour. Forced bolus infusion of potassium solutions (10-15 ml) can bring cardiac arrest.

Potassium level over 5,2 mmol/l is a state called hyperkalemia. To treat this condition use calcium gluconate or calcium chloride solutions (10 ml of 10% solution intravenously), glucose and insulin solution, saluretics, steroids, sodium bicarbonate solution. Hyperkalemia over 7 mmol/l is an absolute indication for dialysis.

Sodium is the main extracellular cation. Its normal plasma concentration is 135-155 mmol/l. Daily required amount of potassium is 2 mmol/kg of body weight.

Sodium concentration which is lower than 135 mmol/l is known as hyponatraemia. This condition is caused by sodium deficiency or water excess. Sodium deficiency is calculated according to the formula:

$$Na_d = (140 - Na_p) \cdot 0,2 \cdot BW,$$

Na_d - sodium deficiency, mmol;

Na_p – sodium concentration of the patient mmol/l;

$0,2 \cdot BW$ – extracellular fluid volume, l.

To treat it use normal saline (1000 ml contains 154 Na mmol) or 5,8% solution of sodium chloride – your choice will depend on osmotic concentration.

Sodium concentration over 155 mmol/l is a state called hypernatremia. This condition usually appears in case of hypertonic dehydration or hypertonic overhydration. Treatment was described in the text above.

Chlorine is the main extracellular anion. Its normal plasma concentration is 98-107 mmol/l. Daily requirement of chlorine is 215 mmol.

Hypochloremia is a condition of decreased plasma chlorine concentration (less than 98 mmol/l).

Chlorine deficiency is calculated according to the formula:

$$Cl_d = (100 - Cl_p) * 0,2 \text{ BW},$$

Cl_d - chlorine deficiency, mmol

Cl_p – plasma chlorine concentration of the patient, mmol/l

$0,2 * BW$ – extracellular fluid volume, l.

To treat hypochloremia use normal saline (1000 ml contains 154 mmol of chlorine) or 5,8% sodium chlorine solution (1 ml contains 1 mmol of chlorine). The choice of solution depends on the osmotic concentration of the plasma.

Hyperchloremia is a condition of increased chlorine concentration (over 107 mmol/l). Intensive therapy of this state includes treatment of the disease, which caused it (decompensated heart failure, hyperchloremic diabetes insipidus, glomerulonephritis). You can also use glucose, albumin solutions and dialysis.

Magnesium is mostly an intracellular cation. Its plasma concentration is 0,8-1,5 mmol/l. Daily requirement of magnesium is 0,3 mmol/kg.

Hypomagnesemia is a state of decreased magnesium concentration: less than 0,8 mmol/l. Magnesium deficiency is calculated according to the formula:

$$Mg_d = (1,0 - Mg_p) * 0,6 \text{ BW},$$

Mg_d - magnesium deficiency, mmol

Mg_p – plasma magnesium concentration of the patient, mmol/l

$0,6 * BW$ – extracellular fluid volume, l.

Use 25% magnesium sulphate solution to treat this state (1 ml of it contains 0,5 mmol of magnesium).

Hypermagnesemia is a state of increased magnesium concentration (more than 1,5 mmol/l). This condition appears usually in case of hyperkalemia and you should treat it as you treat hyperkalemia.

Calcium is one of the extracellular cations. Its normal concentration is 2,35-2,75 mmol/l. Daily requirement of calcium is 0,5 mmol/kg.

Calcium concentration less than 2,35 mmol/l is called hypocalcemia. Calcium deficiency is calculated according to the formula:

$$Ca_d = (2,5 - Ca_p) * 0,2 BW,$$

Ca_d – calcium deficiency, mmol

Cl_p – plasma calcium concentration of the patient, mmol/l

$0,2 * BW$ – extracellular fluid volume, l.

To treat this state use 10% calcium chloride (1 ml of the solution contains 1,1 mmol of calcium), ergocalciferol; in case of convulsions prescribe sedative medicines.

Hypercalcemia is a condition with increased calcium concentration (over 2,75 mmol/l). Treat the disease, which caused it: primary hyperparathyroidism, malignant bone tumors, etc. Additionally use infusion therapy (solutions of glucose with insulin), steroids, dialysis and hemosorbition.

9.5 Acid-base imbalance and its treatment.

There are 2 main types of acid-base imbalance: acidosis and alkalosis.

pH is a decimal logarithm of the reciprocal of the hydrogen ion activity. It shows acid-base state of the blood.

Normal pH of arterial blood is 7,36-7,44. Acid based imbalance is divided according to the pH level into:

pH 7,35-7,21 – subcompensated acidosis

pH < 7,2 – decompensated acidosis

pH 7,45-7,55 – subcompensated alkalosis

pH > 7,56 – decompensated alkalosis

Respiratory part of the acid-base imbalance is characterized with pCO_2 . Normally pCO_2 of arterial blood is 36-44 mm Hg. Hypercapnia (pCO_2 increased over 45 mm Hg) is a sign of respiratory acidosis. Hypocapnia (pCO_2 less than 35 mm Hg) is a symptom of respiratory alkalosis.

Basis excess index is also a characteristic of metabolic processes. Normally H^+ ions produced during metabolic reactions are neutralized with buffer system. BE of arterial blood is $0 \pm 1,5$. Positive value of BE (with +) is a sign of base excess or plasma acid deficiency (metabolic alkalosis). Negative value of BE (with -) is a symptom of bases deficiency, which is caused by acid neutralization in case of metabolic acidosis.

Respiratory acidosis (hypercapnia) is a condition caused by insufficient elimination of CO₂ from the body during hypoventilation. Laboratory tests show:

pH < 7,35,

pCO_{2a} > 46 mm Hg

BE - normal values

However when the respiratory acidosis progresses renal compensation fails to maintain normal values and BE gradually increases. In order to improve this condition you should treat acute and chronic respiratory violations. When pCO₂ is over 60 mm Hg begin artificial lung ventilation (through the mask or tube; when the necessity of ventilation lasts longer than 3 days – perform tracheostomy).

Respiratory alkalosis (hypocapnia) is usually an effect of hyperventilation, caused by excessive stimulation of respiratory centre (injuries, metabolic acidosis, hyperactive metabolism, etc.) or wrong parameters of mechanical ventilation. Gasometry shows:

pH > 7,45,

pCO_{2a} < 33 mm Hg

BE < +1,5 mmol/l.

However prolong alkalosis brings decrease of BE due to compensatory retain of H⁺ ions. To improve this imbalance treat its reason: normalize ventilation parameters; if patients breathing has rate over 40 per minute – sedate the patient, perform the intubation and begin artificial ventilation with normal parameters.

Metabolic acidosis is characterized with absolute and relative increase of H⁺ ions concentration due to acid accumulation (metabolic disorders, block of acid elimination, excessive acid consumption in case of poisonings, etc.). Laboratory tests show:

pH < 7,35,

pCO_{2a} < 35 mm Hg

BE (-3) mmol/l.

Treat the main reason of acid-base disorder: diabetic ketoacidosis, renal insufficiency, poisoning, hyponatremia or hyperchloremia, etc. Normalize pH with 4% sodium bicarbonate solution. Its dose is calculated according to the formula:

$$V = 0,3 * BE * BW$$

V- volume of sodium bicarbonate solution, ml

BE – bases excess with “-”, mmol/l

BW – body weight, kg

Metabolic alkalosis is a condition of absolute and relative decrease of H⁺ ions concentration. Blood tests show:

pH > 7,45,

pCO_{2a} normal or insignificantly increased (compensatory reaction)

BE 3,0 mmol/l.

To treat this condition use “acid” solutions, which contain chlorides (saline, potassium chloride). In case of kaliopenia give potassium solutions.

Respiratory and metabolic imbalances can mix in case of severe decompensated diseases due to failure of compensatory mechanisms. Correct interpretation of these violations is possible only in case of regular and iterative gasometry blood tests.

Control tasks.

Task 1.

Calculate the total body water volume and its extracellular and intracellular volumes of the Patient, the patient of 48 years and body weight 88 kg.

Task 2.

Patient, the patient of 23 with body weight 70 kg has sodium level 152 mmol/l and hematocrit 0,49 l/l. Name the type of water balance disorder.

Task 3.

Patient, the patient of 54 with body weight 76 kg has sodium level 128 mmol/l. Calculate the volume of saline and 7,5% sodium chloride solution necessary for the treatment of this condition.

Task 4.

Patient, the patient of 60 with body weight 60 kg has sodium level 140 mmol/l and hematocrit 0,55 l/l. Name the type of disorder and prescribe infusion therapy.

Task 5.

Patient, the patient of 42 with body weight 80 kg has potassium level 2,6 mmol/l. Calculate the volume of 4% potassium chloride solution necessary for treatment of this condition.

Task 6.

Patient, the patient of 33 with body weight 67 kg and diagnosis “gastric ulcer, complicated with pylorostenosis” has potassium concentration 3 mmol/l, chlorine concentration

88 mmol/l. pH 7,49, pCO_{2a} 42 mm Hg, BE + 10 mmol/l. Name the type of disorder.

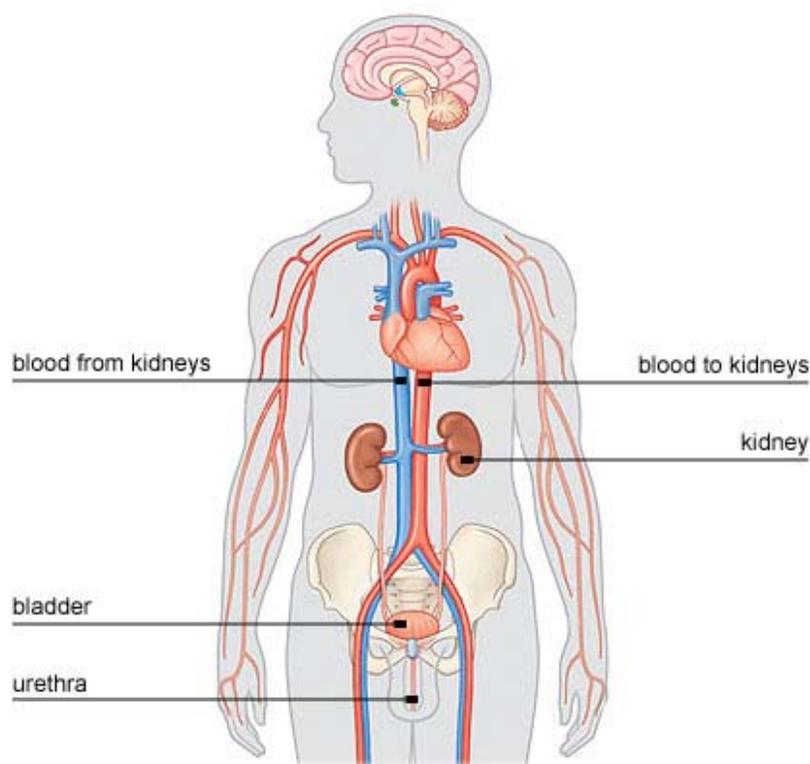

Task 7.

Patience, the patient of 50 with body weight 75 kg, was transported to the admission unit of the hospital with: unconsciousness, cyanotic skin, low blood pressure, shallow breathing. Blood tests show: pH 7,18, pCO_{2a} 78 mm Hg, pO_{2A} – 57 mm Hg, BE -4,2 mmol/l. Name the type of acid-base disorder and prescribe treatment.

Task 8.

Patience, the patient with body weight 62 kg and renal insufficiency has: potassium concentration 5,2 mmol/l, sodium concentration 130 mmol/l, calcium concentration 1,5 mmol/l, pH 7,22, pCO_{2a} 34 mm Hg, BE -9,2 mmol/l. Name the type of disorder.

Violations of homeostasis and their correction.

9.1 The importance of the water to the organism.

Life on earth was born in the water environment. Water is a universal solvent for all the biochemical processes of the organism. Only in case of stable quantitative and qualitative composition of both intracellular and extra cellular fluids homeostasis is remained.

The body of an adult human contains 60% of water. Intracellular water makes 40% of the body weight, the water of intercellular space makes 15% of body weight and 5% of body weight are made by the water in the vessels. It is considered that due to unlimited diffusion of water between vessels and extra vascular space the volume of extracellular fluid is 20% of body weight (15%+5%).

Physiologically insignificant amounts of water are distributed beyond the tissues in the body cavities: gastrointestinal tract, cerebral ventricles, joint capsules (nearly 1% of the body weight). However during different pathologic conditions this “third space” can cumulate large amounts of fluid: for example in case of ascites caused by chronic cardiac insufficiency or cirrhosis abdominal cavity contains up to 10 liters of fluid. Peritonitis and intestinal obstructions remove the fluid part of blood from the vessels into the intestinal cavity.

Severe dehydration is extremely dangerous for the patient. Water gets to the body with food and drinks, being absorbed by the mucous membranes of gastro-intestinal tract in total amount of 2-3 liters per day. Additionally in different metabolic transformations of lipids, carbohydrates and proteins nearly 300 of endogenous water are created. Water is evacuated from the body with urine (1,5-2 liters), stool (300 ml), perspiration and breathing (those two reasons are combined as “perspiration loss” and make from 300 to 1000 ml per day).

Water balance is regulated through complicated, but reliable mechanisms. Control over water and electrolytes excretion is realized by osmotic receptors of posterior hypothalamus, volume receptors of the atrial walls, baroreceptors of carotid sinus, juxtaglomerular apparatus of the kidneys and adrenal cortical cells.

When there is a water deficiency or electrolytes excess (sodium, chlorine) thirst appears and this makes us drink water. At the same time posterior pituitary produces antidiuretic hormone, which decreases urine output. Adrenals reveal into the blood flow aldosterone, which stimulates reabsorption of sodium ions in the tubules and thus also decreases diuresis (due to osmosis laws water will move to the more concentrated solution). This way organism can keep precious water.

On the contrary, in case of water excess endocrine activity of glands is inhibited and water is actively removed from the body through the kidneys.

9.2 Importance of osmolarity for homeostasis.

Water sections of the organism (intracellular and extracellular) are divided with semipermeable membrane – cell wall. Water easily penetrates through it according to the laws of osmosis. Osmosis is a movement of water through a partially permeable membrane from the solution with lower concentration to a solution with higher concentration.

Osmotic concentration (osmolarity) is the concentration of active parts in one liter of solution (water). It is defined as a number of miliosmoles per liter (mOsm/l). Normally osmotic concentration of plasma, intracellular and extracellular fluids is equal and varies between 285mOsm/l. This value is one of the most important constants of the organism, because if it changes in one sector the whole fluid of the body will be redistributed (water will move to the environment with higher concentration). Over hydration of one sector will bring dehydration of

another. For example, when there is a tissue damage concentration of active osmotic parts increases and water diffuses to this compartment, causing oedema. On the contrary plasma osmolarity decreases, when there is a loss of electrolytes and osmotic concentration of the cellular fluid stays on the previous level. This brings cellular oedema, because water moves through the intracellular space to the cells due to their higher osmotic concentration.

Cerebral oedema appears when the plasma osmolarity is lower than 270 mOsm/l. Activity of central nervous system is violated and hypoosmolar coma occurs. Hyperosmolar coma appears when the plasma osmolarity is over 320 mOsm/l: water leaves the cells and fills the vascular bed and this leads to cellular dehydration. The sensitive to cellular dehydration are the cells of the brain.

Plasma osmolarity is measured with osmometer. The principle of measurement is based on difference in freezing temperature between distilled water and plasma. The higher is the osmolarity (quantity of molecules) the lower is freezing temperature.

Plasma osmotic concentration can be calculated according to the formula:

$$\text{Osmotic concentration} = 1,86 * \text{Na} + \text{glucose} + \text{urea} + 10,$$

Plasma osmolarity (osmotic concentration) – mOsm/l

Na- sodium concentration of plasma, mmol/l

Glucose- glucose concentration of the plasma, mmol/l

Urea- urea concentration of the plasma, mmol/l

According to this formula sodium concentration is the main factor influencing plasma osmolarity. Normally sodium concentration is 136-144 mmol/l. Water and electrolytes balance can be violated with external fluid and electrolytes loss, their excessive inflow or wrong distribution.

9.3 Fluid imbalance and principles of its intensive treatment.

Water imbalance is divided into dehydration and overhydration.

Dehydration is caused by:

- excessive perspiration in conditions of high temperature;
- rapid breathing (dyspnea, tachypnea) or artificial ventilation without humidification of the air;
- vomiting, diarrhoea, fistulas;

- blood loss, burns;
- diuretics overdose;
- excessive urine output;
- inadequate enteral and parenteral nutrition or infusion therapy (comatose patients, postoperative care);
- pathological water distribution (“third space” in case of inflammation or injury).

Dehydration signs: weight loss, decrease of skin turgor and eyeballs tone, dry skin and mucous membranes; low central venous pressure, cardiac output and blood pressure (collapse is possible); decreased urine output and peripheral veins tone; capillary refill over 2 seconds (microcirculation disorders) and low skin temperature; intracellular dehydration is characterized with thirst and consciousness disorders. Laboratory tests show blood concentration: hematocrit, hemoglobin concentration, protein level and red blood cells concentration increase.

Overhydration appears in case of:

- excessive water consumption, inadequate infusion therapy;
- acute and chronic renal failure, hepatic and cardiac insufficiency;
- disorders of fluid balance regulation;
- low protein edema.

Clinical findings in case of overhydration are: weight gain, peripheral oedema, transudation of the plasma into the body cavities (pleural, abdominal), high blood pressure and central venous pressure. In case of intracellular overhydration appear additional symptoms: nausea, vomiting, signs of cerebral edema (spoor, coma). Laboratory tests prove hemodilution.

According to the osmotic concentration of plasma dehydration and overhydration are divided into hypotonic, isotonic and hypertonic.

Isotonic dehydration is caused by equal loss of electrolytes and fluid from the extracellular space (without cellular disorders). Blood tests show hemoconcentration; sodium level and osmotic concentration are normal.

To treat this type of water imbalance use normal saline solution, Ringer solution, glucose-saline solutions, etc.. The volumes of infusions can be calculated according to the formula:

$$V_{H_2O} = 0,2 * BW * (H_{tp} - 0,4) / 0,4 ,$$

V_{H_2O} – volume of infusion, l

Ht_p – patient's hematocrit, l/l,

BW – body weight, 0,2*BW – volume of extracellular fluid,

0,4- normal hematocrit, l/l,

Hypertonic dehydration is caused by mostly water loss: first it appears in the vascular bed, than in the cells. Laboratory tests show hemoconcentration: elevated levels of proteins, red blood cells, hematocrit. Plasma sodium is over 155 mmol/l and osmotic concentration increases over 310 mOsm/l.

Intensive treatment: if there is no vomiting allow patients to drink. Intravenously give 0,45% saline solution and 2,5 % glucose solution, mixed with insulin. The volume of infusions is calculated according to the formula:

$$V_{H_2O} = 0,6 * BW (Na_p - 140) / 140,$$

V_{H₂O} – water deficiency, l

Na_p – plasma sodium, mmol/l

BW – body weight, 0,6*BW volume of general body fluid

140 – physiological plasma sodium concentration

Hypotonic dehydration is characterized with clinical features of extracellular dehydration. Laboratory tests show decrease of sodium and chlorine ions. Those changes cause intracellular movement of the water (intracellular overhydration). Hemoglobin, hematocrit and protein levels are increased. Sodium is lower than 136 mmol/l, osmolarity is lower than 280 mOsm/l.

To treat this type of water imbalance use normal or hypertonic saline and sodium bicarbonate solution (depends on blood pH). Do not use glucose solutions!

The deficiency of electrolytes is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

Na_d – sodium deficiency, mmol

Na_p – plasma sodium, mmol/l

BW – body weight, 0,2 BW – volume of extracellular fluid

Isotonic overhydration is caused by excess of the water in the vascular bed and extracellular space; however intracellular homeostasis is not violated. Hemoglobin is less than 120 g/l, protein level is less than 60 g/l, plasma sodium is 136-144 mmol/l, osmotic concentration is 285-310 mOsm/l.

Treat the reason of imbalance: cardiac failure, liver insufficiency, etc. Prescribe cardiac glycosides, limit salt and water consumption. Give osmotic diuretics (mannitol solution 1,5 g/kg), saluretics (furosemide solution 2 mg/kg), aldosterone antagonists (triamterene – 200 mg), steroids (prednisolone solution 1-2 mg/kg) albumin solution if necessary (0,2-0,3 g/kg).

Hypertonic overhydration is a state of extracellular electrolytes and water excess combined with intracellular dehydration. Blood tests show decrease of hemoglobin, hematocrit, protein level, however sodium concentration is increased over 144 mmol/l, osmotic concentration is over 310 mOsm/l.

To treat this condition use solutions without electrolytes: glucose with insulin, albumin solutions and prescribe saluretics (furosemide solution), aldosterone antagonists (spironolactone). If it is necessary perform dialysis and peritoneal dialysis. Do not use crystalloids!

Hypotonic overhydration is a state of extracellular and intracellular water excess. Blood tests show decrease of haemoglobin, hematocrit, proteins, sodium and osmotic concentration. Intensive therapy of this condition includes osmotic diuretics (200-400 ml of 20% mannitol solution), hypertonic solutions (50 ml of 10% saline intravenously), steroids. When it is required use ultrafiltration to remove water excess.

9.4 Electrolytes disorders and their treatment

Potassium is a main intracellular cation. Its normal plasma concentration is 3,8-5,1 mmol/l. Daily required amount of potassium is 1 mmol/kg of body weight.

Potassium level less than 3,8 mmol/l is known as kaliopenia. Potassium deficiency is calculated according to the formula:

$$K_d = (4,5 - K_p) * 0,6 \text{ BW}$$

K- potassium deficiency, mmol;

K_p – potassium level of the patient mmol/l;

0,6*BW – total body water, l.

To treat this state use 7,5% solution of potassium chloride (1ml of this solution contains 1 mmol of potassium). Give it intravenously slowly with glucose and insulin (20-25 ml/hour). You can also prescribe magnesium preparations. Standard solution for kaliopenia treatment is:

10% glucose solution 400 ml

7,5% potassium chloride solution 20 ml

25% magnesium sulphate solution 3 ml

insulin 12 units

Give it intravenously slowly, during one hour. Forced bolus infusion of potassium solutions (10-15 ml) can bring cardiac arrest.

Potassium level over 5,2 mmol/l is a state called hyperkalemia. To treat this condition use calcium gluconate or calcium chloride solutions (10 ml of 10% solution intravenously), glucose and insulin solution, saluretics, steroids, sodium bicarbonate solution. Hyperkalemia over 7 mmol/l is an absolute indication for dialysis.

Sodium is the main extracellular cation. Its normal plasma concentration is 135-155 mmol/l. Daily required amount of potassium is 2 mmol/kg of body weight.

Sodium concentration which is lower than 135 mmol/l is known as hyponatraemia. This condition is caused by sodium deficiency or water excess. Sodium deficiency is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 \text{ BW},$$

Na- sodium deficiency, mmol;

Na_p – sodium concentration of the patient mmol/l;

0,2*BW – extracellular fluid volume, l.

To treat it use normal saline (1000 ml contains 154 Na mmol) or 5,8% solution of sodium chloride – your choice will depend on osmotic concentration.

Sodium concentration over 155 mmol/l is a state called hypernatremia. This condition usually appears in case of hypertonic dehydration or hypertonic overhydration. Treatment was described in the text above.

Chlorine is the main extracellular anion. Its normal plasma concentration is 98-107 mmol/l. Daily requirement of chlorine is 215 mmol.

Hypochloremia is a condition of decreased plasma chlorine concentration (less than 98 mmol/l).

Chlorine deficiency is calculated according to the formula:

$$Cl_d = (100 - Cl_p) * 0,2 \text{ BW},$$

Cl_d- chlorine deficiency, mmol

Cl_p – plasma chlorine concentration of the patient, mmol/l

$0,2 * BW$ – extracellular fluid volume, l.

To treat hyponatremia use normal saline (1000 ml contains 154 mmol of chlorine) or 5,8% sodium chloride solution (1 ml contains 1 mmol of chlorine). The choice of solution depends on the osmotic concentration of the plasma.

Hypernatremia is a condition of increased chlorine concentration (over 107 mmol/l). Intensive therapy of this state includes treatment of the disease, which caused it (decompensated heart failure, hypernatremic diabetes insipidus, glomerulonephritis). You can also use glucose, albumin solutions and dialysis.

Magnesium is mostly an intracellular cation. Its plasma concentration is 0,8-1,5 mmol/l. Daily requirement of magnesium is 0,3 mmol/kg.

Hypomagnesemia is a state of decreased magnesium concentration: less than 0,8 mmol/l. Magnesium deficiency is calculated according to the formula:

$$Mg_d = (1,0 - Mg_p) * 0,6BW,$$

Mg_d - magnesium deficiency, mmol

Mg_p – plasma magnesium concentration of the patient, mmol/l

$0,6 * BW$ – extracellular fluid volume, l.

Use 25% magnesium sulphate solution to treat this state (1 ml of it contains 0,5 mmol of magnesium).

Hypermagnesemia is a state of increased magnesium concentration (more than 1,5 mmol/l). This condition appears usually in case of hyperkalemia and you should treat it as you treat hyperkalemia.

Calcium is one of the extracellular cations. Its normal concentration is 2,35-2,75 mmol/l. Daily requirement of calcium is 0,5 mmol/kg.

Calcium concentration less than 2,35 mmol/l is called hypocalcemia. Calcium deficiency is calculated according to the formula:

$$Ca_d = (2,5 - Ca_p) * 0,2 BW,$$

Ca_d – calcium deficiency, mmol

Ca_p – plasma calcium concentration of the patient, mmol/l

$0,2 * BW$ – extracellular fluid volume, l.

To treat this state use 10% calcium chloride (1 ml of the solution contains 1,1 mmol of calcium), ergocalciferol; in case of convulsions prescribe sedative medicines.

Hypercalcemia is a condition with increased calcium concentration (over 2,75 mmol/l). Treat the disease, which caused it: primary hyperparathyroidism, malignant bone tumors, etc. Additionally use infusion therapy (solutions of glucose with insulin), steroids, dialysis and hemosorbition.

9.5 Acid-base imbalance and its treatment.

There are 2 main types of acid-base imbalance: acidosis and alkalosis.

pH is a decimal logarithm of the reciprocal of the hydrogen ion activity. It shows acid-base state of the blood.

Normal pH of arterial blood is 7,36-7,44. Acid based imbalance is divided according to the pH level into:

pH 7,35-7,21 – subcompensated acidosis

pH < 7,2 – decompensated acidosis

pH 7,45-7,55 – subcompansated alkalosis

pH > 7,56 – decompensated alkalosis

Respiratory part of the acid-base imbalance is characterized with pCO₂. Normally pCO₂ of arterial blood is 36-44 mm Hg. Hypercapnia (pCO₂ increased over 45 mm Hg) is a sign of respiratory acidosis. Hypocapnia (pCO₂ less than 35 mm Hg) is a symptom of respiratory alkalosis.

Basis excess index is also a characteristic of metabolic processes. Normally H⁺ ions produced during metabolic reactions are neutralized with buffer system. BE of arterial blood is 0±1,5. Positive value of BE (with +) is a sign of base excess or plasma acid deficiency (metabolic alkalosis). Negative value of BE (with -) is a symptom of bases deficiency, which is caused by acid neutralization in case of metabolic acidosis.

Respiratory acidosis (hypercapnia) is a condition caused by insufficient elimination of CO₂ from the body during hypoventilation. Laboratory tests show:

pH < 7,35,

pCO_{2a} > 46 mm Hg

BE - normal values

However when the respiratory acidosis progresses renal compensation fails to maintain normal values and BE gradually increases. In order to improve this condition you should treat acute and chronic respiratory violations. When pCO₂ is over 60 mm Hg begin artificial lung

ventilation (through the mask or tube; when the necessity of ventilation lasts longer than 3 days – perform tracheostomy).

Respiratory alkalosis (hypocapnia) is usually an effect of hyperventilation, caused by excessive stimulation of respiratory centre (injuries, metabolic acidosis, hyperactive metabolism, etc.) or wrong parameters of mechanical ventilation. Gasometry shows:

pH > 7,45,

pCO_{2a} < 33 mm Hg

BE < +1,5 mmol/l.

However prolong alkalosis brings decrease of BE due to compensatory retain of H⁺ ions. To improve this imbalance treat its reason: normalize ventilation parameters; if patients breathing has rate over 40 per minute – sedate the patient, perform the intubation and begin artificial ventilation with normal parameters.

Metabolic acidosis is characterized with absolute and relative increase of H⁺ ions concentration due to acid accumulation (metabolic disorders, block of acid elimination, excessive acid consumption in case of poisonings, etc.). Laboratory tests show:

pH < 7,35,

pCO_{2a} < 35 mm Hg

BE (-3) mmol/l.

Treat the main reason of acid-base disorder: diabetic ketoacidosis, renal insufficiency, poisoning, hyponatremia or hyperchloremia, etc. Normalize pH with 4% sodium bicarbonate solution. Its dose is calculated according to the formula:

$$V = 0,3 * BE * BW$$

V- volume of sodium bicarbonate solution, ml

BE – bases excess with “-”, mmol/l

BW – body weight, kg

Metabolic alkalosis is a condition of absolute and relative decrease of H⁺ ions concentration. Blood tests show:

pH > 7,45,

pCO_{2a} normal or insignificantly increased (compensatory reaction)

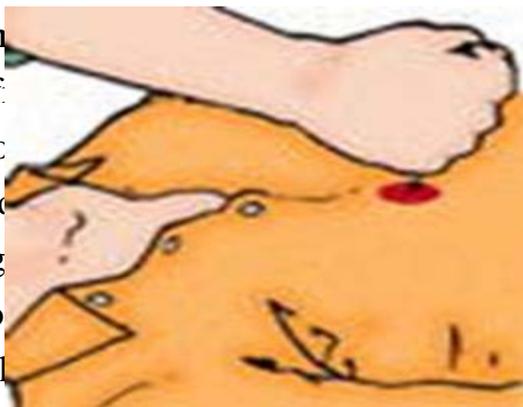

BE 3,0 mmol/l.

To treat this condition use “acid” solutions, which contain chlorides (saline, potassium chloride). In case of kaliopenia give potassium solutions.

Respiratory and metabolic imbalances can mix in case of severe decompensated diseases due to failure of compensatory mechanisms. Correct interpretation of these violations is possible only in case of regular and iterative gasometry blood tests.

 th separate organs
 appears. If organism
 ative mechanisms
 react a terminal

state appears – situation of an absolute life_threat.

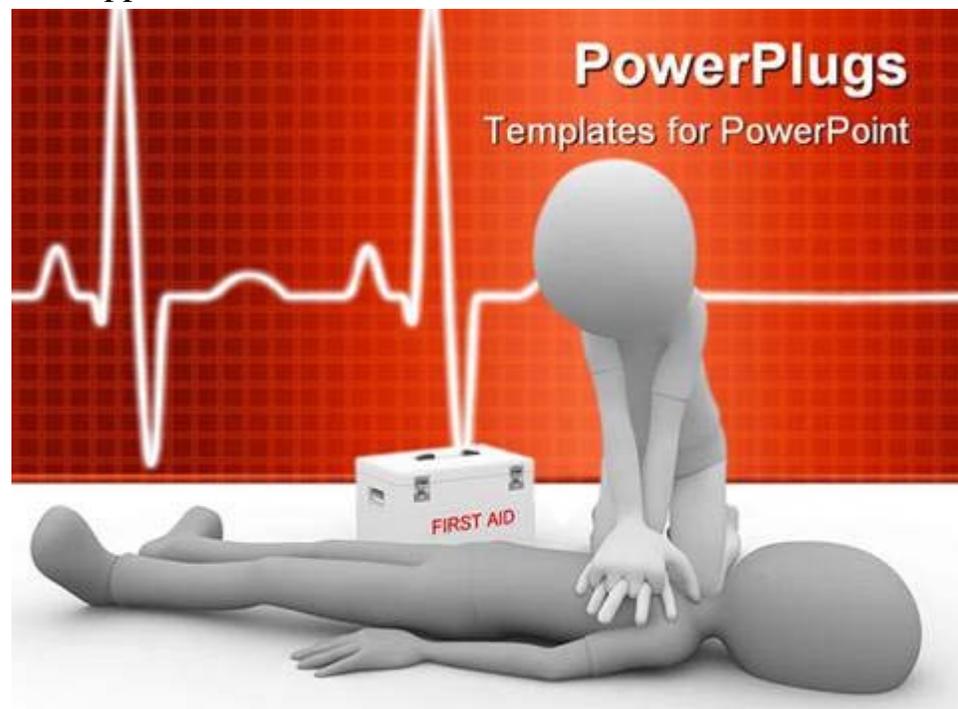

Fig. Importance of CPR

Intensive care and resuscitation in many cases may prevent and eliminate energy and substrate deficiency, which appear during the terminal state and consequently save the organism from death.

Intensive care is a complex of methods, which allows a temporary replacement of vital functions. These methods are used to prevent the adaptation mechanisms exhaustion and to avoid the terminal state appearance.

Fig. Checking of patients condition

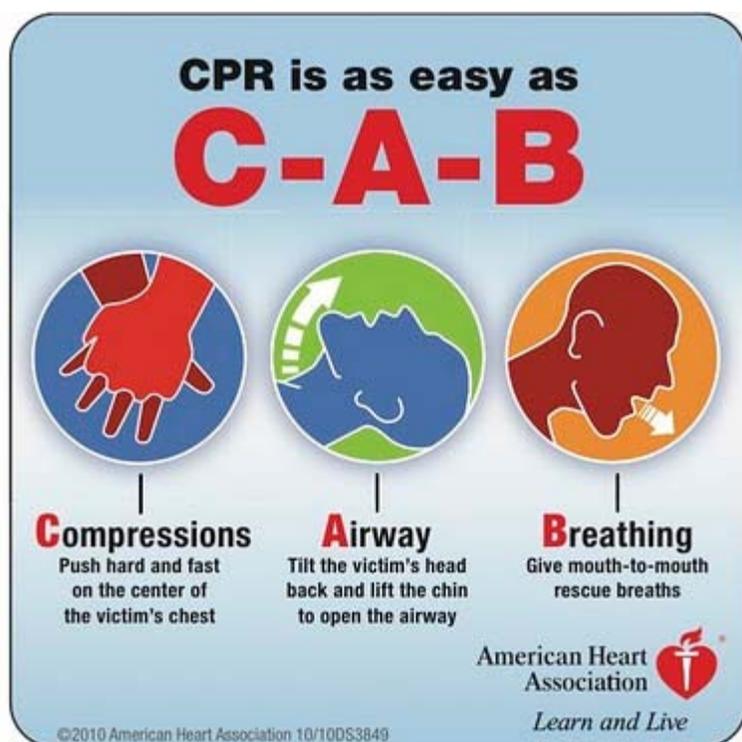

Fig Method of CPR

Reanimatology is a science about vitalization of the organism, prevention and treatment of the terminal states (according to V. Negovski).

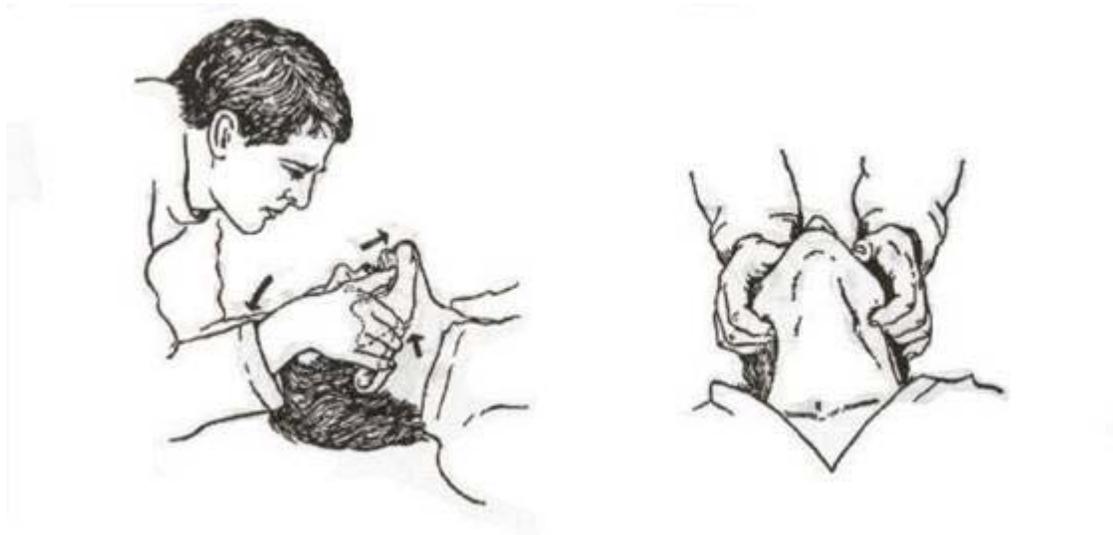

Fig. Artificial lung ventilation

Human being for existence needs continuous entry and consumption of oxygen and elimination of carbonic acid. Those processes are provided with the coordinated functioning of respiration and circulation under the control of the central nervous system. These 3 systems are so called “triple gates of death” (lungs, heart and brain). Arrest of vital functions (death) might be sudden (accidents) or quite predictable consequence of aging or an incurable disease.

Fig. Cleaning of oral cavity

The whole process of dying might be divided into next stages: Preagony. Physiologic mechanisms of vital activity are deeply exhausted: central nervous system is depressed (coma is possible);

heart sounds are weak, pulse is thready, systolic blood pressure is lower than the critical level of 70 mm Hg; external respiration is weak and not effective, tidal volume and respiratory frequency are inadequate; functions of parenchymal organs are violated. Preagony can last for minutes, hours or even days. During this time condition of patient becomes worse and finally everything ends with a terminal pause. Patient faints, blood pressure and pulse become hard to measure, respiratory arrest appears and reflexes are lost.

Fig. Artificial lung ventilation

Terminal pause ends within a minute and final stage – agony begins. According to the complete exhaustion of superior control centers of the CNS lower centers (bulbar respiratory and vasomotor centers, reticular formation) are getting more active. Muscular tone, reflexes and external respiration (chaotic, with auxiliary respiratory muscles participation) are restored.

Fig. Position of hands

The pulse is palpated over the main arteries; systolic blood pressure may rise up to 50_70 mm Hg (due to temporary renewed vascular tone). At the same time irreversible cell metabolic changes take place: reserves of high_energy substances are burnt out and in 20_40 seconds clinical death appear.

Fig. Artificial lung ventilation

In quite a long list of pathological cases (drowning, electrical or lightning injuries, strangulated asphyxia, communication accidents, myocardial infarction, etc.) clinical death appears suddenly, without any previous sings of dying.

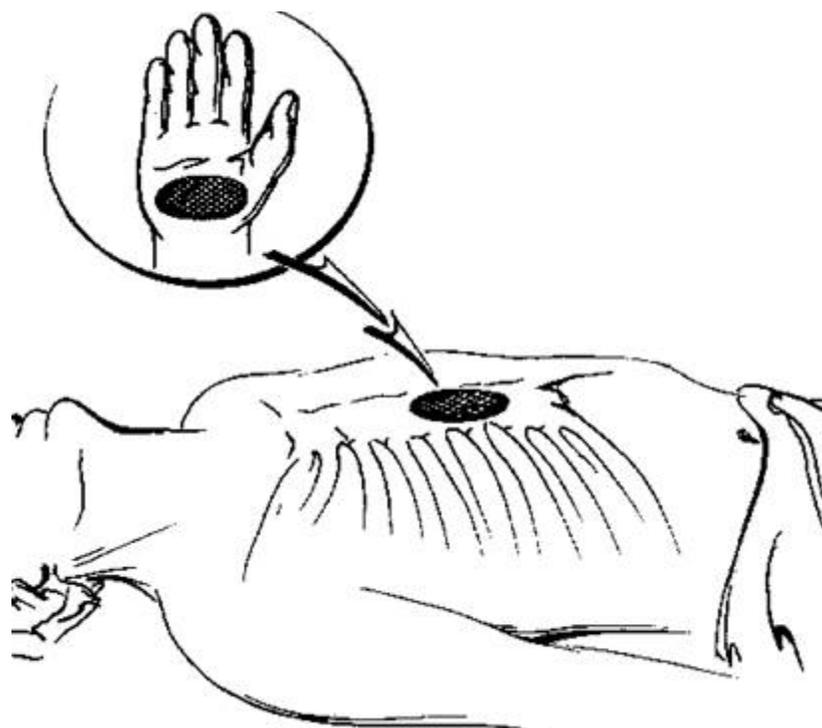

Fig. Position of precordial beat

Main sings of clinical death are:

1. Lack of pulse over the main arteries (carotid, femoral arteries)
2. Persistent pupil's dilatation with a lack of photoreaction.
3. Lack of unassisted ventilation.

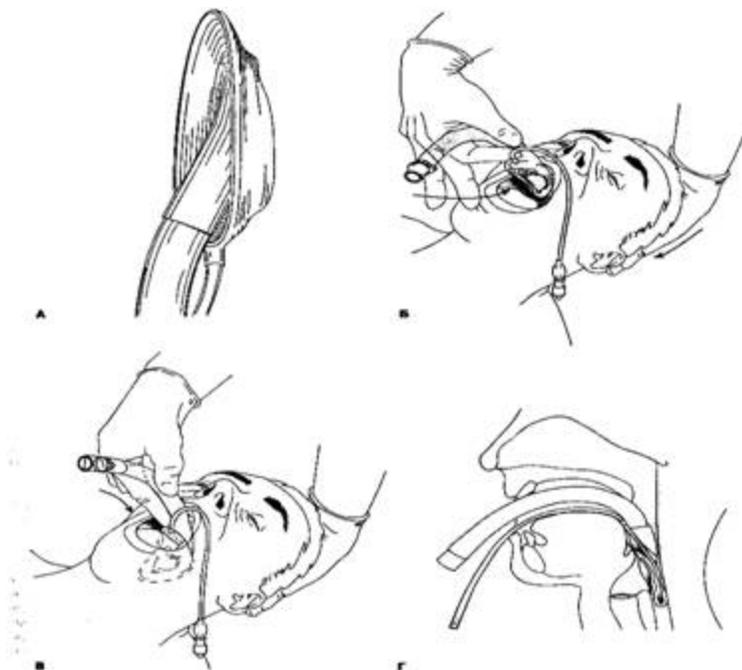

Fig. Laryngeal mask like alternative method of intubation

Additional sings of clinical death:

1. Changes of the skin color (gray or cyanotic)
2. Unconsciousness

3. Lack of reflexes and muscular atony.

The effectiveness of resuscitation is greatly affected by the temperature of the environment and the duration of dying.

Fig. Position of hands during CPR

Normally clinical death caused by a sudden cardiac arrest in case of normal environment temperature lasts nearly 5 minutes. In case of hypothermia – 10 minutes and more.

Fig. Heart massage

The longer process of dying lasts, the shorter clinical death is and thus lower are the chances of positive resuscitation outcome.

Fig. Heart massage

Biological death appears as a result of irreversible changes of the whole organism, especially of the CNS changes.

Stages and phases of resuscitation.

Resuscitation is a complex of actions, which prevent irreversible changes and restore vital functions of an organism in a state of clinical death. A person, who conducts these actions is called a rescuer.

The final goal of resuscitation is to bring back life of full value to a patient after clinical death. This task might be realized only with immediate, professional and sequential measures.

Fig. steps of CPR

Nevertheless always care about your own safety, as your duty is to help, not to increase the number of victims. Pay attention to the conditions in which clinical death appeared, make sure you are not in danger, use gloves and eyewear if they are available. Of course final decision about priorities belongs to you, but every biological liquid contacting your skin and mucosa is a potential infection source. If you feel unwilling to perform rescue breathing mouth_to_mouth or physically it is impossible to ventilate the patient for some reason at least do chest compressions.

Fig. New recommendation for performing CPR

According to the modern level of resuscitation

knowledge blood flow is the most important target of CPR.

The first stage of resuscitation is basic life support. It is

conducted by a rescuer who is not obligatory a health care professional, but a witness who acquired basic life support skills.

Fig. Precardial beat

After clinical death is stated (try not to evaluate respiration (B)

and heart action (C) more than 10 seconds) a rescuer should

immediately start basic life support (optimal position of patient who is on the flat surface lying supinely).

Successful cardiopulmonary resuscitation is based on three pillars:

I. Airways (A). To make

ABC check upper airways free use triple

method of Peter Safar: 1. Open the mouth of the patient and empty the oral cavity, if necessary, from foreign bodies and liquids such as vomit, sputum, false jaws, blood cloths, etc (using your finger or forceps with surgical drape).

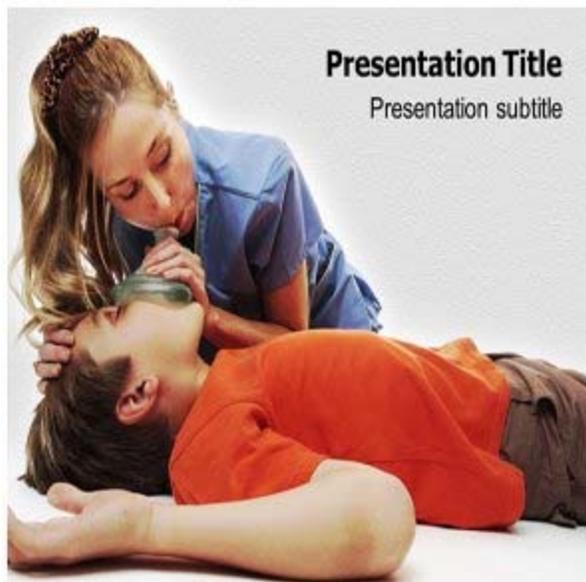

Fig. Ventilation through mask

2. Tilt the head backwards (remember, that in case of each trauma patient we always suspect neck injury, so tilting and sharp neck moves should be rather avoided). After this in most cases upper airways become conductive (soft palate and tongue are not blocking air passage any more).

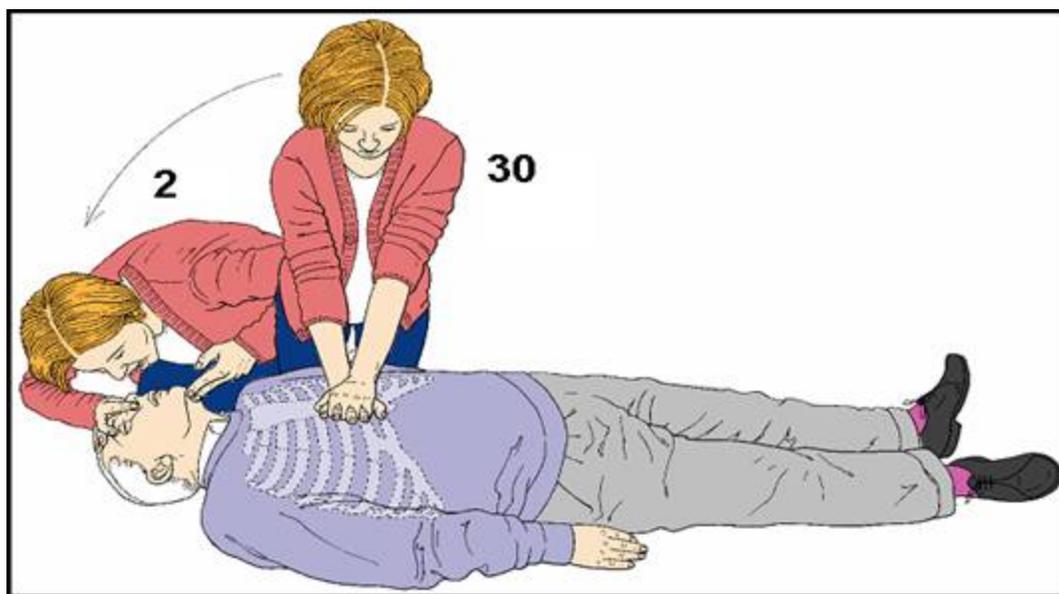

Fig. Artificial lung ventilation and heart massage

Fig. Artificial lung ventilation

3 . Thrust the jaw forward. In all cases this part of Safar method provides final air passage.

Fig. Defibrillation

You can also use simple airway adjuncts such as oropharyngeal and nasopharyngeal airways.

II. Breathing (B). Respiratory support in conditions of BLS is usually mouth_to_mouth ventilation. If only there is a chance use devices for pre_hospital ventilation: pocket resuscitation masks of different types or at least handkerchief. Place closely your mouth

over that of the patient and make a normal exhale (volume 600_800 ml). Remember to keep the airways conductive using the methods

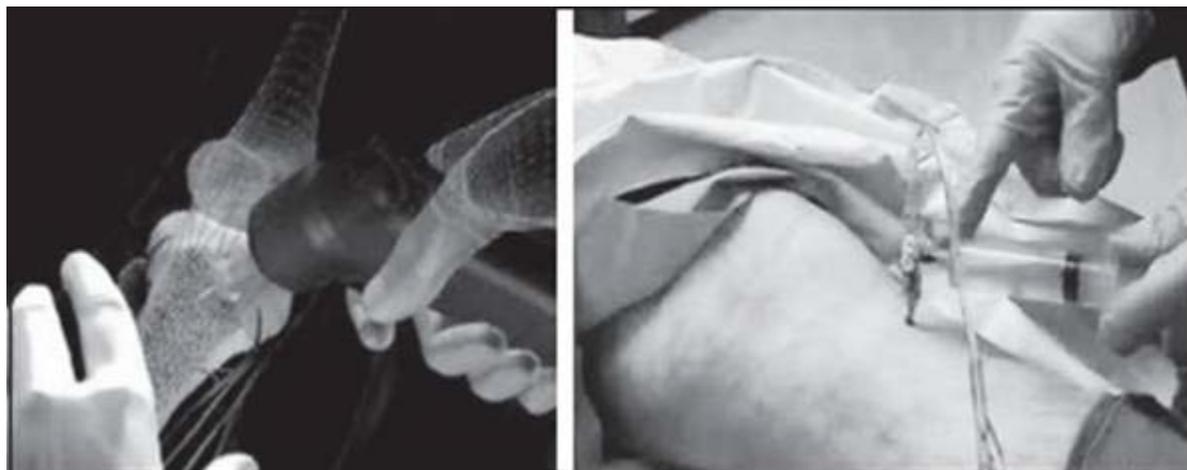

Fig. Using of intraosseal injection during CPR

described above; use fingers of your free hand to close the nostrils of the patient. In case of correct ventilation chest rises and falls silently. Repeat this action one more time.

III. External heart massage (C– circulation). Standing aside the patient (on your knees), place your hands in the center of the chest: heel of the hand in the middle of the lower part of sternum or between lower and middle thirds of sternum. Don't lose precious time looking for anatomic landmarks, as soon as possible start heart massage. Pay attention to your fingers – they should not lean on the chest, otherwise you will break the ribs during compressions. The frequency of compressions should be 100 per minute. It means that until you haven't provided airways with endotracheal tube you make 30 compressions per every 2 breathes. Heart massage is extremely important: do it correctly as its efficiency (and thus cerebral blood circulation) depends on your technique. Use the most developed muscles of your body – back muscles, keep your elbows straight and compress the chest with the power of your trunk, not upper limbs. Every compression should be 5_6 cm deep. After each compression don't forget to let the chest recoil completely. Signs of effective resuscitation actions are pupils contraction,

normalization of the skin color, appearance of peripheral pulse synchronized with the massage, sometimes even possibility of blood pressure measurement. Sometimes heart action restores even during BLS.

Fig. Defibrillation

Fig. Defibrillation

Second stage is advanced life support, which is provided by health_ care professionals in hospitals with the usage of medicines, diagnostic and therapy equipment. The main ideas of ALS are: determination of cardiac arrest type (shockable/nonshockable rhythm), pharmaceutical and electric treatment, usage of advanced artificial ventilation (if available also devices for heart massage) and therapy of reversible clinical death reasons.

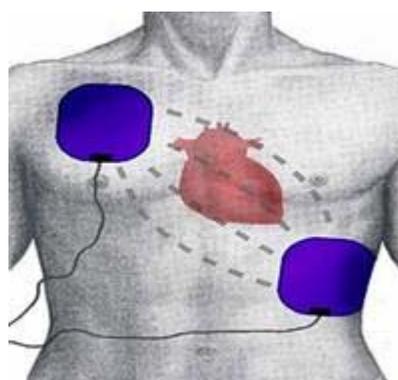

Fig. Defibrillation

When resuscitation team works together functions of rescuers must be divided in order to gain maximal efficiency. After CPR started the main purpose is to decide whether the

defibrillation is necessary or not, other words: to monitor the type of cardiac arrest. Shockable rhythms are ventricular fibrillation (VF) and pulseless ventricular tachycardia (VT without pulse); nonshockable rhythms are asystole (A) and pulseless electrical activity (PEA) of the heart.

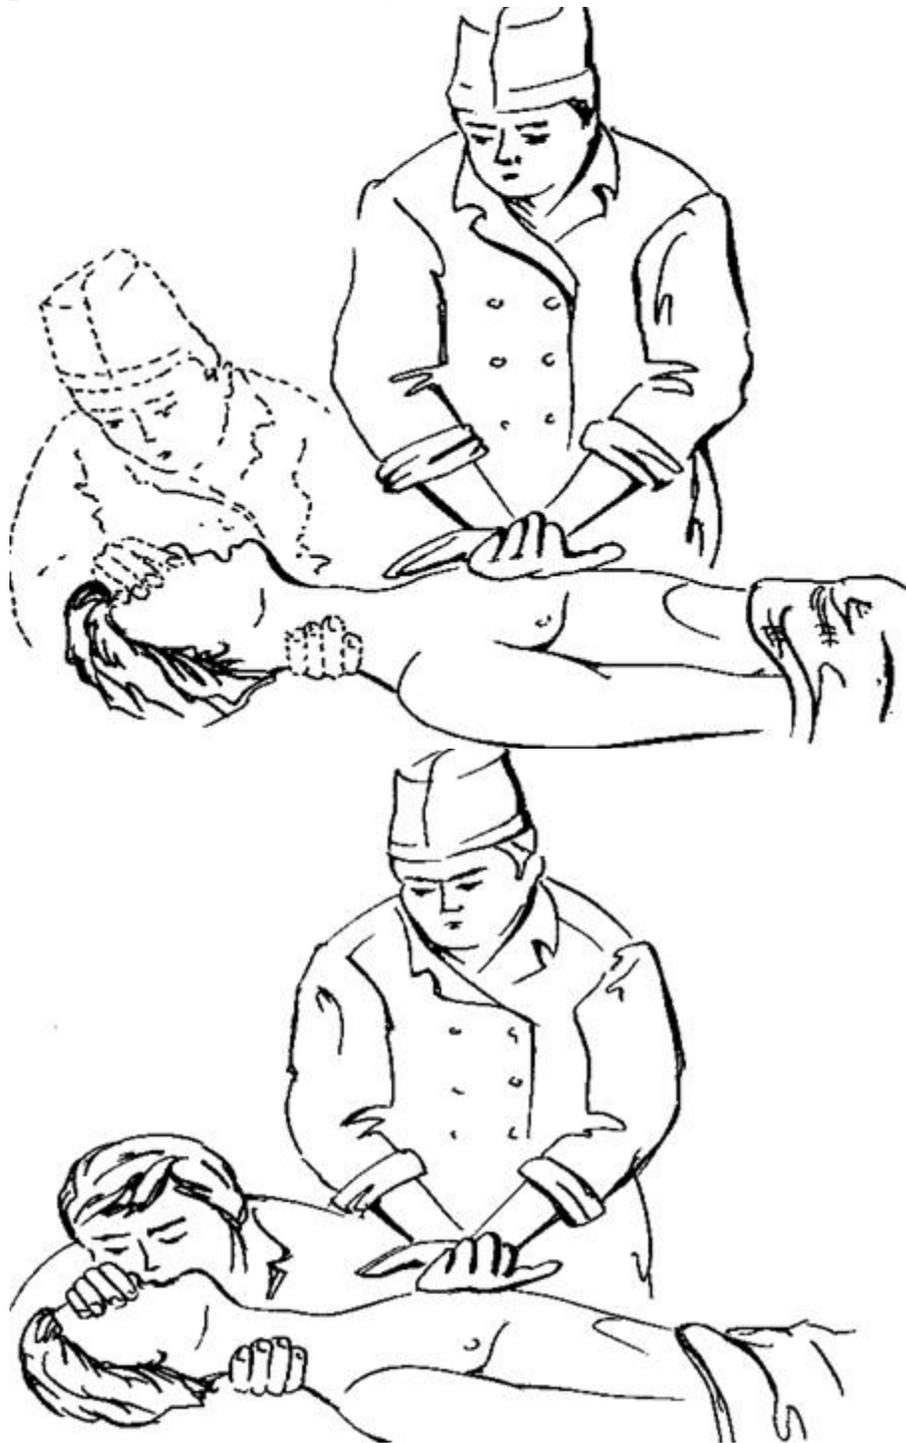

Fig. Performing CPR by team

Without energetic resources VF and pulseless VT quickly change into PEA and asystole, so to shorten the time between arrest and defibrillation paddles

visualization (apex_sternum position) should be used even before the electrodes will be placed on the chest. For the first defibrillation use the dose of 360 Joules for monophasic defibrillators (old models) and 150_200 Joules for biphasic defibrillators (modern devices).

Subsequent shocks might be of the same (200 J) or escalated energy (150_360 J) – the efficiency of energy increase is not proved, so it depends on you and local standards.

Cardiac arrest types:

1. Asystole – flat line on ECG
2. Ventricular fibrillation – chaotic contractions of myocardial fibers visualized on ECG as waves of different shape and amplitude (high, medium and low).
3. PEA – different ECG rhythms, including normal, but combined with the lack of effective systole (pulse).

Simultaneously a venous access attempt should be done, as after third defibrillation administration of adrenaline (1 ml of 0,1% solution = 1 mg followed by 20 ml of 0,9% NaCl solution) and amiodarone (6 ml of 5% solution = 300 mg with 5% Glucose solution, total volume – 20 ml) are required. Adrenaline administration should be repeated every 3_5 minutes in the same dose. In case of PEA and asystole adrenaline should be given from the moment of intravascular access achievement. Atropine is not any more included into the official algorithms of ALS if the cardiac arrest is not caused by vagal effect.

However according to actual Ukrainian standards single administration of Atropine is still recommended (3 ml of 0,1% solution=3 mg, followed by 20 ml of 0,9% NaCl solution).

If, however, venous access attempts are unsuccessful within 2 minutes you should think about alternatives, such as intraosseous access. As for the medicine delivery via the tracheal tube – it is no longer recommended. Central venous line insertion is a prerogative of the most skilled and competent members of the team. Previously it was thought, that triple doses of resuscitation drugs given through endotracheal tube or through the needle in the crico_thyroid membrane will be effective, but according to the actual

recommendations such way of admission is unpredictable and thus can not be an alternative. Intracardiac delivery of drugs nowadays has rather historical value: in most developed countries it is not practiced any more.

Mechanical ventilation is much more effective than the mouth_to_mouth one. There are different types of devices for respiration (carrying and stationary) and numerous devices which play the role of connector between patient's airways and apparatus for artificial pulmonary ventilation (ventilation masks, laryngeal masks and tubes, combitubes, endotracheal tubes, etc). In case of CPR the endotracheal tube with cuff is an absolute golden standard, as it allows asynchronous ventilation/massage and protects patient from aspiration (cardiac arrests are mostly sudden, so there is always a risk of regurgitation, aspiration and thus aspiration syndrome development). Under control of direct laryngoscopy it's possible to clean upper airways with electric or pneumatic suction device and what is even more important – to intubate the trachea.

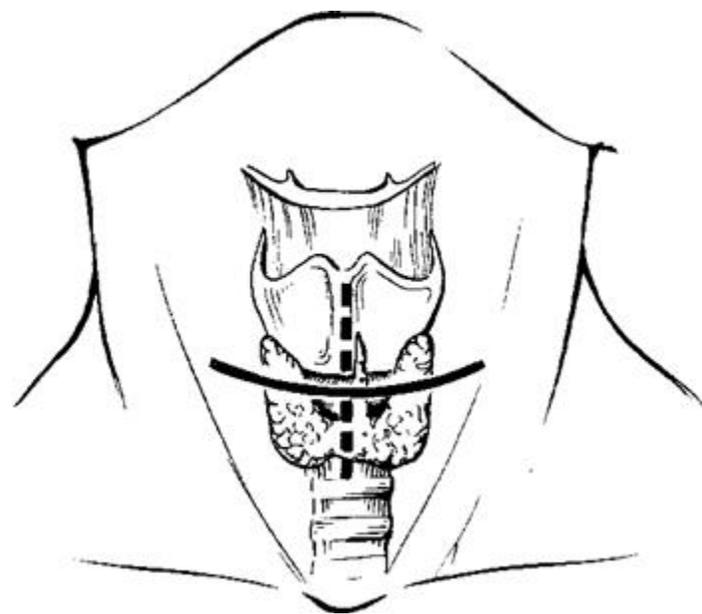

Fig. Conicotomy

During the CPR think about reversible cardiac arrest reasons and try to treat them: there are easy mnemonic schemes of 4 H and 4 T for this purpose. So, the reversible causes of the clinical death are: hypoxia tension pneumothorax hypovolemia tamponade (cardiac)

hypothermia toxins hypo/hyper electrolytic and metabolic disorders thrombosis
 Treat them with: oxygen and artificial ventilation in case
 of hypoxia; crystalloids and colloids in case of hypovolemia; warming
 (including warm infusions) in case of hypothermia and proper
 electrolyte infusions in case of electrolytes and metabolic disorders
 (for example use 5_10 ml of 10% calcium chloride solution if you
 suspect hyperkalemia or hypocalcemia caused by dialysis, hemolysis,
 massive tissue damage, etc.).

Fig. Scheme of CPR

Use needle thoracocentesis for tension pneumothorax, needle pericardiocentesis for cardiac tamponade, antidotes and detoxification methods for toxic agents and thrombolytic therapy for thrombosis (if required).

The third stage of resuscitation is post_resuscitation care provided also in intensive treatment unit.

Fig. Scheme of CPR

On the first stage of this care check again the patient's condition: monitor constantly condition of cardiovascular and respiratory systems, measure blood pressure and central venous pressure, evaluate CNS state (reflexes, neurological deficiency), perform laboratory tests (take blood and urine samples, liquor if necessary), etc. Well_planned, comprehensive examination allows us to identify homoeostasis disorder and choose optimal treatment. After main parameters are stabilized central nervous system becomes your main concern: protect the brain from hypoxia by all available means, because hypoxic damage of neurons is usually irreversible. To achieve this purpose you should:

– provide adequate oxygenation (however excess of oxygen is no longer recommended, so keep blood saturation at the level 94_98%); hyperventilation might be used in case of brain oedema (first 12_24 hours of artificial ventilation);

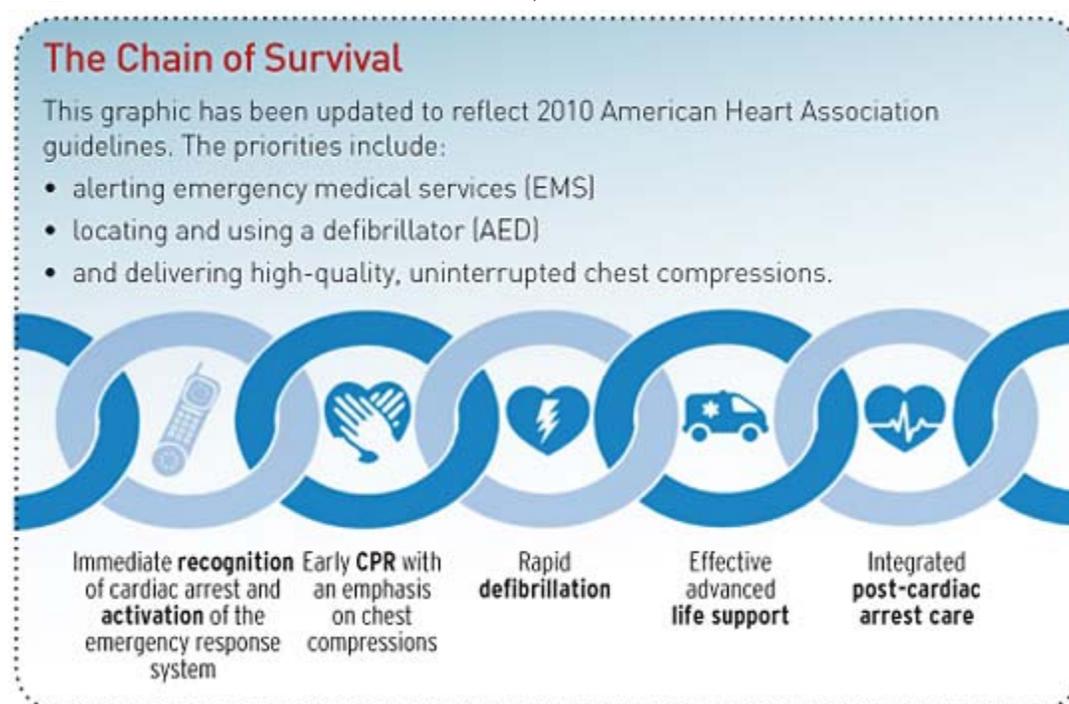

Fig. The chain of survival

– decrease metabolic needs of the CNS by craniocerebral hypothermia (give saline solution with the temperature 2 °C in order to lower body temperature to 32_34 °C for 12_24 hours) or by continuous narcosis (sodium thiopental 3_5 mg/kg, diazepam 0,2 mg/kg, neuroleptics, etc.);

- control blood glucose level (avoid hyperglycaemia over 10 mmol/l; hypoglycaemia can not be accepted at all);
- additionally prescribe antihypoxants like sodium oxybate (20_40 mg/kg every 4 hours), cytochrome C (0,5 mg/kg i/v); antioxidants like tocopheryl acetate (500 mg i/v), B_vitamins (2_3 ml), ascorbic acid (5 ml of 5% solution 3 times a day); calcium antagonists like verapamil (2 ml 3 times a day), magnesium sulphate (5_10 ml of 25% solution i/v every 4 hours with blood pressure control);
- improve cerebral perfusion with haemodilution (give crystalloids to get hematocrit 0,3_0,35 l/l), relative hypertension (20_30% over the normal level), solutions influencing rheological properties of the blood and microcirculation (rheopolyglucin, 2 ml of 0,5% curantil solution, heparin 5000 units every 4 hours, etc);
- treat cerebral oedema with mannitol (1g/kg), furosemide solution 10 mg i/v 3 times a day), dexametazon solution (8 mg every 4 hours);
- use hyperbaric oxygenation from the 5_th day of post_resuscitation care (totally 10 procedures);
- give nootropic drugs and neuroprotectors (piracetam, cerebrolysin, aminalon, etc.)

Fig. Trainings

Cardiac arrest in special circumstances

Regardless to the cardiac arrest reasons the main factors of thanatogenesis [*Thanatos – god of death in Ancient Greece] are hypoxia, hypercapnia, electrolytic disorders and pathological reflexes. In 90% of cases heart stops in the moment of diastole, in 10% – systole. Heart, lungs and brain are the death entrance gate.

In_hospital cardiac arrest.

The most common reasons of primary cardiac arrest:

- a. acute cardiac failure (coronary disease, myocardial infarction, rhythm disorders, sudden coronary death)
- b. acute obstruction of main vessels (pulmonary thromboembolism)
- c. acute and severe deficiency of blood volume (significant blood loss, dehydration)
- d. acute decline of peripheral vessels resistance (acute suprarenal failure, anaphylactic shock, somatogenic collapse in case of acute intoxication, orthostatic medication collapse)

The most common reasons of acute respiratory failure:

- a. airways obstruction (tongue, vomit, foreign bodies)
- b. inhibition of respiratory center (opiates, anesthetics)
- c. disorders of breathing biomechanics (convulsions, myasthenia, tension pneumothorax or hemothorax)
- d. restrictive disorders (massive pneumonias, shock lung syndrome, pneumothorax or hemothorax).

The most common reasons of primary brain death: acute vascular disorders (subarachnoid hemorrhage, hemorrhagic and ischemic strokes, brain dislocation).

Patients with a predictably high risk of sudden death should be constantly under complex vital monitoring. In case of compensation failures medical personnel of the department should intrude with a treatment directed at correction of disorders and intensive care. That is why an in_hospital sudden death should be an exception. Never the less hospital staff should be prepared to provide immediate life support.

Here is the list of equipment for in_hospital resuscitation:

1. Portable manual respirator.
2. Oxygen supply (cylinder).
3. Electric suction device with suction catheters.
4. Electrocardiograph, defibrillator, tonometer.
5. Mouth_gag, tongue forceps, clips.
6. Set of face masks and airways.
7. Laryngoscope with a set of tubes.
8. Set for conicotomy and for pericardiocentesis.
9. Solutions of adrenaline, atropine, sodium bicarbonate, lidocaine, steroids, colloids and crystalloids.
10. Infusion sets, i/v catheters, syringes of different sizes.
11. Bandages, medical napkins, antiseptic solutions.

Peculiarities of in_hospital resuscitation.

Patient is usually lying in bed.

1. To get a firm surface [efficiency of chest compressions depends on this] lay under the patient spinal board or move him/her on the floor.
2. Duration of the first stage should be minimal (5 to 7 minutes) as the beginning of advanced life support in intensive care unit is more important.
3. In witnessed primary cardiac arrest caused by ventricular fibrillation during first 20_30 seconds precordial thump might be effective (so called “mechanical defibrillation”).
4. Sometimes tracheostomy or conicotomy might be necessary in case of upper airways obstruction (laryngospasm, stenosis of larynx, foreign body in the glottis).

The most favorable resuscitation prognosis is connected with primary respiratory arrest and the most unfavorable – with the primary cerebral death.

Drowning: types and resuscitation.

There are different types of drowning thanatogenesis.

True drowning. Most victims under the water according to a reflex stop breathing. But after some time due to hypercapnic

stimulation of the respiratory center they unwillingly begin to make respiratory movements. Liquid gets to the lungs: fresh water, which is hypoosmolar to plasma, diffuses easily through blood-air barrier into the blood, thus increasing its volume. Extra 1500-2000 ml of water in addition to hypoxia lead to cardiac arrest. At the same time osmotic hemolysis (caused by rapid lowering of plasma osmolarity) and hyperpotassemia are also cardiac arrest factors.

In case of salt water true drowning fluid part of blood according to the osmotic gradient moves from bloodstream into the bronchi and trachea. This way surfactant is being destroyed and pulmonary edema begins.

Dry drowning. 8-10% of victims in the moment of water aspiration have reflexive vocal cords closure. This prevents further water entering into the lower airways. The cardiac arrest is caused by hypoxia.

Syncopal drowning happens in 5 % of cases. Due to fear, immersion in cold water, injury of reflexogenic zones caused by falling primary cardiac arrest appears. It is called "syncope". Those victims have gray color of skin and there is no water in their airways.

Peculiarities of resuscitation.

1. In case of true drowning early respiratory support is the most important. Right after airways management (head titling, oral cavity cleaning) rescue breathing should be provided. Don't waste victim's precious time on shaking out the water by pressing the abdomen or lowering the head: the amount of water inside is not that dangerous and your efforts are hopeless and unnecessary. The only thing you really can achieve by these actions is vomiting and aspiration of gastric contents, which are much more dangerous, than aspiration of water.
2. During resuscitation of the patient, who drowned in sweet water, 10 % solution of calcium chloride is used (5 or 10 ml).
3. All patients who were drowning should be transported to the ICU and observed most carefully (few days).
4. To avoid secondary drowning (fulminant pulmonary edema causing death) patients with true drowning should receive respiratory support with positive end expiratory pressure.

5. On the third stage of resuscitation patients with true drowning in sweet water should receive solution of sodium bicarbonate in order to prevent renal failure (renal tubules are being blocked by hemoglobin, which accumulates due to hemolysis) and diuretics.

6. On the third stage of resuscitation patients with true drowning in salt water should receive hypotonic infusions (in order to correct hyperosmotic hypohydration).

In case of dry drowning and syncopal drowning prognosis is favorable even after prolonged clinical death, unlike drowning in sweet water. In case of drowning in cold water (0°C) biological death is not stated until the body becomes warm, resuscitation lasts much longer, than in conditions with normal temperature.

Resuscitation in case of mechanical injuries (fall from a height, car accidents).

1. Clinical death might be caused by severe injuries incompatible with life or reflex cardiac arrest. It is obvious, that resuscitation will be successful in second case, but not first. If it is a witnessed cardiac arrest precordial thump might be effective.

2. In trauma cases you should be careful with the neck of the patient: always suspect backbone injury until it is not excluded with additional methods of diagnostics (computer tomography diagnostics, X_ray diagnostics). Don't tilt the head backwards: in such cases it's enough to thrust the jaw forward.

3. If the patient has fractures of facial skeleton or injuries of face soft tissues mouth_to mouth respiration might be ineffective or even impossible, however mouth_to_nose respiration might be useful.

Transportation, if it's possible, should be in a save position with head turned aside.

4. Constantly examine patient's condition: injuries, which seem to be unimportant at the beginning sometimes change into life threatening; this is why examinations should be repeated and accurate.

Transportation of severe patients sometimes ends with decompensation of main vital systems.

Electric trauma and lightning stroke.

1. After electric injury or lightning stroke clinical death might happen due to primary respiratory arrest (spasms of respiratory muscles, respiratory center damage), ventricular fibrillation or cerebral affection (in last case vital signs are minimal, so there were cases, when patients were buried “alive” and “raised”; this could be the reason of a superstitious belief that for bringing back life after lightning stroke victim should be buried).
2. As soon as possible break the contact between victim and electricity source. Still, remember that your own safety is of not less importance.
3. In most cases electric defibrillation will be necessary (so called shockable rhythms).
4. Even patients who seem to be fine according to their vital parameters should be admitted to the ITU and observed most carefully for few days. There is always a risk of sudden cardiac arrest due to violation of myocardial excitability and conductivity during first 24 hours after electric trauma or lightning stroke.

Mechanical asphyxia.

1. In case of mechanical asphyxia first of all provide the patency of airways (clear the oral cavity, throat, larynx with your finger or any available equipment (clamp, forceps, aspirator) with laryngoscopy or without it and then decide what type of respiratory support patient needs.
2. If there is no chance to treat the obstruction of upper airways using usual methods or tries were unsuccessful urgent cricoidotomy (3.3) or tracheostomy (3.4, in hospital conditions) are the only ways of rescuing patient’s life.
3. Never ever try to push “deeper” the foreign body you can’t take out!

Medical operations and manipulations

Mouth_to_mouth ventilation.

Indications: respiratory arrest or ineffective patient’s breathing, when there is no respiratory apparatus.

Necessary equipment: napkin or handkerchief; artificial airway,

gloves– if available.

Procedure: First of all free upper airways – open the mouth of the patient and clear oral cavity as mentioned above: turn the head aside, open the mouth and remove vomit, blood clots, foreign bodies with a finger. Then tilt head backwards and thrust the jaw forward.

To make mouth-to-mouth ventilation less unpleasant you can put a napkin or a piece of bandage on the mouth of the victim. Close patient's nostrils with your fingers, press your mouth against the mouth of the patient and make a forced expiration. Inhaling the air observe the chest: if it moves according to your respiratory efforts breathing is effective. However if chest is not rising check again airways patency: thrust the jaw placing your fingers over its angle and moving them forward (lower teeth should overlap upper teeth).

Your aim is to exhale nearly 600_800 ml of air with the frequency of 10 times per minute (2 breathes to 30 compressions) during CPR. If it is respiratory arrest alone you can make 15_20 breathes per minute.

Chest compressions (External heart massage).

Indications: cardiac arrest (clinical death).

Necessary equipment: doesn't need any; gloves if they are available.

Procedure: place the patient on the firm flat surface in supine position; if you have an assistant one of you should provide airways patency and breathing, another – chest compressions. Staying on your knees beside the patient place one hand in the middle of the chest and cover it with another. Your fingers should not touch the chest, otherwise while compressions you will break the ribs. Frequency of compressions should be 100 per minute*, depth – 5_6 cm. Keep your elbows straight and use mainly muscles of your back (weight of the body): thus you will exhaust slower. In case of effectively provided CPR you might observe constriction of pupils, normalization of skin color, pulse on peripheral vessels, sometimes it's even possible to measure blood pressure.

Heart puncture.

There are two types of heart puncture: puncture of heart cavity

(previously used for adrenaline injection or in case of air embolism) and pericardial puncture performed for extraction of blood in case of haemopericardium.

Indications: air embolism, haemopericardium.

Necessary equipment: 7_10 cm needle, 10_20 ml syringe.

Procedure: find the fourth intercostal space and puncture the skin with a saline filled syringe 1_1,5 cm to the left from the sternum border.

Needle should be directed over the fifth rib sagittally and a bit to the middle, all the time control the needle position pulling the plunger back. At a depth of 4_5 cm you will feel a kind of resistance – wall of the right ventricle, after that expect appearance of blood in the syringe – sign of the needle located in the left ventricle. Control the hub with your left hand and push the plunger with the right hand to infuse the medicine from the syringe (or aspirate the air in case of air embolism).

Electric heart defibrillation

Indications: ventricular fibrillation, ventricular tachycardia without pulse.

Necessary equipment: defibrillator, electrode paste (electricity conductive gel).

Procedure: evaluate the rhythm during CPR as soon as possible.

After stating “shockable rhythm” defibrillate immediately. According to the actual CPR recommendations heart massage should be interrupted only for a moment of defibrillation itself and continued during paddles placement and charging. So while 2 rescuers are continuing CPR the third should place the paddles in sternum_apex position (previously putting on them layer of electrode gel), choose the correct mode on the defibrillator and press charge button. Begin with 150_200 J in case of biphasic defibrillator and 360 J in case of monophasic. Make sure neither you nor your colleagues are contacting the patient or equipment, otherwise you might get injured. At the moment of defibrillation remove the source of the oxygen from the patient and stop the infusion. After defibrillator is loaded press “defibrillate” button on the paddle and at the moment

defibrillation is over restart the massage. Put paddles on their place without crossing or contacting them in the air. In two minutes check the rhythm and vital signs again and if necessary – repeat the defibrillation with a greater voltage (300_360J).

Paddles placement: a) one electrode is placed in front of the heart (anterior position) and another one on the back, behind the heart, between the scapula (posterior position); b) apex_ sternum position: one electrode is placed over the heart and another one on the right side of the sternum.

2.5. Control tests

1. Name the stages of dying:

A.Preagony, terminal pause, agony, clinical death;

B.Agoty, clinical and biological death;

C.Coma, agony, clinical death;

D.Preagony, agony, clinical death, social death;

E.Hypotension (blood pressure lower than 80 mm Hg)

2. What sign is not one of the main clinical death signs?

A.lack of blood pressure

B.lack of pulse on femoral arteries

C.lack of breathing

D.mydriasis and lack of photoreaction

E.lack of pulse on carotid arteries

3. What should be expiratory volume during “mouth_to_mouth” ventilation?

A.1700_2000 ml

B.500_700 ml

C. 1200_1600 ml

D. 800_1100 ml

E. maximal exhalation

4. The duration of clinical death in conditions of normal temperature is:

A. 7_12 minutes

B.1_3 minutes

C. 4_5 minutes

- D. 5_7 minutes
- E. 10 minutes
5. Name the exact hand placement during heart massage:
- A. on the chest, fingers to chin
- B. lower third of the sternum, fingers along ribs
- C. middle of the chest
- D. 4_th intercostal space, left part of the chest
- E. on the chest in the heart area
6. What are the signs of effective artificial ventilation?
- A. narrowing of the pupils
- B. noises during ventilation
- C. silent chest movements
- D. bulged out epigastrium
- E. dizziness of the rescuer
7. Choose an absolute sign of cardiac arrest:
- A. flat line on ECG
- B. unconsciousness
- C. cyanotic color of skin
- D. lack of pulse over carotid arteries
- E. lack of blood pressure
8. Choose the place of heart puncture:
- A. 5_th intercostal space, in the place of apex projection
- B. 3_d intercostal space, on the left from sternum
- C. lower edge of the 4_th rib
- D. 4_th intercostal space, 1,5 cm on the left from the sternum
- E. in the place where heart action is noticeable
9. What medicines are usually used during CPR?
- A. adrenaline, atropine, cordaron
- B. adrenalin, dopamine
- C. atropine, dopamine
- D. atropine, steroids, dopamine, magnesium
- E. adrenaline, magnesium
10. What is the reason of Sodium bicarbonate usage during CPR?
- A. correction of metabolic acidosis

- B. prevention of respiratory acidosis
 - C. liquidation of hypoxia
 - D. treatment of metabolic alkalosis
 - E. protection of central nervous system
11. Choose the indication for defibrillation during CPR:
- A. low blood pressure
 - B. asystole
 - C. PEA
 - D. VF
 - E. lack of pulse over carotid arteries

Task 1.

Andrew, the student of medicine, is a witness of an accident: wireman, who was working with a transformer, suddenly was kicked few meters from it. During examination it turned out, that victim is unconscious, his pupils are dilated and do not react on light, his skin is pale; there is no pulse over carotid arteries; fingers of the right hand are burnt, in the middle of the palm there is a lacerated wound.

What diagnosis should Andrew think about? What should be done?

What is the order of these actions?

Task 2.

Annie, the nurse, is a witness of such situation: a man of 40, lying at the city bus station, is being ventilated by a passing pedestrian through chest pressing and arms abducting. The victim is unconscious, his pupils are dilated, skin is pale and there are no pulse, no breathing and no reflexes.

What diagnoses should Annie think about? What way should Annie provide the CPR?

Task 3.

Walking near the lake Andrew, the student of medicine, suddenly notices a 4-year old girl who fell to the water and disappeared under the surface. What should Andrew do?

Task 4.

„The laymen”, local group of amateur rescuers, dragged from the water a young girl. They turned her down at the same time pressing with the knee her abdomen in order to force the water out from the airways. After

that they putted her on her back, attached with a pin her tongue to the chin (in order to provide airways potency). Next they started CPR: forced maximal breathes (14 per minute) together with chest compressions (4 cm deep, 60 per minute). Name 5 mistakes of „The layman”.

Task 5.

„The Dream team”, group of professional rescuers, started CPR of a patient in a state of clinical death. Then they cleared the upper airways with an electric suction machine, connected respiratory machine. Next they gave adrenaline (0,5 ml of 0,1% solution) sodium bicarbonate (4% solution, 10 ml), calcium chloride (10%, 5 ml) and atropine (0,5 ml of 0,1% solution) at the same time and connected patient to a monitor (flat line on the ECG). After that rescuers did a defibrillation of 300 J, which resulted in a flat line on the ECG. They repeated everything again, this time with defibrillation of 400J. Unfortunately there was no effect. Patient died.

Name 5 mistakes of „The Dream team

The importance of the water to the organism.

Life on earth was born in the water environment. Water is a universal solvent for all the biochemical processes of the organism. Only in case of stable quantitative and qualitative composition of both intracellular and extra cellular fluids homoeostasis is remained.

The body of an adult human contains 60% of water. Intracellular water makes 40% of the body weight, the water of intercellular space makes 15% of body weight and 5% of body weight are made by the water in the vessels. It is considered that due to unlimited diffusion of water between vessels and extra vascular space the volume of extracellular fluid is 20% of body weight (15%+5%).

Physiologically insignificant amounts of water are distributed beyond the tissues in the body cavities: gastrointestinal tract, cerebral ventricles, joint capsules (nearly 1% of the body weight). However during different pathologic conditions this “third space” can cumulate large amounts of fluid: for example in case of ascites caused by chronic cardiac insufficiency or cirrhosis abdominal cavity contains up to 10 liters of fluid. Peritonitis and intestinal obstructions remove the fluid part of blood from the vessels into the intestinal cavity.

Severe dehydration is extremely dangerous for the patient. Water gets to the body with food and drinks, being absorbed by the mucous membranes of gastro-intestinal tract in total amount of 2-3 liters per day. Additionally in different metabolic transformations of lipids, carbohydrates and proteins nearly 300 of endogenous water are created. Water is evacuated from the body with urine (1,5-2 liters), stool (300 ml), perspiration and breathing (those two reasons are combined as “perspiration loss” and make from 300 to 1000 ml per day).

Water balance is regulated through complicated, but reliable mechanisms. Control over water and electrolytes excretion is realized by osmotic receptors of posterior hypothalamus, volume receptors of the atrial walls, baroreceptors of carotid sinus, juxtaglomerular apparatus of the kidneys and adrenal cortical cells.

When there is a water deficiency or electrolytes excess (sodium, chlorine) thirst appears and this makes us drink water. At the same time posterior pituitary produces antidiuretic hormone, which decreases urine output. Adrenals reveal into the blood flow aldosterone, which stimulates reabsorption of sodium ions in the tubules and thus also decreases diuresis (due to osmosis laws water will move to the more concentrated solution). This way organism can keep precious water.

On the contrary, in case of water excess endocrine activity of glands is inhibited and water is actively removed from the body through the kidneys.

Importance of osmolarity for homoeostasis.

Water sections of the organism (intracellular and extracellular) are divided with semipermeable membrane – cell wall. Water easily penetrates through it according to the laws of osmosis. Osmosis is a movement of water through a partially permeable membrane from the solution with lower concentration to a solution with higher concentration.

Osmotic concentration (osmolarity) is the concentration of active parts in one liter of solution (water). It is defined as a number of miliosmoles per liter (mOsm/l). Normally osmotic concentration of plasma, intracellular and extracellular fluids is equal and varies between 285mOsm/l. This value is one of the most important constants of the organism, because if it changes in one sector the whole fluid of the body will be redistributed (water will move to the environment with higher concentration). Over hydration of one sector will bring dehydration of another. For example, when there is a tissue damage concentration of active osmotic parts increases and water diffuses to this compartment, causing oedema. On the contrary plasma osmolarity decreases, when there is a loss of electrolytes and osmotic concentration of the cellular fluid stays on the previous level. This brings cellular oedema, because water moves through the intracellular space to the cells due to their higher osmotic concentration.

Cerebral oedema appears when the plasma osmolarity is lower than 270 mOsm/l. Activity of central nervous system is violated and hyposmolar coma occurs. Hyperosmolar coma appears when the plasma osmolarity is over 320 mOsm/l: water leaves the cells and fills the vascular bed and this leads to cellular dehydration. The sensitive to cellular dehydration are the cells of the brain.

Plasma osmolarity is measured with osmometer. The principle of measurement is based on difference in freezing temperature between distilled water and plasma. The higher is the osmolarity (quantity of molecules) the lower is freezing temperature.

Plasma osmotic concentration can be calculated according to the formula:

$$\text{Osmotic concentration} = 1,86 * \text{Na} + \text{glucose} + \text{urea} + 10,$$

Plasma osmolarity (osmotic concentration) – mOsm/l

Na- sodium concentration of plasma, mmol/l

Glucose- glucose concentration of the plasma, mmol/l

Urea- urea concentration of the plasma, mmol/l

According to this formula sodium concentration is the main factor influencing plasma osmolarity. Normally sodium concentration is 136-144 mmol/l. Water and electrolytes balance can be violated with external fluid and electrolytes loss, their excessive inflow or wrong distribution.

9.3 Fluid imbalance and principles of its intensive treatment.

Water imbalance is divided into dehydration and overhydration.

Dehydration is caused by:

- excessive perspiration in conditions of high temperature;
- rapid breathing (dyspnea, tachypnea) or artificial ventilation without humidification of the air;
- vomiting, diarrhoea, fistulas;
- blood loss, burns;
- diuretics overdose;
- excessive urine output;
- inadequate enteral and parenteral nutrition or infusion therapy (comatose patients, postoperative care);
- pathological water distribution (“third space” in case of inflammation or injury).

Dehydration signs: weight loss, decrease of skin turgor and eyeballs tone, dry skin and mucous membranes; low central venous pressure, cardiac output and blood pressure (collapse is possible); decreased urine output and peripheral veins tone; capillary refill over 2 seconds (microcirculation disorders) and low skin temperature; intracellular dehydration is characterized with thirst and consciousness disorders. Laboratory tests show blood concentration: hematocrit, hemoglobin concentration, protein level and red blood cells concentration increase.

Overhydration appears in case of:

- excessive water consumption, inadequate infusion therapy;
- acute and chronic renal failure, hepatic and cardiac insufficiency;
- disorders of fluid balance regulation;
- low protein edema.

Clinical findings in case of overhydration are: weight gain, peripheral oedema, transudation of the plasma into the body cavities (pleural, abdominal), high blood pressure and central venous pressure. In case of intracellular overhydration appear additional symptoms: nausea, vomiting, signs of cerebral edema (spoor, coma). Laboratory tests prove hemodilution.

According to the osmotic concentration of plasma dehydration and overhydration are divided into hypotonic, isotonic and hypertonic.

Isotonic dehydration is caused by equal loss of electrolytes and fluid from the extracellular space (without cellular disorders). Blood tests show hemoconcentration; sodium level and osmotic concentration are normal.

To treat this type of water imbalance use normal saline solution, Ringer solution, glucose-saline solutions, etc.. The volumes of infusions can be calculated according to the formula:

$$V_{H_2O} = 0,2 * BW * (H_{tp} - 0,4) / 0,4 ,$$

V_{H_2O} – volume of infusion, l

H_{tp} – patient's hematocrit, l/l,

BW – body weight, $0,2 * BW$ – volume of extracellular fluid,

0,4- normal hematocrit, l/l,

Hypertonic dehydration is caused by mostly water loss: first it appears in the vascular bed, than in the cells. Laboratory tests show hemoconcentration: elevated levels of proteins, red blood cells, hematocrit. Plasma sodium is over 155 mmol/l and osmotic concentration increases over 310 mOsm/l.

Intensive treatment: if there is no vomiting allow patients to drink. Intravenously give 0,45% saline solution and 2,5 % glucose solution, mixed with insulin. The volume of infusions is calculated according to the formula:

$$V_{H_2O} = 0,6 * BW (Na_p - 140) / 140,$$

V_{H_2O} – water deficiency, l

Na_p – plasma sodium, mmol/l

BW – body weight, 0,6* BW volume of general body fluid

140 – physiological plasma sodium concentration

Hypotonic dehydration is characterized with clinical features of extracellular dehydration. Laboratory tests show decrease of sodium and chlorine ions. Those changes cause intracellular movement of the water (intracellular overhydration). Hemoglobin, hematocrit and protein levels are increased. Sodium is lower than 136mmol/l, osmolarity is lower than 280 mOsm/l.

To treat this type of water imbalance use normal or hypertonic saline and sodium bicarbonate solution (depends on blood pH). Do not use glucose solutions!

The deficiency of electrolytes is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

Na_d – sodium deficiency, mmol

Na_p – plasma sodium, mmol/l

BW – body weight, 0,2 BW – volume of extracellular fluid

Isotonic overhydration is caused by excess of the water in the vascular bed and extracellular space; however intracellular homeostasis is not violated. Hemoglobin is less than 120 g/l, protein level is less than 60 g/l, plasma sodium is 136-144 mmol/l, osmotic concentration is 285-310 mOsm/l.

Treat the reason of imbalance: cardiac failure, liver insufficiency, etc. Prescribe cardiac glycosides, limit salt and water consumption. Give osmotic diuretics (mannitol solution 1,5 g/kg), saluretics (furosemide solution 2 mg/kg), aldosterone antagonists (triamterene – 200 mg), steroids (prednisolone solution 1-2 mg/kg) albumin solution if necessary (0,2-0,3 g/kg).

Hypertonic overhydration is a state of extracellular electrolytes and water excess combined with intracellular dehydration. Blood tests show decrease of hemoglobin, hematocrit, protein level, however sodium concentration is increased over 144 mmol/l, osmotic concentration is over 310 mOsm/l.

To treat this condition use solutions without electrolytes: glucose with insulin, albumin solutions and prescribe saluretics (furosemide solution), aldosterone antagonists (spironolactone). If it is necessary perform dialysis and peritoneal dialysis. Do not use crystalloids!

Hypotonic overhydration is a state of extracellular and intracellular water excess. Blood tests show decrease of haemoglobin, hematocrit, proteins, sodium and osmotic concentration. Intensive therapy of this condition includes osmotic diuretics (200-400 ml of 20% mannitol solution), hypertonic solutions (50 ml of 10% saline intravenously), steroids. When it is required use ultrafiltration to remove water excess.

Electrolytes disorders and their treatment

Potassium is a main intracellular cation. Its normal plasma concentration is 3,8-5,1 mmol/l. Daily required amount of potassium is 1 mmol/kg of body weight.

Potassium level less than 3,8 mmol/l is known as kaliopenia. Potassium deficiency is calculated according to the formula:

$$K_d = (4,5 - K_p) * 0,6 \text{ BW}$$

K - potassium deficiency, mmol;

K_p - potassium level of the patient mmol/l;

$0,6 * \text{BW}$ - total body water, l.

To treat this state use 7,5% solution of potassium chloride (1ml of this solution contains 1 mmol of potassium). Give it intravenously slowly with glucose and insulin (20-25 ml/hour). You can also prescribe magnesium preparations. Standard solution for kaliopenia treatment is:

10% glucose solution 400 ml

7,5% potassium chloride solution 20 ml

25% magnesium sulphate solution 3 ml

insulin 12 units

Give it intravenously slowly, during one hour. Forced bolus infusion of potassium solutions (10-15 ml) can bring cardiac arrest.

Potassium level over 5,2 mmol/l is a state called hyperkalemia. To treat this condition use calcium gluconate or calcium chloride solutions (10 ml of 10% solution intravenously), glucose and insulin solution, saluretics, steroids, sodium bicarbonate solution. Hyperkalemia over 7 mmol/l is an absolute indication for dialysis.

Sodium is the main extracellular cation. Its normal plasma concentration is 135-155 mmol/l. Daily required amount of potassium is 2 mmol/kg of body weight.

Sodium concentration which is lower than 135 mmol/l is known as hyponatraemia. This condition is caused by sodium deficiency or water excess. Sodium deficiency is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 \text{ BW},$$

Na- sodium deficiency, mmol;

Na_p – sodium concentration of the patient mmol/l;

0,2*BW – extracellular fluid volume, l.

To treat it use normal saline (1000 ml contains 154 Na mmol) or 5,8% solution of sodium chloride – your choice will depend on osmotic concentration.

Sodium concentration over 155 mmol/l is a state called hypernatremia. This condition usually appears in case of hypertonic dehydration or hypertonicoverhydration. Treatment was described in the text above.

Chlorine is the main extracellular anion. Its normal plasma concentration is 98-107 mmol/l. Daily requirement of chlorine is 215 mmol.

Hypochloremia is a condition of decreased plasma chlorine concentration (less than 98 mmol/l).

Chlorine deficiency is calculated according to the formula:

$$Cl_d = (100 - Cl_p) * 0,2 \text{ BW},$$

Cl_d- chlorine deficiency, mmol

Cl_p – plasma chlorine concentration of the patient, mmol/l

0,2*BW – extracellular fluid volume, l.

To treat hypochloremia use normal saline (1000 ml contains 154 mmol of chlorine) or 5,8% sodium chlorine solution (1 ml contains 1 mmol of chlorine). The choice of solution depends on the osmotic concentration of the plasma.

Hyperchloremia is a condition of increased chlorine concentration (over 107 mmol/l). Intensive therapy of this state includes treatment of the disease, which caused it (decompensated heart failure, hyperchloremic diabetes insipidus, glomerulonephritis). You can also use glucose, albumin solutions and dialysis.

Magnesium is mostly an intracellular cation. Its plasma concentration is 0,8-1,5 mmol/l. Daily requirement of magnesium is 0,3 mmol/kg.

Hypomagnesemia is a state of decreased magnesium concentration: less than 0,8 mmol/l. Magnesium deficiency is calculated according to the formula:

$$Mg_d = (1,0 - Mg_p) * 0,6BW,$$

Mg_d - magnesium deficiency, mmol

Mg_p - plasma magnesium concentration of the patient, mmol/l

0,6*BW - extracellular fluid volume, l.

Use 25% magnesium sulphate solution to treat this state (1 ml of it contains 0,5 mmol of magnesium).

Hypermagnesemia is a state of increased magnesium concentration (more than 1,5 mmol/l). This condition appears usually in case of hyperkalemia and you should treat it as you treat hyperkalemia.

Calcium is one of the extracellular cations. Its normal concentration is 2,35-2,75 mmol/l. Daily requirement of calcium is 0,5 mmol/kg.

Calcium concentration less than 2,35 mmol/l is called hypocalcemia. Calcium deficiency is calculated according to the formula:

$$Ca_d = (2,5 - Ca_p) * 0,2 BW,$$

Ca_d - calcium deficiency, mmol

Ca_p - plasma calcium concentration of the patient, mmol/l

0,2*BW - extracellular fluid volume, l.

To treat this state use 10% calcium chloride (1 ml of the solution contains 1,1 mmol of calcium), ergocalciferol; in case of convulsions prescribe sedative medicines.

Hypercalcemia is a condition with increased calcium concentration (over 2,75 mmol/l). Treat the disease, which caused it: primary hyperparathyroidism, malignant bone tumors, etc. Additionally use infusion therapy (solutions of glucose with insulin), steroids, dialysis and hemosorbition.

Acid-base imbalance and its treatment.

There are 2 main types of acid-base imbalance: acidosis and alkalosis.

pH is a decimal logarithm of the reciprocal of the hydrogen ion activity. It shows acid-base state of the blood.

Normal pH of arterial blood is 7,36-7,44. Acid based imbalance is divided according to the pH level into:

pH 7,35-7,21 – subcompensated acidosis

pH < 7,2 – decompensated acidosis

pH 7,45-7,55 – subcompensated alkalosis

pH > 7,56 – decompensated alkalosis

Respiratory part of the acid-base imbalance is characterized with pCO₂. Normally pCO₂ of arterial blood is 36-44 mm Hg. Hypercapnia (pCO₂ increased over 45 mm Hg) is a sign of respiratory acidosis. Hypocapnia (pCO₂ less than 35 mm Hg) is a symptom of respiratory alkalosis.

Basis excess index is also a characteristic of metabolic processes. Normally H⁺ ions produced during metabolic reactions are neutralized with buffer system. BE of arterial blood is 0±1,5. Positive value of BE (with +) is a sign of base excess or plasma acid deficiency (metabolic alkalosis). Negative value of BE (with -) is a symptom of bases deficiency, which is caused by acid neutralization in case of metabolic acidosis.

Respiratory acidosis (hypercapnia) is a condition caused by insufficient elimination of CO₂ from the body during hypoventilation. Laboratory tests show:

pH < 7,35,

pCO_{2a} > 46 mm Hg

BE - normal values

However when the respiratory acidosis progresses renal compensation fails to maintain normal values and BE gradually increases. In order to improve this condition you should treat

acute and chronic respiratory violations. When $p\text{CO}_2$ is over 60 mm Hg begin artificial lung ventilation (through the mask or tube; when the necessity of ventilation lasts longer than 3 days – perform tracheostomy).

Respiratory alkalosis (hypocapnia) is usually an effect of hyperventilation, caused by excessive stimulation of respiratory centre (injuries, metabolic acidosis, hyperactive metabolism, etc.) or wrong parameters of mechanical ventilation. Gasometry shows:

$$\text{pH} > 7,45,$$

$$p\text{CO}_{2a} < 33 \text{ mm Hg}$$

$$\text{BE} < +1,5 \text{ mmol/l.}$$

However prolong alkalosis brings decrease of BE due to compensatory retain of H^+ ions. To improve this imbalance treat its reason: normalize ventilation parameters; if patients breathing has rate over 40 per minute – sedate the patient, perform the intubation and begin artificial ventilation with normal parameters.

Metabolic acidosis is characterized with absolute and relative increase of H^+ ions concentration due to acid accumulation (metabolic disorders, block of acid elimination, excessive acid consumption in case of poisonings, etc.). Laboratory tests show:

$$\text{pH} < 7,35,$$

$$p\text{CO}_{2a} < 35 \text{ mm Hg}$$

$$\text{BE} (-3) \text{ mmol/l.}$$

Treat the main reason of acid-base disorder: diabetic ketoacidosis, renal insufficiency, poisoning, hyponatremia or hyperchloremia, etc. Normalize pH with 4% sodium bicarbonate solution. Its dose is calculated according to the formula:

$$V = 0,3 * \text{BE} * \text{BW}$$

V- volume of sodium bicarbonate solution, ml

BE – bases excess with “-”, mmol/l

BW – body weight, kg

Metabolic alkalosis is a condition of absolute and relative decrease of H^+ ions concentration. Blood tests show:

$$\text{pH} > 7,45,$$

$$p\text{CO}_{2a} \text{ normal or insignificantly increased (compensatory reaction)}$$

BE 3,0 mmol/l.

To treat this condition use “acid” solutions, which contain chlorides (saline, potassium chloride). In case of kaliopenia give potassium solutions.

Respiratory and metabolic imbalances can mix in case of severe decompensated diseases due to failure of compensatory mechanisms. Correct interpretation of these violations is possible only in case of regular and iterative gasometry blood tests.

Control tasks.

Task 1.

Calculate the total body water volume and its extracellular and intracellular volumes of the Patient, the patient of 48 years and body weight 88 kg.

Task 2.

Patient, the patient of 23 with body weight 70 kg has sodium level 152 mmol/l and hematocrit 0,49 l/l. Name the type of water balance disorder.

Task 3.

Patient, the patient of 54 with body weight 76 kg has sodium level 128 mmol/l. Calculate the volume of saline and 7,5% sodium chloride solution necessary for the treatment of this condition.

Task 4.

Patient, the patient of 60 with body weight 60 kg has sodium level 140 mmol/l and hematocrit 0,55 l/l. Name the type of disorder and prescribe infusion therapy.

Task 5.

Patient, the patient of 42 with body weight 80 kg has potassium level 2,6 mmol/l. Calculate the volume of 4% potassium chloride solution necessary for treatment of this condition.

Task 6.

Patient, the patient of 33 with body weight 67 kg and diagnosis “gastric ulcer, complicated with pylorostenosis” has potassium concentration 3 mmol/l, chlorine concentration 88 mmol/l. pH 7,49, pCO_{2a} 42 mm Hg, BE + 10 mmol/l. Name the type of disorder.

Task 7.

Patient, the patient of 50 with body weight 75 kg, was transported to the admission

unit of the hospital with: unconsciousness, cyanotic skin, low blood pressure, shallow breathing. Blood tests show: pH 7,18, $p\text{CO}_2\text{a}$ 78 mm Hg, $p\text{O}_2\text{A}$ – 57 mm Hg, BE -4,2 mmol/l. Name the type of acid-base disorder and prescribe treatment.

Task 8.

Patience, the patient with body weight 62 kg and renal insufficiency has: potassium concentration 5,2 mmol/l, sodium concentration 130 mmol/l, calcium concentration 1,5 mmol/l, pH 7,22, $p\text{CO}_2\text{a}$ 34 mm Hg, BE -9,2 mmol/l. Name the type of disorder.

ACUTE VIOLATION OF CIRCULATORY ACTIVITY

Diagnosis and treatment

Introduction

Acute circulatory insufficiency

Anatomy and physiology

Life is provided through a variety of mechanisms, however all of them depend on proper circulation. Circulation itself consists of 2 parts: work of heart (pump of the body) and vessels, through which blood is pumped to the most remote organs and tissues. During every systolic contraction heart pumps 70_80 ml of blood (so called stroke volume). So if the heart rate is 70 beats per minute, heart pumps nearly 5 liters of blood, what makes more than 7 tones per day.

From the left ventricle blood gets to the arterial system of the systemic circuit. Arteries contain 15% of the whole circulating blood volume; they carry blood from the heart to their distal departments – arterioles (vessels of resistance). Arterioles themselves are defining blood distribution: in condition of constriction (spasm) they make blood supply of the capillaries impossible (ischemia appears). On the contrary, in condition of dilatation they provide maximal oxygenation. When arterioles are blocked due to the spasm blood is flowing through the arterio_venous anastomoses directly to the venous system.

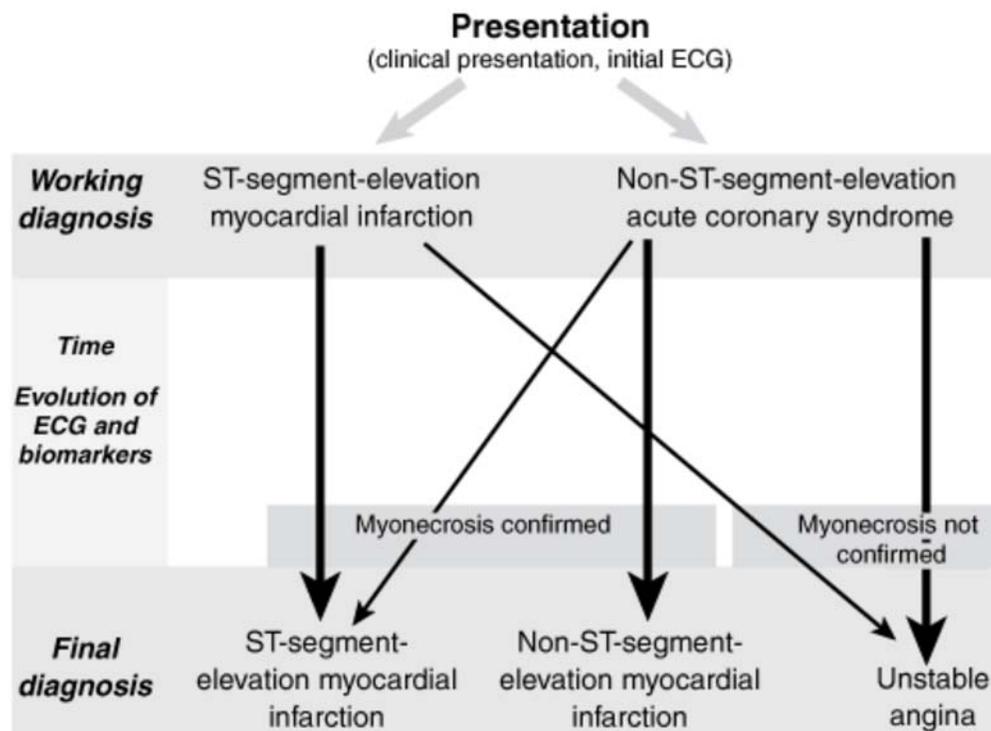

Distribution of blood in the vascular bed (% of CBV).

- a. heart cavity 3%
- b. arteries 15%
- c. capillaries 12%
- d. venous system 70%

Among the natural vasoconstrictors (agents, which cause constriction of the blood vessel) are epinephrine, norepinephrine,

serotonin, angiotensin II. Stress enhances the secretion of catecholamines, their blood concentration increases and arterioles constrict. Spasm of the arterioles is the basis of blood flow centralization: peripheral flow is disregarded in order to provide brain with the oxygenated blood as long as possible. To the group of vasodilators (agents, which provide dilatation of the vessels) belong “acid” metabolites (lactate, pyruvate, adenylic acid, inosinic acid),

—
bradykinin, acetylcholine, different medicines (neuroleptics, β -adrenergic antagonists, peripheral vasodilators, ganglionic blocking agents, etc.), some exogenous poisons. All of them cause blood flow decentralization: opening of arterioles and distribution of the blood from central vessels to the capillary bed.

Capillaries are the interweaving network of the smallest body vessels with the general length of 90_100 thousands kilometers. However simultaneously work only 20_25% of them. They provide metabolic exchange bringing oxygen and nutrients to the tissues and take back wastes of metabolism. Periodically, every 30_40 seconds one of them get closed and others open (vasomotion effect). Capillaries contain 12% of the whole circulating blood volume, but

different pathological conditions can increase this amount even 3 and more times.

“Used” blood from the capillaries flows to the venous system.

Veins are the blood reservoir, which contains 70% of the total circulating blood volume. Unlike arteries they are capable of volume control and thus they influence the amount of blood, which returns to the heart.

The most important haemodynamic index of venous system is central venous pressure. CVP represents the pressure which blood causes to the walls of cava veins and right atrium. This parameter is an integral index of circulating blood volume, systemic vascular resistance and pump function of the heart. It can be measured with a special device called “phlebotonometer” (pic. 4.9) or with a usual infusion set and a ruler. Normally CVP measured from the sternum point is 0_14 cm H₂O and from midaxillary line _ 8_15 cm H₂O.

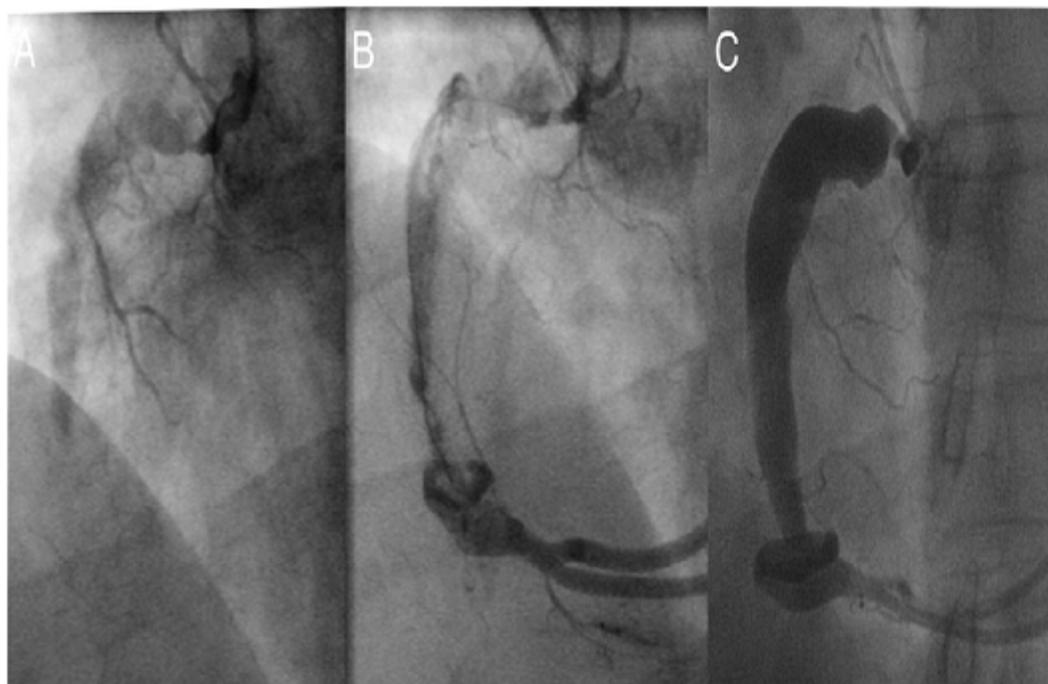

Fig. Angiografia of patient with MI

Central venous pressure decreases (sometimes even to negative)

in case of:

- blood loss
- excessive water loss (dehydration)

– distributive shock (decrease of peripheral resistance due to venous and arterial dilatation)

In those conditions decreases volume of blood returning to the heart and thus suffers cardiac output. In case of negative CVP cardiac arrest is highly probable.

–
Central venous pressure increases in case of:

- heart failure (insufficiency of left or right ventricle)
- hypervolemia (excessive blood infusion, improper infusion therapy)
- obstructions to blood flow (pulmonary embolism, cardiac tamponade, etc.)

When CVP over 15_16 cm H₂O is combined with left ventricle insufficiency the risk of pulmonary edema is very high.

Blood pressure is an integral index of arterial part of systemic haemodynamics. Talking about blood pressure we may refer to systolic, diastolic, pulse and mean arterial pressure. Systolic (P_{syst}) and diastolic (P_{diast}) pressures are measured with the manometer (method with the usage of phonendoscope was invented by M. Korotkoff). Pulse pressure (PP) is a difference between systolic and diastolic blood pressure.

Mean arterial pressure (MAP) is calculated according to the formula:

$$\text{MAP} = P_{\text{dias}} + \frac{1}{3} \text{PP} \text{ mm Hg}$$

MAP defines the level of pressure necessary for the metabolic exchange in the tissues. Its measurement allows the evaluation of tissue perfusion level.

Blood pressure depends on different factors, but the most important are cardiac output and vascular resistance (mostly arterioles). This dependence is direct, thus you can increase blood pressure using:

- infusion of vasoconstrictors – solutions of epinephrine, phenylephrine (mesaton), etc. (they will increase the vascular resistance);

- infusion of hydroxyethyl starch solutions or saline (they will increase circulating blood volume)
- infusion of cardiac glycosides or other medicine which stimulate Myocardium

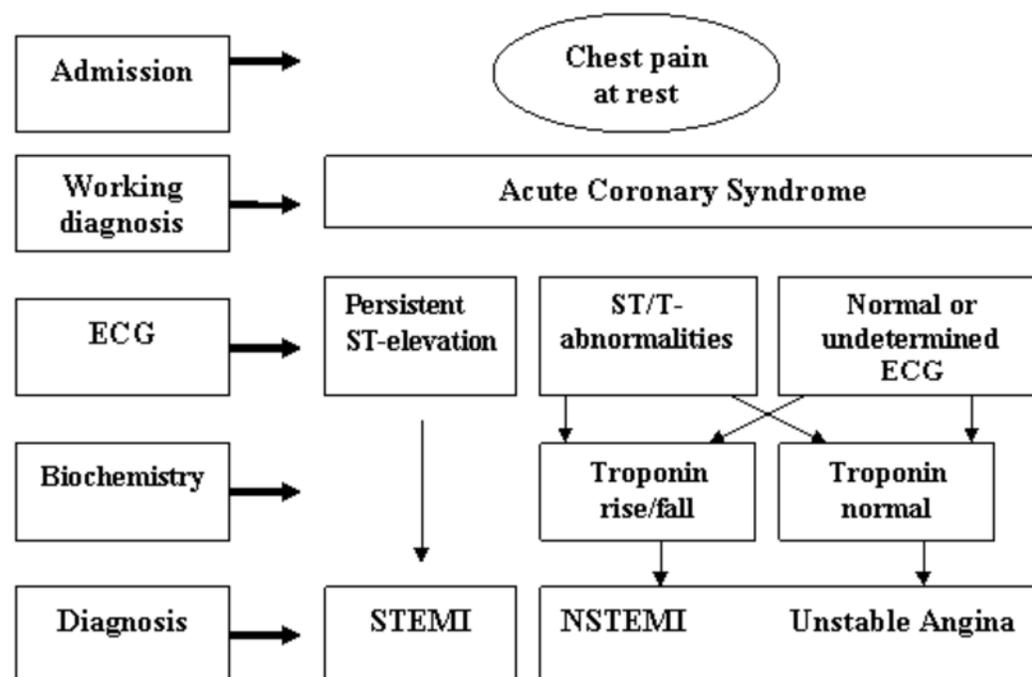

Fig. Chest pain

General volume of blood in the body of a healthy adult is nearly 7% from the body weight: 70 ml per kilogram for male and 65 ml per kilogram of body weight for female. Of course circulating blood volume is lower, because part of blood is out of metabolic processes

– as a reserve. CBV can be measured with the infusion of coloring substance to the blood flow (Evans blue, polyglucin) and later evaluation of its dissolution degree.

Therefore measurement of CVP, BP, cardiac output and circulating blood volume allow to evaluate condition of circulation system of the patients and to provide adequate correction.

4.2. Acute heart failure; shock and collapse

Acute cardiovascular failure is a state of cardiac and vascular inability to provide adequate supply of tissue metabolic needs with oxygenated blood and nutrients. This, earlier or later, causes cellular death.

The reasons of the failure vary greatly: mechanic injuries, blood loss, burns, dehydration, exogenous and endogenous intoxications, immediate hypersensitivity reaction, ischemic heart disease, neural and humoral regulation disorders of vascular tone.

Acute cardiac failure is a disorder of heart pumping action. It develops due to primary heart problems or secondary, under the influence of extracardiac factors such as infection or intoxication.

There are two types of heart failure: left_sided and right_sided.

Left_sided heart failure is an inability of left ventricle to pump blood from the pulmonary circuit to the systemic circuit. The most common reasons of it are myocardial infarction, mitral insufficiency, left AV valve stenosis, aortic valve stenosis, aortal insufficiency, hypertonic disease, coronary sclerosis, acute pneumonia.

Coronary circulation is possible only during the diastole and in those conditions every violation of coronary passability decreases cardiac output. This way during the systole part of the blood is not injected into aorta, but stays in the left ventricle. Diastolic pressure in the left ventricle increases and blood is literally forced to stagnate in the left atrium. At the same time right ventricle functions normally and continues to pump usual amounts of blood to the pulmonary circuit.

Thus hydrostatic pressure in the vessels of pulmonary circulation increases, fluid part of the blood moves first to the lung tissue and then, through alveolar_capillary membrane, to the alveolar lumen.

Clinically pulmonary edema begins with dyspnea (during physical activity or rest). Later attacks of dyspnea are connected with persistent cough with white or pink blood_tinged phlegm. During the attack patient tries to sit as in this position breathing is easier.

This condition is called "heart asthma". When hydrostatic pressure is over 150_200 mm Hg, fluid part of blood moves to the alveolar lumen causing development of pulmonary edema.

Pulmonary edema is divided into interstitial and alveolar edema.

Interstitial edema is a condition during which serous part of stagnated in the pulmonary circuit blood infiltrates the lung tissue, including peribronchial and perivascular spaces.

During alveolar edema not only the plasma, but also blood components (red and white blood cells, platelets) get out from the vessels. During the respiratory act blood mixes with the air creating large amount of “foam”, which violates gas exchange. This way, in addition to circulatory hypoxia, hypoxic hypoxia appears.

Condition of the patient gets worse quickly. Sitting position is optimal, but not as helping as previously. Respiratory rate is nearly 30_35 breathes per minute, but attacks of breathlessness are constant. Skin is pale with acrocyanosis. Hypoxia of central nervous system usually causes psychomotor agitation. Respiratory acts are noisy; during cough pink blood_tinged phlegm is released. Auscultation allows you to hear different wet rales, sometimes it's even possible to hear them standing aside the patient without phonendoscope.

Pulmonary edema can be also divided according to the blood pressure level: the one with elevated pressure is caused by a hypertonic disease, aorta valve insufficiency or disorders of cerebral perfusion; another one is caused by total myocardial infarction, acute inflammation of myocardial muscle, terminal valve defects, severe pneumonia and is characterized with normal or low blood pressure.

Immediate aid

- make sure patient is sitting with his legs down (orthopnea)
- provide oxygenation through nasal catheter (before placing oil it with glycerin, insert it to the depth of 10_12 cm – distance from the wing of the nose to auricle) or face mask. Do not use Vaseline, because it can burn in atmosphere with high concentration of oxygen. However if catheter is not deep enough patient will suffer from an unpleasant “burning” feeling, because oxygen flow will dry mucosa layer of the nasal cavity; also in this situation concentration of oxygen will be lower than expected.
- put venous tourniquets on the limbs in order to reduce amount of blood returning to heart: venous bed of limbs can reserve up to 1,7 liters of blood;
- constantly control heart and kidney activity (ECG, SaO₂ , and blood pressure are checked automatically through the monitor; to

control diuresis you should insert Foley catheter;

- catheterize central vein, because amount of infusions should be based on central venous pressure;

- use medical “defoamers” if they are available (ethyl alcohol or antiphomsylan solution) combined with oxygen inhalation;

- medical treatment: 1% morphine solution (decreases intravascular pressure of pulmonary circuit, inhibits respiration center in medulla oblongata preventing dyspnea progress, sedates patient);

- solutions of diuretics are used to decrease the circulating blood volume (6_12 ml of 1% furosemid solution, solution of ethacrynic acid), however be careful with them in case of low blood pressure; diuretic effect will last up to 3 hours after i/v infusion, the expected diuresis is 2_3 liters;

- if blood pressure allows you can try to use nitroglycerin to reduce intravascular pressure of pulmonary circuit (1 or 2 tablets with 10 minutes interval);

- cardiac glycosides for improvement of the heart action (0,025% digoxin solution, 0,05% strophanthin solution, 0,06% corglicon solution);

- in case of high pressure (over 150 mm Hg) use ganglionic blocking agents (1 ml of 5% pentamin solution diluted in 150 ml of saline, give i/v slowly; diluted with saline 250 mg of trimethaphan solution), because they reduce pressure in pulmonary circuit and lower the amount of blood getting to right half of the heart, however be careful with the dosage and monitor blood pressure level carefully;

- never use osmotic diuretics in case of pulmonary edema – they will increase blood volume and thus heart load!!!;

- when everything listed above failed and patient is worsening with every second you should intubate him and start artificial ventilation with positive end expiratory pressure (begin with 4_6 cm H2O).

Right_sided heart failure is an inability of right ventricle to pump blood from systemic circuit to the pulmonary circuit due to its weakness or an obstruction to the blood flow.

It occurs in case of pulmonary embolism, right ventricle infarction, excessive infusion therapy (especially including citrated blood) in patients with heart insufficiency, lung diseases (bronchial asthma, emphysema, pneumosclerosis) which cause increase of right ventricular load.

Patients have acrocyanosis, tachycardia, dyspnea, pronounced neck veins, ankle swelling, enlarged liver, ascytis. Central venous pressure is highly increased (up to 20_25 cm H₂O), however pulmonary edema does not appear.

Intensive treatment is mostly pathogenetic:

- limit the infusions (give only life_necessary solutions, check the water balance of the patient and reduce drinking water if necessary);
- in case of citrated blood transfusions use 5_10 ml of 10% calcium gluconate solution per every 500 ml of blood to prevent hypocalcaemia;
- in case of bronchial spasm use bronchial spasmolytics;
- to remove excessive fluid from the body use diuretics (furosemide solution for example);
- metabolic acidosis is corrected with 4% solution of sodium bicarbonate (i/v slowly with acid_base state control);
- in case of pulmonary embolism anticoagulants are used – fraxiparine 0,6 mg subcutaneously; heparin solution – 5000 IU every 4 hours; fibrinolytic drugs (streptokinase, fibrinolysin, urokinase, etc.)

Shock is a pathological state which can be described as a tissue hypoxia caused by hypoperfusion. Pathogenetic basis of shock depends on its reason (trauma, toxins, thermal injury) and at the same time on reactivity of the organism (level of defense mechanisms mobilization).

Stimulation of sympathetic nervous system – production of catecholamines and other vasoactive substances by hypothalamus and adrenal glands is the universal response of the body to the stress. Those mediators interact with the receptors of peripheral vessels causing their constriction and at the same time they dilatate the

vascular bed of life_important organs. This is so called “centralization of the flow”: rational decrease of blood flow in less important tissues (skin, organs of abdominal cavity, kidneys) in case of aggressive external influence for the protection of life itself (brain, heart, lungs). However influence of shock agents (pain, hypovolemia, destroyed cells, toxic metabolites), extended microcirculation violations (vascular spasm, microthrombosis and sludge) and caused by them tissue ischemia lead to hypoxic affection and cellular death of the internal organs. Further it can bring multiple organ dysfunction syndrome.

Collapse is a vascular failure. It occurs when body is not able to provide blood flow according to the new level of its needs (either because reaction is not fast enough or because sympathetic activation fails). Vascular bed volume and circulating blood volume are disproportional: too much blood gets to the microcirculation vascular reserve and the amount, which returns to the heart is not enough for the systemic needs (so called “decentralization” of the blood flow). Cardiac output and blood pressure decrease, that causes hypoperfusion of the central nervous system and thus unconsciousness and life_threatening complications.

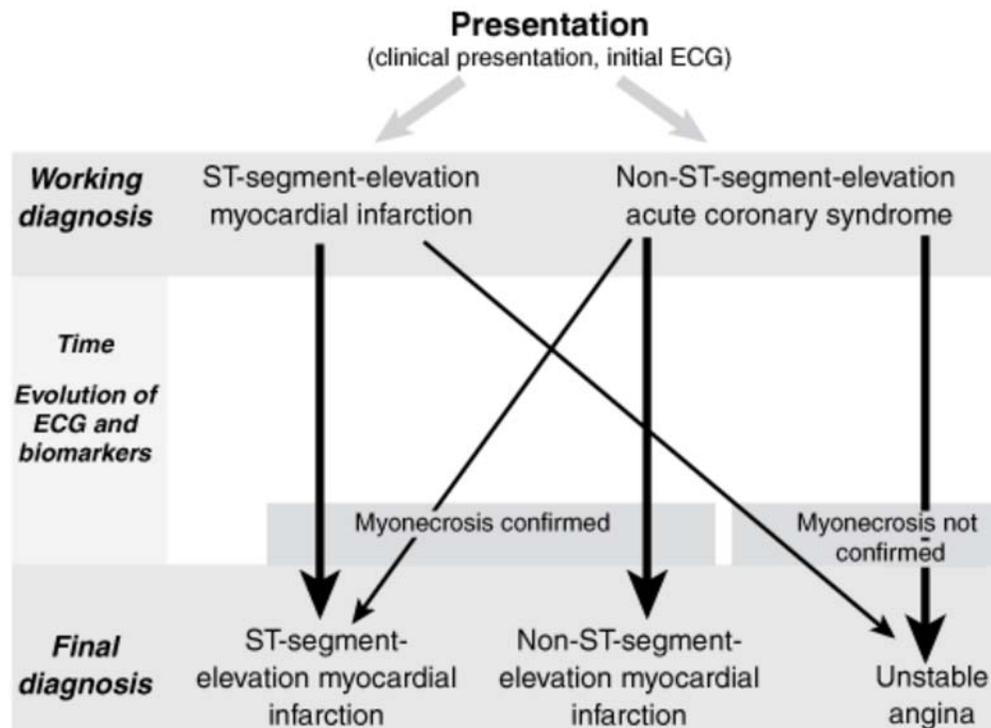

Collapse definition is a bit nominal, because if such reaction extends in time the state of shock develops. Shock itself can equally run as a vascular failure or as a sudden clinical death.

New acute coronary syndromes terminology and implications for diagnosis

The terminology used to describe ACS continues to evolve, with the emergence of the term “non-ST-segment-elevation acute coronary syndrome” (NSTEMACS). This reflects a shift away from establishing a definitive diagnosis at presentation, and towards a more clinically appropriate strategy of forming a rapid working diagnosis with its implications for initial clinical decision making.

At presentation, the initial diagnostic nomenclature focuses on risk stratification to direct treatment strategies. Establishing a definitive diagnosis often requires time, particularly for evidence of myocardial necrosis to emerge, and has important implications pertaining to prognosis, diagnostic coding, and social issues such as insurance and licensure.

1 Defining acute coronary syndromes over time: presentation to final diagnosis

ECG = electrocardiogram.

Initial working diagnosis

The initial working diagnosis is based on the clinical presentation and the initial electrocardiogram (ECG) findings and, in particular, the presence or absence of ST-segment elevation. As the vast majority of patients who present with initial ST-segment elevation develop biochemical evidence of myonecrosis, the term “ST-segment-elevation myocardial infarction” (STEMI) is often used from the outset in these patients.

ACS without ST-segment elevation on the presenting ECG represent a broad spectrum of risk, but are collectively referred to as NSTEMACS. This grouping is useful because emergency reperfusion therapy is not indicated (unless ST-segment elevation develops later), and further investigation is required to classify the patient’s risk and determine the most suitable treatment (see sections on [Investigations](#) and [Management of patients with STEMI](#) for further details).

Final diagnosis

The final diagnostic attribution (ie, clinical label) has important and persisting implications for the patient, both prognostically and socially. Current international criteria for the diagnosis of myocardial infarction have a strong emphasis on biomarkers, specifically troponin, given its high sensitivity and, in particular, specificity for myonecrosis.⁵ The diagnostic criteria for acute, evolving or recent myocardial infarction are defined as:

Typical rise in the serum level of troponin or a more rapid rise in the serum level of the MB isoenzyme of creatine kinase (CK-MB) with at least one of the following:

Ischaemic symptoms;

Development of pathological Q waves on the ECG;

ECG changes indicative of ischaemia (ST-segment elevation or depression); and

Coronary artery intervention (eg, coronary angioplasty or coronary bypass surgery);

or

Pathological findings of an acute myocardial infarction.

This definition requires a temporal appreciation of the cardiac markers, and therefore differentiation between non-ST-segment-elevation myocardial infarction and unstable angina (without evidence of myonecrosis) must be delayed.

Acute management of chest pain

Getting to hospital

Chest discomfort at rest or for a prolonged period (more than 10 minutes, not relieved by sublingual nitrates), recurrent chest discomfort, or discomfort associated with syncope or acute heart failure are considered medical emergencies. Other presentations of ACS may include back, neck, arm or epigastric pain, chest tightness, dyspnoea, diaphoresis, nausea and vomiting. Very atypical pain, including sharp and pleuritic pain, is more common in women, people with diabetes and older people.^{3,7,8}

People experiencing such symptoms should seek help promptly and activate emergency medical services to enable transport to the nearest appropriate health care facility for urgent assessment (grade D recommendation). Ideally, transport should be by ambulance. However, where ambulance response times are long, alternatives may need to be considered. Patients should be strongly discouraged from driving themselves because of the risk to other road users.

The most important initial requirement is access to a defibrillator to avoid early cardiac death from reversible arrhythmias. All Australian ambulances now carry defibrillators, and there is promise in further exploring public access defibrillation opportunities. In the case of cardiac arrest occurring in a setting where a defibrillator is not immediately available, cardiopulmonary resuscitation should be commenced immediately.

Actions in transit

Aspirin (300 mg) should be given unless already taken or contraindicated (grade A recommendation), and should preferably be given early (eg, by emergency or ambulance personnel) (grade D recommendation). Oxygen should also be given (grade D recommendation).

Glyceryl trinitrate and intravenous morphine should be given as required (grade D recommendation).

Where appropriate, a 12-lead ECG should be taken en route and transmitted to a medical facility (grade B recommendation).

Receiving medical facilities should be given warning of incoming patients in whom there is a high suspicion of ACS, particularly STEMI, or those whose condition is unstable (grade B recommendation).

Where formal protocols are in place, prehospital treatment should be given, including fibrinolysis in appropriate cases (grade A recommendation). See [section on management of patients with STEMI](#) for further discussion of prehospital fibrinolysis.

On arrival

All patients presenting with suspected ACS should be subject to ongoing surveillance and have an ECG completed within 5 minutes of arrival at the medical facility (grade A recommendation). The ECG should be assessed promptly by an appropriately qualified person (grade D recommendation).

Oxygen and pain control should be given as required (grade D recommendation).

People experiencing symptoms of ACS should seek help promptly and activate emergency medical services.

The most important initial requirement is access to a defibrillator to avoid early cardiac death from reversible arrhythmias.

Aspirin should be given early (eg, by emergency or ambulance personnel) unless already taken or contraindicated.

Oxygen should be given, as well as glyceryl trinitrate and intravenous morphine as required.

As a minimum, receiving medical facilities should be given warning of incoming patients in whom there is a high suspicion of ACS, particularly STEMI, or whose condition is unstable.

Where appropriate, a 12-lead ECG should be taken en route and transmitted to a medical facility.

Where formal protocols are in place, prehospital treatment (including fibrinolysis in appropriate cases) should be facilitated.

Patients presenting with a suspected ACS should undergo immediate electrocardiography. Further investigations may be necessary, but should not delay treatment.

While other serious diagnoses can present similarly to ACS (eg, pulmonary embolism, aortic dissection, pericarditis), once these have been excluded and ACS is considered the most likely diagnosis further delay in treatment is unnecessary and inappropriate.

Investigations and invasive vascular access techniques should not delay reperfusion therapy if indicated on the basis of ST-segment elevation on the ECG.

Patients whose condition is unstable should have early consultation with a cardiologist.

Cardiac biomarkers are becoming increasingly important to the diagnosis of myocardial infarction. See [Box 2](#) for recommendations and rationale regarding their measurement.

Electrocardiography

Electrocardiography is necessary to detect ischaemic changes or arrhythmias. It should be noted that the initial ECG has a low sensitivity for ACS, and a normal ECG does not rule out ACS. However, the ECG is the sole test required to select patients for emergency reperfusion (fibrinolytic therapy or direct PCI). Patients with STEMI who present within 12 hours of the onset of ischaemic symptoms should have a reperfusion strategy implemented promptly (grade A recommendation) — see the [section on management of patients with STEMI](#) for recommendations.

Accurate ECG interpretation in a patient with chest pain is critical. Basically, there can be three types of problems - ischemia is a relative lack of blood supply (not yet an infarct), injury is acute damage occurring right now, and finally, infarct is an area of dead myocardium. It is important to realize that certain leads represent certain areas of the left ventricle; by noting which leads are involved, you can localize the process. The prognosis often varies depending on which area of the left ventricle is involved (i.e. anterior wall myocardial infarct generally has a worse prognosis than an inferior wall infarct).

[Video: MI site and coronary thrombosis](#)

V1-V2	anteroseptal wall
V3-V4	anterior wall
V5-V6	anterolateral wall
II, III, aVF	inferior wall
I, aVL	lateral wall
V1-V2	posterior wall (reciprocal)

Infarct	
1. Ischemia	Represented by symmetrical T wave inversion (upside down). The definitive leads for ischemia are: I, II, V2 - V6.
2. Injury	Acute damage - look for elevated ST segments. (Pericarditis and cardiac aneurysm can also cause ST elevation; remember to correlate it with the patient.

3. Infarct	Look for significant "pathologic" Q waves. To be significant, a Q wave must be at least one small box wide or one-third the entire QRS height. Remember, to be a Q wave, the initial deflection must be down; even a tiny initial upward deflection makes the apparent Q wave an R wave.
------------	--

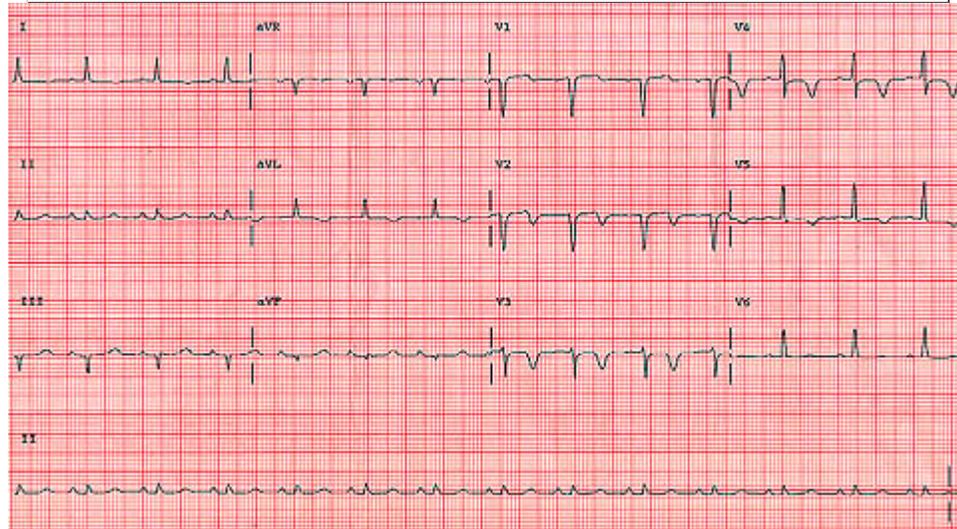

Figure: Ischemia: Note symmetric T wave inversions in leads I, V2-V5.

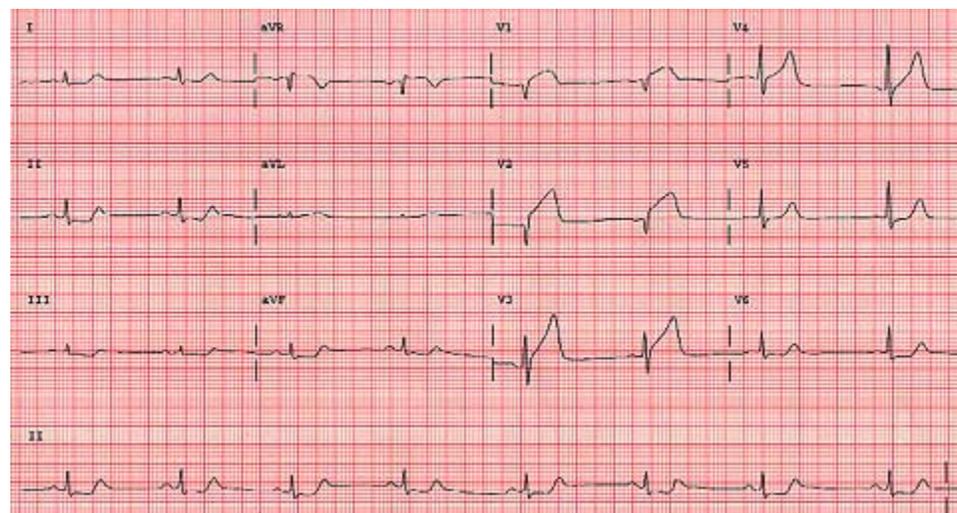

Figure: Injury: Note ST segment elevation in leads V2-V3 (anteroseptal/anterior wall).

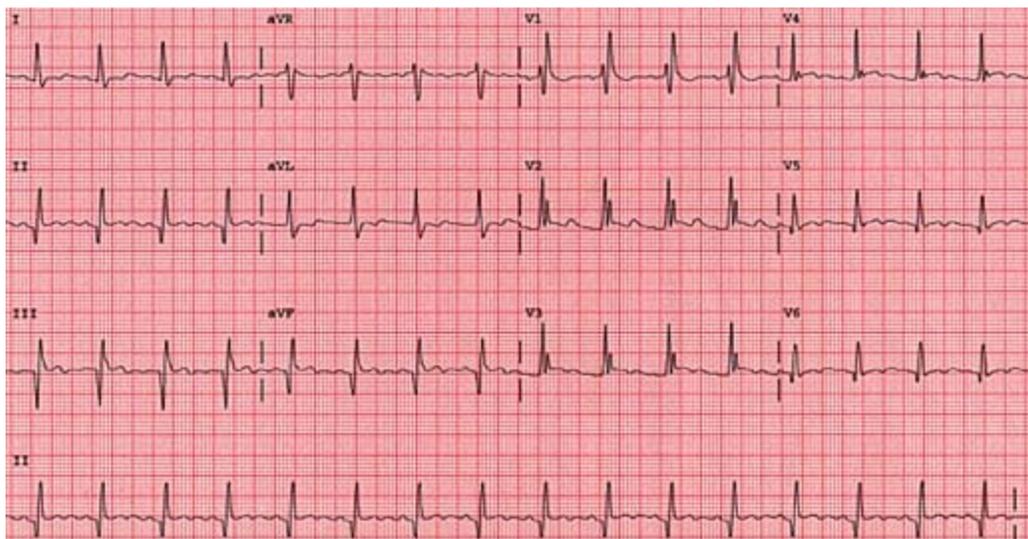

Figure 36: Infarct: Note Q waves in leads II, III, and aVF (inferior wall).

For the posterior wall, remember that vectors representing depolarization of the anterior and posterior portion of the left ventricle are in opposite directions. So, a posterior process shows up as opposite of an anterior process in V1. Instead of a Q wave and ST elevation, you get an R wave and ST depression in V1.

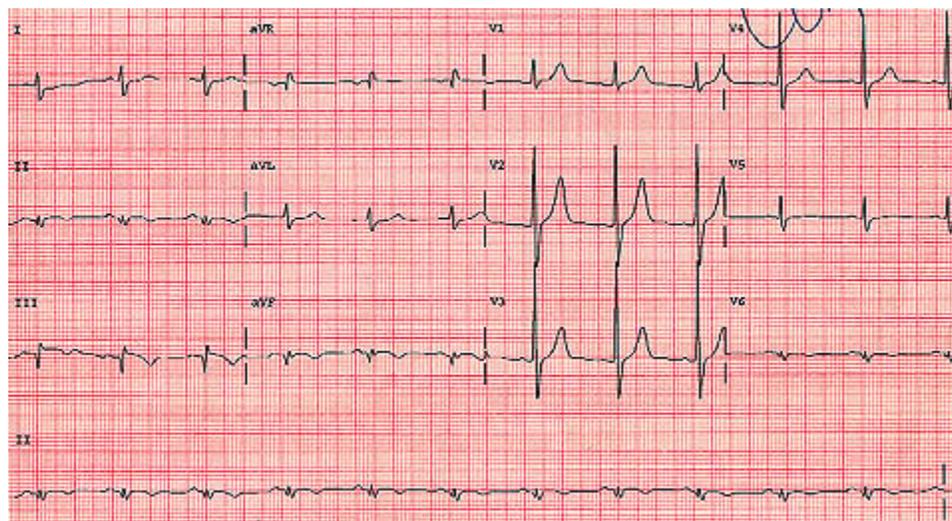

Figure: Posterior wall infarct. Notice tall R wave in V1. Posterior wall infarcts are often associated with inferior wall infarcts (Q waves in II, III and aVF).

Two other caveats: One is that normally the R wave gets larger as you go to V1 to V6. If there is no R wave "progression" from V1 to V6 this can also mean infarct. The second caveat is that, with a left bundle branch block, you cannot evaluate "infarct" on that ECG. In a patient with chest pain and left bundle branch block, you must rely on cardiac enzymes (blood tests) and the history.

Blood tests

Measurements should include:

Serum troponin I or T levels (or CK-MB if troponin is not available).

Full blood count.

Serum creatinine and electrolyte levels, particularly potassium concentration, as hypokalaemia is associated with an increased risk of arrhythmias, especially ventricular fibrillation¹⁰ (grade B recommendation). Knowledge of kidney function (expressed as estimated glomerular filtration rate) is strongly encouraged (grade B recommendation) given the association between renal impairment and adverse outcomes (evidence level III).¹¹

Serum creatine kinase (CK) level.

Serum lipid levels (fasting levels of total cholesterol, low-density-lipoprotein cholesterol, high-density-lipoprotein cholesterol and triglycerides) within 24 hours.

Blood glucose level.

Chest x-ray

A chest x-ray is useful for assessing cardiac size, evidence of heart failure and other abnormalities (grade D recommendation), but should not delay reperfusion treatment where indicated.

Further investigations

Patients without ST-segment elevation on the initial ECG should be further observed and investigated to promptly identify patients suitable for an emergency reperfusion strategy (based on ECG changes) and/or determine the best management protocol for NSTEMI based on risk stratification (see section on [Management of patients with NSTEMI](#)).

The ECG is the sole test required to select patients for emergency reperfusion (fibrinolytic therapy or direct PCI).

Patients with STEMI who present within 12 hours of the onset of ischaemic symptoms should have a reperfusion strategy implemented promptly.

Patients with a suspected ACS without ST-segment elevation on the ECG should undergo further observation and investigation to rule out other diagnoses, enable risk stratification and determine the most appropriate treatment strategy.

Patients with a normal ECG and cardiac biomarker levels after an appropriate period of observation should, where practicable, undergo provocative testing (eg, stress test) before discharge.

2 Recommendations and rationale for measuring cardiac biomarker levels

Cardiac

Recommendation Rationale

biomarker

Troponin level(Cardiac troponin I or T)

On arrival

Troponin rise indicates myonecrosis, and is a high-risk feature in NSTEMACS. Troponin is the preferred marker because about a third of patients with elevated troponin, but normal CK and CK-MB levels, will develop an adverse outcome.⁹

Not repeated if positive

Troponin remains elevated for 5–14 days, and therefore may not be useful for identifying early re-infarction.

Repeated > 8 hours after last episode of pain or other symptoms of coronary insufficiency if initially negative

Troponin elevation is often delayed by 4–6 hours. Therefore, repeat troponin testing is

necessary to identify patients at high risk who may benefit from aggressive therapy and an early invasive strategy.

Serial troponin measurements of typical in patients with rise of NSTEMI/ACS troponin suspected to be indicates high risk NSTEMI/ACS and may be an indication for more aggressive therapy.

Total level CK Serial measurements performed for 48 hours in patients with myocardial infarction Can be remeasured to confirm a second event if re-infarction is suspected later.

CK-MB level Should be measured in all patients with an ACS if troponin assay unavailable While troponin is the preferred marker of myocardial damage, if it is unavailable CK-MB is more specific

than CK for myocardial injury. CK-MB may also be used to confirm a re-infarction.

NSTEACS = non-ST-elevation acute coronary syndromes. CK = creatine kinase. CK-MB = creatine kinase-MB isoenzyme. ACS = acute coronary syndrome

Management of patients with ST-segment-elevation myocardial infarction

STEMI is defined as presentation with clinical symptoms consistent with an acute coronary syndrome with ECG features including any of:

- § **Persistent ST-segment elevation of ≥ 1 mm in two contiguous limb leads;**
- § **ST-segment elevation of ≥ 2 mm in two contiguous chest leads; or**
- § **New left bundle branch block (LBBB) pattern.⁶ (Note that LBBB is presumed new unless there is evidence otherwise; echocardiography may be useful to detect regional wall contraction abnormalities.)**

Patients with STEMI usually have a completely occluded coronary artery with thrombus at the site of a ruptured plaque. Restoring coronary patency as promptly as possible is a key determinant of short-term and long-term outcomes (level I evidence).¹⁴⁻¹⁸

Patients with STEMI who present within 12 hours of the onset of ischaemic symptoms should have a reperfusion strategy implemented promptly (grade A recommendation).

Reperfusion therapy

Reperfusion may be obtained with fibrinolytic therapy or PCI. A combination of fibrinolysis and PCI may also be used (facilitated or rescue PCI). Coronary artery bypass graft (CABG) surgery may occasionally be more appropriate — particularly in patients who have suitable anatomy and are not candidates for fibrinolysis or PCI. CABG surgery may also be considered in patients with cardiogenic shock¹⁹ or in association with mechanical repair.¹²

Antiplatelet therapy

Aspirin (300 mg) should be given to all patients with STEMI unless contraindicated and, in the absence of significant side effects, low-dose therapy should be continued in the long term (grade A recommendation).[16,20](#)

There is evidence that clopidogrel (300–600 mg loading dose) should be prescribed in addition to aspirin for patients undergoing PCI with a stent.[21-23](#) In patients selected for fibrinolytic therapy, clopidogrel (300 mg) should be given in addition to aspirin, unless contraindicated (grade B recommendation).[24](#) Note, however, that if it is thought that the patient is likely to require CABG acutely, clopidogrel should be withheld.

Clopidogrel (75 mg daily) should be continued for at least a month after fibrinolytic therapy, and for up to 12 months after stent implantation, depending on the type of stent and circumstances of implantation (level II evidence; grade B recommendation).[25](#)

Antithrombin therapy

With PCI: Antithrombin therapy should be used in conjunction with PCI (grade A recommendation). The dose of unfractionated heparin therapy will depend on concomitant use of glycoprotein (GP) IIb/IIIa inhibitors. The aim should be to obtain an activated clotting time (ACT) between 200 and 300 seconds if using GP IIb/IIIa inhibitors, or between 300 and 350 seconds if these drugs are not used (grade B recommendation). It may be advisable to give a bolus of heparin while the patient is in transit to the catheterisation laboratory (grade D recommendation).

The role of enoxaparin in acute STEMI in conjunction with PCI remains to be determined, but it appears to be safe and effective at a dose of 0.75 mg/kg (grade D recommendation).

With fibrinolysis: Antithrombin therapy should be used with fibrin-specific fibrinolytic agents (grade A recommendation).[26,27](#)

Unfractionated heparin should be given as an initial bolus dose of 60 units per kilogram of body weight (with a maximum dose of 4000 units) followed by an initial infusion of 12 units per kilogram per hour (maximum units 1000 per hour), adjusted to attain the activated partial thromboplastin time (APTT) at 1.5 to 2 times control (about 50–70 seconds; grade B recommendation).[12](#)

Enoxaparin may be used in conjunction with fibrin-specific fibrinolytic agents in patients under the age of 75 years, provided they do not have significant renal dysfunction. An intravenous bolus dose of 30 mg followed by a 1 mg/kg subcutaneous injection every 12 hours in combination with tenecteplase is the most comprehensively studied therapy.[12](#) Care should be taken in patients who are aged over 75 years, or who have renal dysfunction, as dose adjustment is required.[12](#)

The use of antithrombin therapy in conjunction with streptokinase therapy is optional.[28](#)

Glycoprotein IIb/IIIa inhibitors

It is reasonable to use abciximab with primary PCI, although there are conflicting data (grade B

recommendation). It appears the earlier it is used, the greater the advantage.²⁹ When used in patients with STEMI undergoing primary PCI, the timing of administration of abciximab is a matter of clinical judgement.^{30,31}

Full-dose GP IIb/IIIa inhibitors should be avoided with fibrinolytic therapy (grade B recommendation) as there is evidence of excessive bleeding (including intracranial haemorrhage) with this combination.³² It is unclear how early full-dose GP IIb/IIIa inhibitors can be safely given after fibrinolysis, but it is probably at least 4 hours after administration of fibrin-specific fibrinolytic agents and 24 hours after administration of streptokinase.³²

The combination of GP IIb/IIIa inhibitors with reduced doses of fibrinolytic therapy is not recommended. There is no significant advantage over full-dose fibrinolytic therapy alone, and the risk of bleeding is increased, particularly in the elderly.³² This combination has been used for facilitated PCI.³²

§ All patients undergoing reperfusion therapy (PCI or fibrinolysis) for STEMI should be given aspirin and clopidogrel unless contraindicated.

§ Antithrombin therapy should be given in combination with PCI or fibrinolytic therapy with fibrin-specific fibrinolytic agents, but its use in conjunction with streptokinase is optional.

§ It is reasonable to use abciximab with primary PCI, but GP IIb/IIIa inhibitors should generally be avoided with full or reduced doses of fibrinolytic therapy.

3 Summary of adjuvant therapy associated with reperfusion

Medication	Primary percutaneous coronary intervention	Fibrin-specific fibrinolytic
Aspirin	Yes	Yes
Clopidogrel	Yes (unless the need for acute CABG is likely)	Yes (unless the need for acute CABG is likely)
Heparin	Unfractionated heparin (ACT 200–300 s if using glycoprotein IIb/IIIa inhibitors, 300–350 s if not) or Enoxaparin*	Unfractionated heparin (APTT 1.5–2 times control [approx 50–70 s]) or Enoxaparin*
Glycoprotein IIb/IIIa inhibitors	Abciximab optional	No

CABG = coronary artery bypass graft. ACT = activated clotting time. APTT = activated partial thromboplastin time.

* Care should be taken in patients aged over 75 years, or those who have significant renal dysfunction — dose adjustment is required.

Choice of reperfusion therapy

§ Choice of reperfusion strategy depends on a number of factors, with time delay (both to presentation and potential PCI or fibrinolytic therapy) playing a major role in determining best management.

§ In general, PCI is the treatment of choice, provided it can be performed promptly by a qualified interventional cardiologist in an appropriate facility.

§ In general, the maximum acceptable delay from presentation to balloon inflation is:

- 60 minutes if a patient presents within 1 hour of symptom onset; and
- 90 minutes if a patient presents later.

Note: for patients who present late (3–12 hours after symptom onset) to a facility without PCI capability, it is appropriate to consider transfer for primary PCI if balloon inflation can be achieved within 2 hours (including transport time).

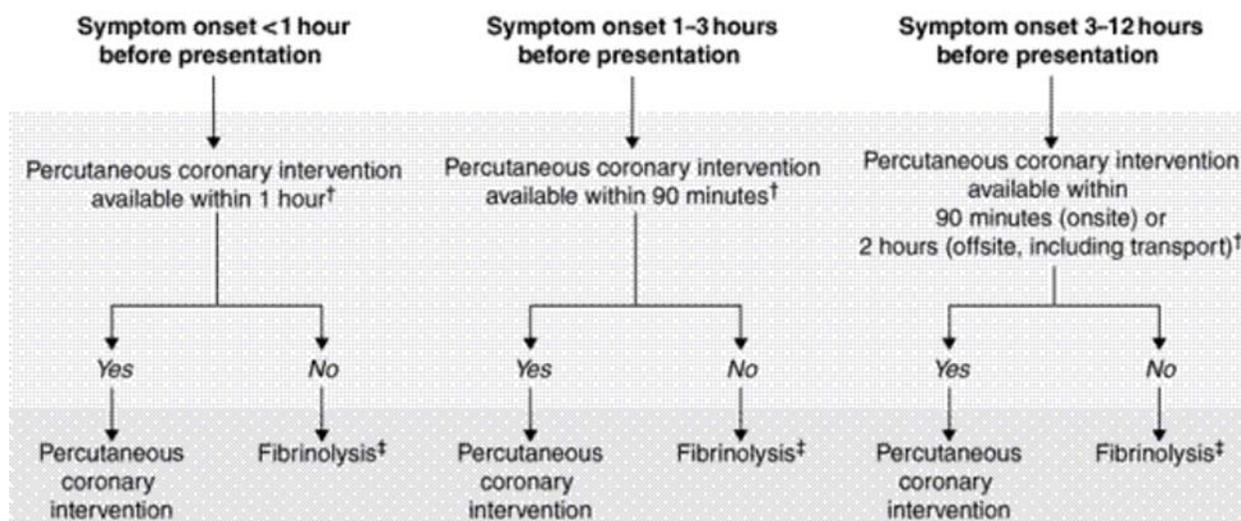

§ All PCI facilities should be able to perform angioplasty within 90 minutes of patient presentation.

§ Fibrinolysis should be considered early if PCI is not readily available, particularly in rural and remote areas.

§ When there are major delays to hospitalisation (more than 30 minutes), prehospital fibrinolysis should be considered.

§ Reperfusion is not routinely recommended in patients who present more than 12 hours after symptom onset and who are asymptomatic and haemodynamically stable.

4 Hospital management of ST-segment-elevation myocardial infarction*

Assuming no contraindications to fibrinolytic therapy — see [Box 5](#). [†] Time delay refers to time from first medical contact to balloon. [‡] Patients with ongoing symptoms or instability should be transferred for PCI.

Note: Reperfusion after 12 hours is indicated for cardiogenic shock, ongoing pain or

haemodynamic instability (see text).

5 Contraindications and cautions for fibrinolysis use in ST-segment-elevation myocardial infarction*

Absolute contraindications

Risk of bleeding

- § Active bleeding or bleeding diathesis (excluding menses)
- § Significant closed head or facial trauma within 3 months
- § Suspected aortic dissection (including new neurological symptoms)[50](#)

Risk of intracranial haemorrhage

- § Any prior intracranial haemorrhage
- § Ischaemic stroke within 3 months
- § Known structural cerebral vascular lesion (eg, arteriovenous malformation)
- § Known malignant intracranial neoplasm (primary or metastatic)

Relative contraindications

Risk of bleeding

- § Current use of anticoagulants: the higher the international normalised ratio (INR), the higher the risk of bleeding
- § Non-compressible vascular punctures
- § Recent major surgery (< 3 weeks)
- § Traumatic or prolonged (> 10 minutes) cardiopulmonary resuscitation
- § Recent (within 4 weeks) internal bleeding (eg, gastrointestinal or urinary tract haemorrhage)
- § Active peptic ulcer

Risk of intracranial haemorrhage

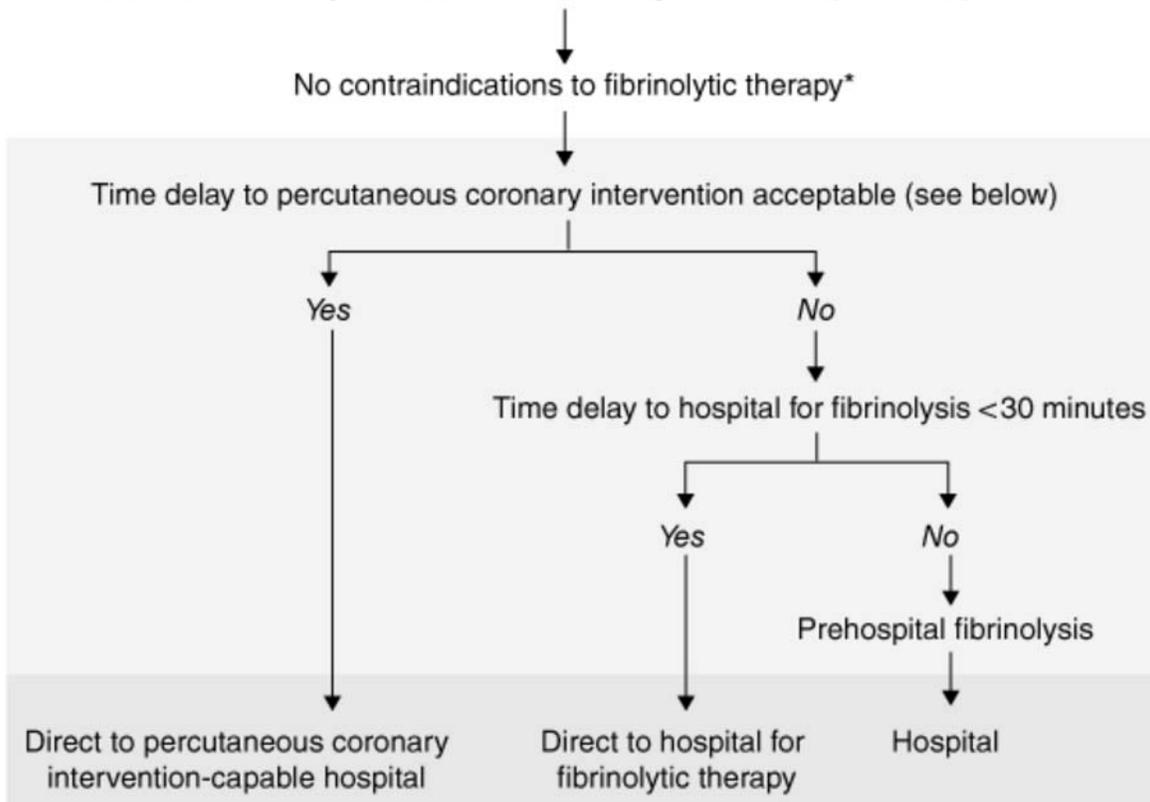

- § History of chronic, severe, poorly controlled hypertension
- § Severe uncontrolled hypertension on presentation (> 180 mmHg systolic or > 110 mmHg diastolic)
- § Ischaemic stroke more than 3 months ago, dementia, or known intracranial abnormality not covered in contraindications

Other

- § Pregnancy
-

6 Prehospital management of ST-segment-elevation myocardial infarction (STEMI)

STEMI confirmed by 12-lead electrocardiogram with expert interpretation

Time since onset of symptoms

	< 1 hour	1–3 hours	3–12 hours	> 12 hours
Acceptable delay to percutaneous coronary intervention (from first medical contact to balloon inflation)	60 minutes	90 minutes	120 minutes	Not routinely recommended (see text)

*If fibrinolysis is contraindicated, it is important that an attempt to reperfuse is made, even if there is a long delay (up to 12 hours).

Choice of fibrinolytic agent

There are four fibrinolytic agents currently available in Australia; streptokinase and the tissue

fibrin-specific fibrinolytic agents alteplase, reteplase and tenecteplase. The properties of these agents are summarised in [Box 7](#).

Fibrin-specific fibrinolytic agents have been shown to reduce mortality compared with streptokinase in patients with STEMI who present within 6 hours of symptom onset (level I evidence).⁵⁵ Fibrin-specific fibrinolytic agents also lack the significant acute side effects of hypotension and allergy caused by streptokinase (level I evidence). Streptokinase may be associated with a lower incidence of intracranial haemorrhage, particularly in older people (level I evidence), but the overall mortality is still lower with the use of fibrin-specific fibrinolytic agents (level II evidence).⁵⁶ Tenecteplase is associated with a lower rate of bleeding than alteplase (level II evidence).⁵⁷

Second-generation fibrin-specific fibrinolytic agents can be given as either single or double bolus injections, which makes them significantly easier to use than streptokinase.

In combination therapy, PCI combined with fibrin-specific fibrinolytic agents appears to have greater efficacy and results in fewer complications than PCI combined with streptokinase (level III evidence, grade B recommendation).⁵⁸

Streptokinase should not be given to patients with previous exposure (more than 5 days ago) to the drug (grade B recommendation). There is also evidence that streptokinase may be less effective in Aboriginal and Torres Strait Islander peoples because of the high levels of skin infection (and thus streptococcal antibodies), particularly in remote populations.^{45,59} It is therefore an inappropriate choice of agent in these populations (level III evidence, grade B recommendation). Making second-generation fibrin-specific fibrinolytic agents the standard choice is likely to decrease inequalities of care between Indigenous and non-Indigenous populations, in addition to providing superior reperfusion.

Therefore, second-generation fibrin-specific fibrinolytic agents which are available as a bolus (ie, reteplase, tenecteplase) are the fibrinolytics of choice (grade A recommendation). These agents should be available at all centres where fibrinolysis may be required (grade D recommendation).

§ Second-generation fibrin-specific fibrinolytic agents that are available as a bolus (ie, reteplase, tenecteplase) are the fibrinolytics of choice.

§ These agents should be available at all centres where fibrinolysis may be required.

§ Streptokinase is a particularly inappropriate choice for Aboriginal and Torres Strait Islander patients or patients with previous exposure to the drug.

§

7 Fibrinolytic agents — prescribing information and properties

Details	Tenecteplase (TNK)	Reteplase (r-PA)	Alteplase (rt-PA)	Streptokinase

§ Patients who have had STEMI should be considered for early transfer to a tertiary cardiac centre with PCI facilities and links to cardiac surgical facilities.

§ If early transfer is not possible, all patients should be transferred or referred as soon as is practicable for assessment of the need for revascularisation through PCI or CABG.

Management of patients with non-ST-segment-elevation acute coronary syndromes. Risk stratification

The initial objective of evaluation is to define the likelihood of an ACS as the cause of a patient's presentation. Most patients will present with prolonged or recurrent central chest

discomfort but others, particularly the elderly, people with diabetes and women, may present with atypical symptoms. These include neck, jaw, back or epigastric discomfort or dyspnoea, diaphoresis, nausea and vomiting. Age is an important risk factor, and the presence (or absence) of coronary risk factors adds little to the accuracy of the diagnosis in middle-aged or elderly patients, but is more useful in making a diagnosis in younger patients. A history of physical or emotional stress before symptom onset increases the likelihood of an ACS. Most patients with NSTEMACS are normal on physical examination. An abnormal ECG, particularly dynamic ST-segment deviation (≥ 0.5 mm) or new T-wave inversion (≥ 2 mm) will confirm the diagnosis, but the ECG may be normal or show minor changes in up to 50% of cases.

The second objective of evaluation is to determine the risk of short-term adverse outcomes, which will direct the management strategy. [Box 8](#) provides a paradigm for the risk stratification of patients presenting with suspected NSTEMACS, and a simplified risk assessment algorithm is shown in [Box 9](#). Most patients admitted to hospital with possible NSTEMACS will have intermediate-risk or high-risk features ([Box 8](#)), and these patients are best managed with a structured clinical pathway (see [Investigation](#) section). Patients with clinical features consistent with NSTEMACS and high-risk features are best managed with aggressive medical and invasive therapy (detailed later). Patients with diabetes or chronic kidney disease with typical symptoms of ACS would be considered to be at high risk, but those with atypical symptoms and normal ECGs and cardiac biomarker levels may initially be considered at intermediate risk until a diagnosis is made. Patients with low-risk unstable angina may be managed with upgraded medical therapy and outpatient cardiac referral.

8 Features associated with high-risk, intermediate-risk and low-risk non-ST-segment-elevation acute coronary syndromes (NSTEMACS)

High-risk features

Presentation with clinical features consistent with acute coronary syndromes (ACS) and any of the following high-risk features:

- § Repetitive or prolonged (> 10 minutes) ongoing chest pain or discomfort;
- § Elevated level of at least one cardiac biomarker (troponin or creatine kinase-MB isoenzyme);
- § Persistent or dynamic electrocardiographic changes of ST-segment depression ≥ 0.5 mm or new T-wave inversion ≥ 2 mm;
- § Transient ST-segment elevation (≥ 0.5 mm) in more than two contiguous leads;
- § Haemodynamic compromise — systolic blood pressure < 90 mmHg, cool peripheries, diaphoresis, Killip Class $> I$, and/or new-onset mitral regurgitation;
- § Sustained ventricular tachycardia;
- § Syncope;
- § Left ventricular systolic dysfunction (left ventricular ejection fraction < 0.40);
- § Prior percutaneous coronary intervention within 6 months or prior coronary artery bypass surgery;

- § Presence of known diabetes (with typical symptoms of ACS); or
- § Chronic kidney disease (estimated glomerular filtration rate < 60 mL/minute) (with typical symptoms of ACS).

Intermediate-risk features

Presentation with clinical features consistent with ACS and any of the following intermediate risk features AND NOT meeting the criteria for high-risk ACS:

- § Chest pain or discomfort within the past 48 hours that occurred at rest, or was repetitive or prolonged (but currently resolved);
- § Age > 65 years;
- § Known coronary heart disease — prior myocardial infarction with left ventricular ejection fraction ≥ 0.40 , or known coronary lesion more than 50% stenosed;
- § No high-risk changes on electrocardiography (see above);
- § Two or more of the following risk factors: known hypertension, family history, active smoking or hyperlipidaemia;
- § Presence of known diabetes (with atypical symptoms of ACS);
- § Chronic kidney disease (estimated glomerular filtration rate < 60 mL/minute) (with atypical symptoms of ACS); or
- § Prior aspirin use.

Low-risk features

Presentation with clinical features consistent with an acute coronary syndrome without intermediate-risk or high-risk features. This includes onset of anginal symptoms within the last month, or worsening in severity or frequency of angina, or lowering of anginal threshold.

Treatment of NSTEMI/ACS

Aspirin is recommended (unless contraindicated) in all low-risk, intermediate-risk and high-risk patients (grade A recommendation).

High-risk patients should be treated with aggressive medical management (level I evidence, grade A recommendation) (see below) and arrangements should be made for coronary angiography and revascularisation (level I evidence, grade A recommendation), except in those with severe comorbidities, including general frailty (grade A recommendation). Age alone should not be a barrier to aggressive therapy.

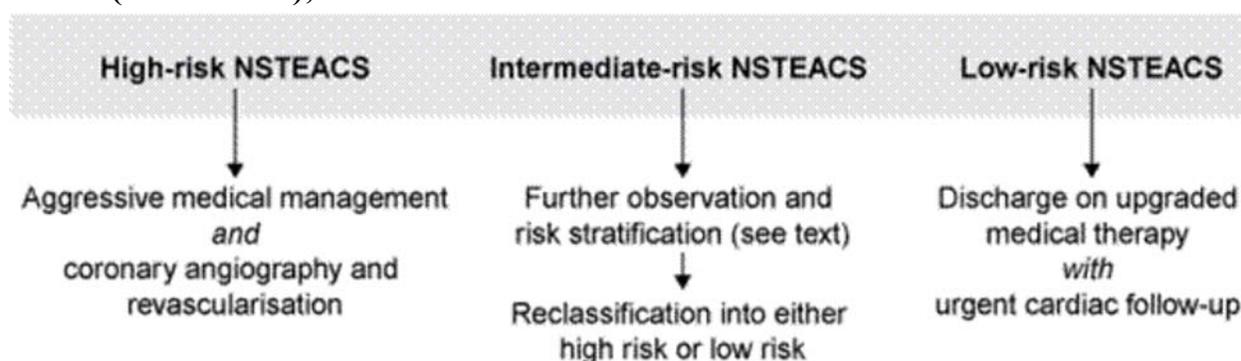

Patients at intermediate risk should be observed by staff trained in cardiac care practice and should undergo an accelerated diagnostic evaluation and further risk stratification (level III evidence, grade B recommendation). Accurate assessment can be improved by the use of structured forms for admission and continuing evaluation.⁷⁹⁻⁸² During the evaluation process, intermediate-risk patients are observed as described in the [Investigations](#) section, with frequent

electrocardiography (with or without continuous ST-segment monitoring), repeat troponin testing and provocative testing if a repeat troponin assay is negative.

Low-risk patients may be discharged on upgraded medical therapy after an appropriate period of observation and assessment (see [Investigations](#) section). These patients (including those manifesting anginal symptoms for the first time within the previous month or with a change in the tempo of their angina) are considered unstable, as some will have atherothrombotic disease with a definite risk of progression to myocardial infarction. These patients should be treated with β -blockers and aspirin, and cardiac assessment should be obtained urgently.

Treatment of patients with NSTEMACS on the basis of risk is summarised in [Box 10](#).

10 Treatment strategies for patients with non-ST-segment-elevation acute coronary syndromes (NSTEMACS), based on risk stratification

Medical management of high-risk patients

Antiplatelet therapy: Early treatment should be initiated with aspirin⁸³⁻⁸⁶ (grade A recommendation) and clopidogrel (300 mg loading dose and 75 mg daily)⁸⁷ (grade B recommendation), with the following considerations:

- § Clopidogrel should be avoided in patients likely to require emergency coronary bypass surgery (those with severe widespread ST-segment depression or haemodynamic instability);
- § If possible, clopidogrel should be discontinued 5 days before coronary bypass surgery;
- § Clopidogrel should be given (preferably more than 6 hours) before planned percutaneous coronary intervention (level I evidence, grade A recommendation),^{21,22} but may be omitted if coronary angiography is planned immediately;
- § If relevant, warfarin therapy should be discontinued and heparin given along with the recommended antiplatelet therapy (grade D recommendation).

Antithrombin therapy: Unfractionated heparin or subcutaneous enoxaparin should be given until angiography or for 48–72 hours (level I evidence, grade A recommendation).⁸⁸⁻⁹⁰ The enoxaparin dose must be reduced in patients with impaired renal function.

GP IIb/IIIa inhibitors: Intravenous tirofiban or eptifibatid is particularly recommended in high-risk patients in whom an invasive strategy is planned (level I evidence, grade A

recommendation). Administration should commence as soon as a high-risk feature is identified.^{91,92} Intravenous tirofiban or eptifibatid are also recommended if patients continue to have ischaemia while receiving enoxaparin or unfractionated heparin (level III evidence, grade B recommendation).

Concomitant tirofiban is particularly beneficial and recommended in patients with diabetes (level I evidence, grade A recommendation).

Other: A β -blocker should be given unless contraindicated (level I evidence, grade A recommendation).⁹³ Intravenous glyceryl trinitrate can be given for refractory pain (grade D recommendation).

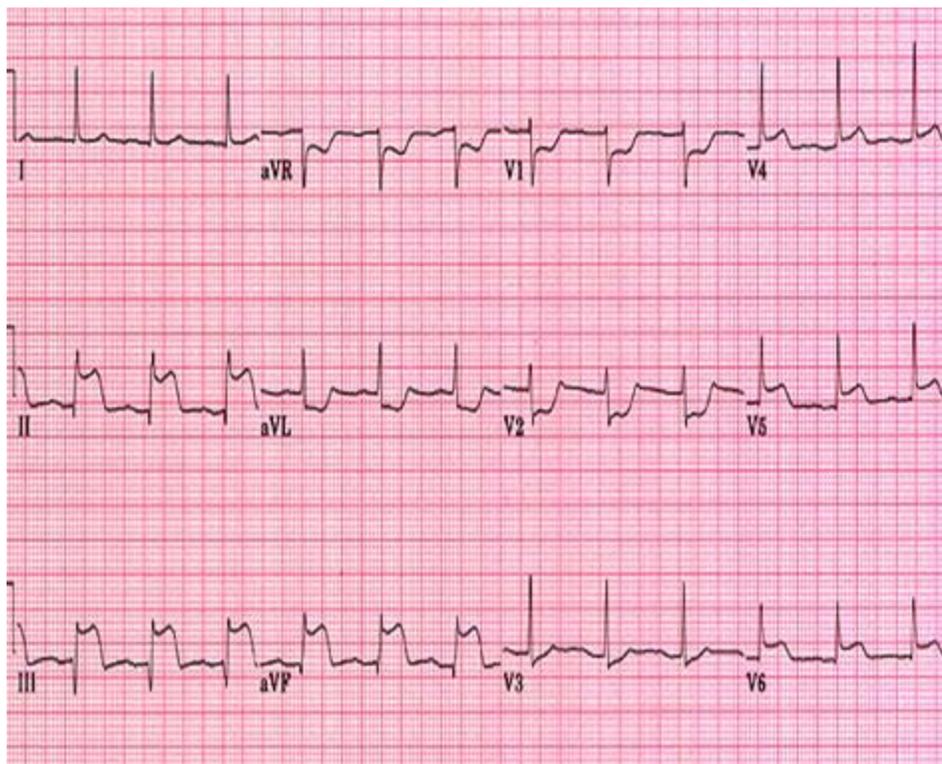

In patients with diabetes, good glycaemic control should be targeted in hospital and after discharge. This may require considering an insulin-based regimen in hospital and for 3 or more months after discharge in selected patients (grade B recommendation).⁹⁴

Early medical management of NSTEMACS is summarised in [Box 11](#).

Early coronary angiography (within 48 hours) and revascularisation is recommended in patients with NSTEMACS and high-risk features (grade A recommendation), except in patients with severe comorbidities. In addition to the features listed in [Box 8](#), pain or ischaemia refractory to medical therapy and high-risk features on early exercise testing can also identify patients suitable for early invasive therapy.

A risk score devised by the TIMI (Thrombolysis In Myocardial Infarction) study group⁹⁵ has been validated as a valuable measure of early risk in NSTEMACS.^{66,91,96} It uses a seven-point score derived from:

- § age greater than or equal to 65 years;
- § more than three coronary risk factors;
- § prior angiographic coronary obstruction;
- § ST-segment deviation;
- § more than two angina events within 24 hours;
- § use of aspirin within 7 days; and
- § elevated levels of cardiac biomarkers.

§

§

Fig. ECG with MI

Additional risk stratification on the basis of a TIMI risk score of greater than three for deciding which patients might be transferred for early invasive management may be considered where funding is constrained, but it must be remembered that 14-day cardiac event rates are still considerable, even for those with low scores (see [Box 12](#)). Appropriate patients should be transferred for angiography within 48 hours, and aggressive medical therapy with initial stabilisation of symptoms does not mitigate the need for early angiography.

12 TIMI risk scores and 14-day cardiac event rates

14-day adverse cardiac event
TIMI score rate95

0/1	4.7%
2	8.3%
3	13.2%
4	19.9%
5	26.2%
6/7	40.9%

TIMI = Thrombolysis In Myocardial Infarction study group.

§ All patients with NSTEMI should have their risk stratified to direct management decisions.

§ All patients with NSTEMI should be given aspirin unless contraindicated.

§ Patients with high-risk NSTEMI should be treated with aggressive medical management (including aspirin and clopidogrel, unfractionated heparin or subcutaneous enoxaparin, intravenous tirofiban or eptifibatid, and a β -blocker), and arrangements should be made for coronary angiography and revascularisation, except in those with severe comorbidities.

§ Patients with intermediate-risk NSTEMI should undergo an accelerated diagnostic evaluation and further assessment to allow reclassification into low-risk or high-risk categories.

§ Patients with low-risk NSTEMI, after an appropriate period of observation and assessment, may be discharged on upgraded medical therapy for urgent outpatient cardiac follow-up.

Long-term management after control of myocardial ischaemia

§ Before discharge of patients who have had an ACS, therapy with an appropriate medication regimen should be initiated, including antiplatelet agent(s), β -blocker, angiotensin-converting enzyme inhibitor, statin and other therapies as appropriate.

§ Implantable cardiac defibrillators should be considered in some patients who, despite optimal medical therapy, have persistently depressed left ventricular function more than 6 weeks after STEMI.

§ Patients should be given advice on lifestyle changes that will reduce the risk of further coronary heart disease events, including smoking cessation, good nutrition, moderate alcohol intake, regular physical activity and weight management, as appropriate.

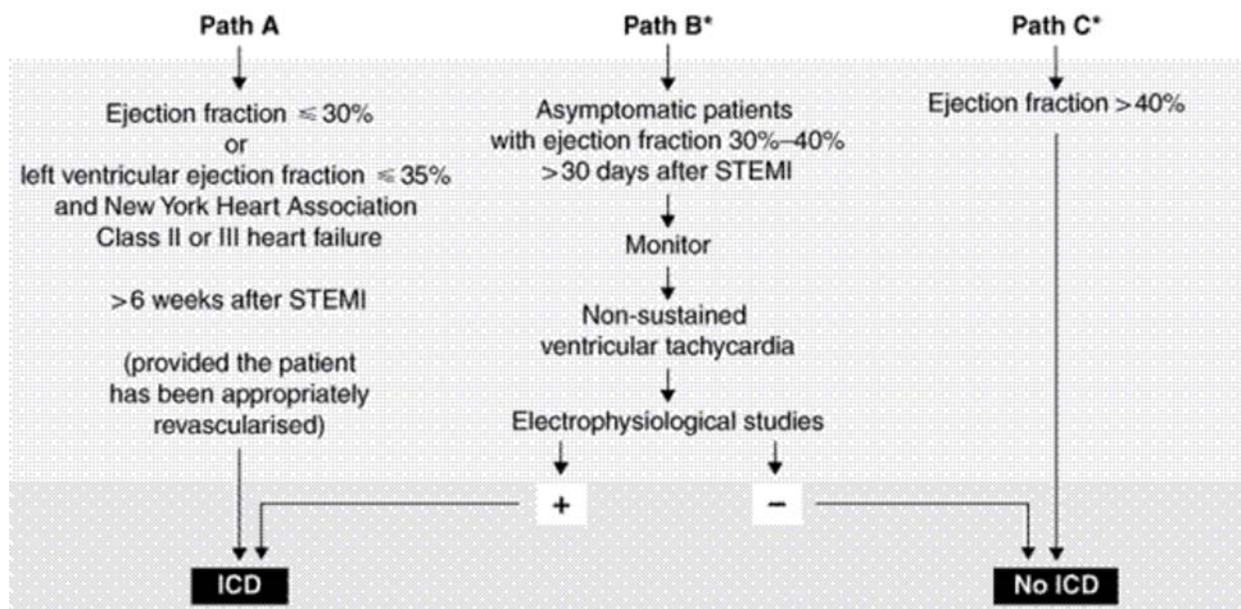

§ All patients should have access, and be actively referred, to comprehensive ongoing prevention and cardiac rehabilitation services.

§ All patients should be provided with a written action plan for chest pain.

§ Depression and coronary heart disease frequently coexist, and in patients with heart disease, depression, social isolation and lack of social support are more likely to lead to poorer outcomes. All patients with coronary heart disease should be assessed for depression and level of social support.

Appendix: Implantable cardiac defibrillator (ICD) implantation after ST-segment-

elevation myocardial infarction (STEMI): proposed management algorithm^{104,105}

This algorithm is for suggested management in an area which is still evolving. There may be considerable resource issues that will need to be explored, and cost-effectiveness data are currently lacking. Other factors such as comorbidities and conditions that significantly shorten life expectancy and reduce quality of life should be considered before ICD implantation. The evidence for benefit is strongest in patients with a left-ventricular ejection fraction $\leq 30\%$ and New York Heart Association Class II or III heart failure.

* Patients with sustained ventricular tachyarrhythmias or unexplained syncope after STEMI and an ejection fraction $> 35\%$ should also be considered for electrophysiological evaluation.

Overview of keypoints

Acute coronary syndrome (ACS) refers to a group of clinical conditions caused by myocardial ischemia including unstable angina pectoris (UA), non-ST-segment elevation myocardial infarction (NSTEMI), and ST-segment elevation myocardial infarction (STEMI) (Fig. 1).

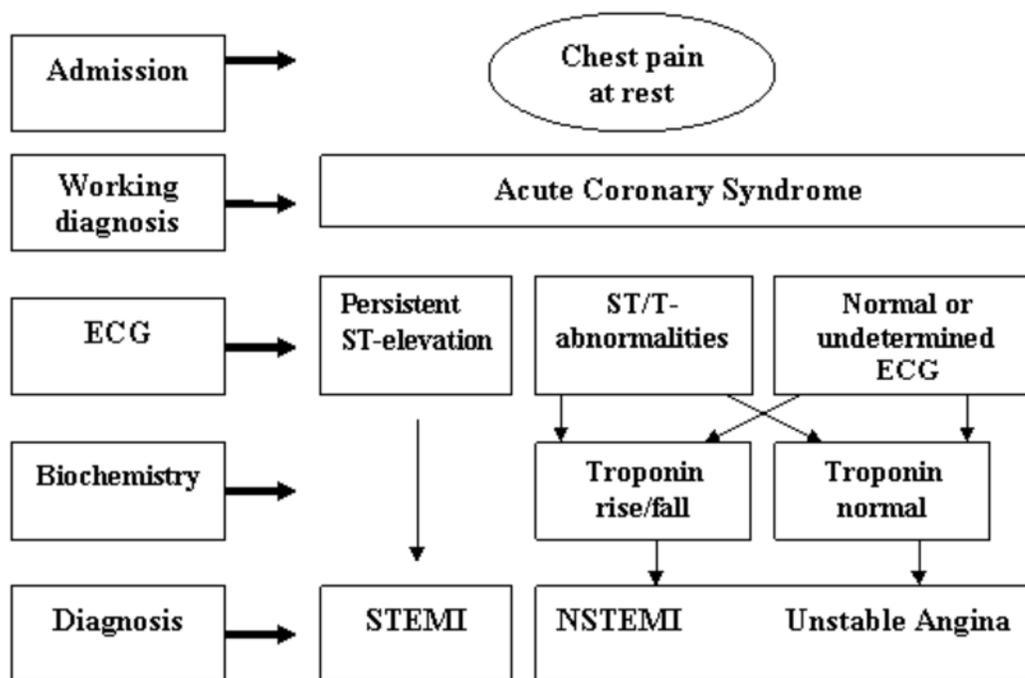

Figure 1. The spectrum of acute coronary syndrome.

ECG = electrocardiogram; NSTEMI = non-ST-elevation myocardial infarction; STEMI = ST-elevation myocardial infarction

From Hamm et al. *Eur Heart J* 2011;32:2999-3054.

Definition and terminology

Patients presenting with acute chest pain and persistent (>20 min.) ST-elevation on electrocardiogram (ECG) will have the working diagnosis of ST-elevation ACS. Most of these patients will ultimately develop STEMI and progress to Q wave myocardial infarction (MI). Patients with acute chest pain, but without persistent ST-segment elevation (presenting with persistent or transient ST depression or T-wave inversion, flat T waves, pseudo-normalization of T waves or normal ECG) will have the working diagnosis of non-ST-elevation ACS. On the basis of troponin measurements patients with non-ST-elevation ACS will be further qualified as having NSTEMI or UA.

The distinction between non-ST segment elevation ACS and ST-segment elevation ACS is clinically important because rapid recanalization therapy is critical for improving the outcome in ST elevation ACS/STEMI, but is less urgent in non-ST-segment elevation ACS.

MI is defined pathologically as myocardial cell death due to prolonged ischemia. In the clinical setting, these conditions are met when the following criteria are present: detection of a rise and/or fall of cardiac biomarkers with at least one value above the 99th percentile of the upper reference limit (URL) together with evidence of myocardial ischemia as recognized by at least one of the following:

- symptoms of ischemia;
- ECG changes of new ischemia (ST-elevation or depression) or development of pathologic Q waves; or
- imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.

Pathophysiology

Acute coronary syndrome represents a life-threatening manifestation of atherosclerosis. ACS most frequently develops as a result of plaque rupture or erosion with overlying thrombosis. A thin fibrous cap is more likely to rupture than a thick one. Factors such as the lipid and tissue factor content of the plaque, the severity of the plaque rupture, the degree of inflammation at the site, the blood flow in the area, and the patient's antithrombotic and prothrombotic balance are important in determining whether a given plaque rupture will result in ACS.

Less frequent pathophysiological causes of ACS include dynamic obstruction due to coronary vasospasm as in Prinzmetal angina or in cocaine use, coronary dissection, secondary UA in patients with fever, thyrotoxicosis, severe anemia, hypoxemia or hypotension.

Clinical presentation

The typical clinical presentation of ACS is prolonged (>20 min.) retrosternal pressure or heaviness radiating to the left arm, neck or jaw. These complaints may be accompanied by other symptoms such as diaphoresis, nausea, abdominal pain and syncope (Table 1).

Table 1. Likelihood that signs and symptoms represent an ACS

Feature	Likelihood		
	High	Intermediate	Low
	Any of the following:	Absence of high-likelihood features and presence of any of the following:	Absence of high- or intermediate-likelihood features and presence of any of the following:
History	- Chest or left arm pain reproducing previously documented angina; - known history of CAD, including MI	- Chest or left arm pain or discomfort; - age > 70 years; - male gender; - diabetes mellitus	- Probable ischemic symptoms in absence of any of the intermediate-likelihood characteristics; - recent cocaine use
Examination	Transient MR murmur, hypotension, diaphoresis, pulmonary edema, râles	Extracardiac vascular disease	Chest discomfort reproduced by palpation
ECG	New, or presumably new ST-segment elevation ($\geq 0,1$ mV) or T wave inversion ($\geq 0,2$ mV) in multiple precordial leads	- Fixed Q-waves; - ST-segment depression 0,05-0,1 mV or T wave inversion $> 0,1$ mV	- T wave flattening or inversion $< 0,1$ mV in leads with dominant R waves; - normal ECG
Cardiac markers	Elevated cardiac TnI, TnT, or CK-MB	Normal	Normal

CAD = coronary artery disease; ECG = electrocardiogram; MI = myocardial infarction; MR = mitral regurgitation; Tn = troponin; CK-MB = creatine kinase MB isoenzyme
 From Sabatine M.S., Cannon C.P. Approach to patient with chest pain. In: Bonow R.O., Mann D.L., Zipes D.P., Libby P., eds. *Braunwald's Heart Disease: a textbook of cardiovascular medicine*. 9th ed. Philadelphia, Pa: Saunders Elsevier; 2011:chap. 53.

Atypical presentations include epigastric pain, neck, jaw, ear, arm discomfort. Some patients, especially those who are elderly or who have diabetes, present with no pain, complaining only of episodic shortness of breath, severe weakness, light-headedness, diaphoresis, or nausea and vomiting. Elderly persons may also present only with altered mental status (Table 2).

Table 2. Killip Classification in acute MI

Class	Definition	Mortality (%)
I	No congestive heart failure signs	6
II	+S ₃ and/or basilar rales	17
III	Pulmonary edema	30-40
IV	Cardiogenic shock	60-80
From Killip T. 3rd, Kimball J.T. <i>Am J Cardiol</i> 1967;20:457		

The physical examination is frequently normal. Worrisome findings include hypotension, new jugular venous distension, pulmonary edema, or a new systolic murmur. An important goal of the physical examination is to exclude non-cardiac causes of chest pain (e.g., pulmonary embolism, aortic dissection, pericarditis, valvular heart disease, pneumothorax, pneumonia, or pleural effusion). The Killip classification system (Table 2) and TIMI risk score (Table 3) are helpful in using physical exam findings to assess a patient's 30-day mortality.

Table 3. TIMI risk score for ST-elevation MI

Risk factor (weight)	Risk score/30-day mortality (%)
Age 65-74 years (2 points)	0 (0.8)
Age >75 years (3 points)	1 (1.6)
Diabetes mellitus/hypertension or angina (1 point)	2 (2.2)
Systolic BP <100 mmHg (3 points)	3 (4.4)
Heart rate >100 bpm (2 points)	4 (7.3)
Killip class II-IV (2 points)	5 (12.4)
Weight <67 kg (1 point)	6 (16.1)
Anterior ST-elevation or left bundle branch block	7 (23.4)
Time to Rx >4 hours (1 point)	8 (26.8)
Risk score = total points (0-14)	>8 (35.9)
From Morrow D.A., Antman E.M., Charlesworth A, et al. <i>Circulation</i> 2000;102:2031-2037	

Diagnosis

The diagnosis is based on a combination of history, ECG, and biochemical markers of cardiac injury.

ECG. ST segment elevation of ≥ 2 mm in two adjacent chest leads and of ≥ 1 mm in adjacent limb leads suggests of STEMI. Other associated findings may include tall peaked T waves and reciprocal ST-segment depression. Pathological Q waves indicating significant transmural myocardial damage should be $\geq 25\%$ of the R wave, ≥ 0.04 sec in duration. The infarction site can be localized from ECG changes (Table 4).

Patients with UA/NSTEMI may have a normal ECG or may have changes ranging from new T wave inversions, ST segment depression, or normalization of previously inverted T waves (pseudonormalization).

Table 4. Localization of infarcts from ECG changes

Infarct localization	ECG signs	Coronary artery
Anterior	ST elevation and/or Q waves in V ₁ -V ₄ /V ₅	LAD
Antero-septal	ST elevation and/or Q waves in V ₁ -V ₃	LAD
Antero-lateral	ST elevation and/or Q waves in V ₁ -V ₆ and in I and aVL	Proximal LAD
Lateral	ST elevation and/or Q waves in V ₅ -V ₆ and T wave inversion/ST elevation/Q waves in I and aVL	Diagonal branch of LAD or proximal LCx
Inferolateral	ST elevation and/or Q waves in II, III, aVF, and V ₅ -V ₆ (sometimes in I and aVL)	RCA or LCx, if left dominant
Inferior	ST elevation and/or Q waves in II, III, aVF	RCA or LCx, if left dominant
True posterior	Tall R waves in V ₁ -V ₂ with ST depression in V ₁ -V ₃ *. Usually occurs in conjunction with inferior or lateral infarct	RCA or obtuse marginal branch of LCx
RV infarction	ST elevation in the right precordial leads V _{3R} -V _{4R} . Usually found in conjunction with inferior or lateral infarction.	RCA
LAD = left anterior descending artery; LCx = left circumflex artery; RCA = right coronary artery; RV = right ventricular		
*The "mirror-test" is useful here to demonstrate that ST depressions are actually ST elevations of the posterior wall, and tall R waves are actually posterior Q waves.		

Biochemical markers of cardiac injury

Creatine kinase (CK). Levels twice the upper limit of normal are taken as being abnormal. Serum levels rise within 4-8 hours post-STEMI and fall to normal within 3-4 days. CK-MB isoenzyme is more specific for myocardial disease.

Cardiac troponins (TnT, TnI). Serum levels start to rise by 3 hours post-MI, and elevation may persist up to 7-14 days. Troponins can also be elevated in non-ischaemic myocardial

damage such as myocarditis, cardiomyopathy, pericarditis.

Treatment

Stabilizing measures are similar in all patients with ACS. Patients should be placed in an environment with continuous ECG monitoring and defibrillation capacity. Patients should receive aspirin 300 mg orally, analgesia, secure i.v. access and oxygen. Intramuscular injections and not be given as they cause rise in total CK and risk of bleeding with thrombolysis/anticoagulation.

STEMI

Patients presenting with ST-segment elevation or left bundle branch block on ECG benefit significantly from immediate reperfusion and are treated as one group under the term STEMI.

1. Relief of pain, breathlessness and anxiety.

Titrated **i.v. opioids** (e.g. morphine) are the analgesics most commonly used in this context. Repeated doses may be necessary. Side-effects include nausea and vomiting, hypotension with bradycardia, and respiratory depression. Anti-emetics (e.g., metoclopramide 10 mg i.v.) may be administered concurrently with opioids to minimize nausea.

Nitrates (sublingual or intravenous) may lessen pain and can be given, providing the patient is not hypotensive.

Oxygen (at 2-5 L/min for at least 2-3 hours by mask or nasal prongs) should be administered to those who are breathless, hypoxic ($\text{SaO}_2 < 95\%$), or who have heart failure. Non-invasive monitoring of blood oxygen saturation greatly helps when deciding on the need to administer oxygen or ventilatory support.

Anxiety is a natural response to the pain and the circumstances surrounding a heart attack. Reassurance of patients and those closely associated with them is of great importance. If the patient becomes excessively disturbed, it may be appropriate to administer a tranquillizer, but opioids are frequently all that is required.

2. Correction of electrolytes. Potassium and magnesium should be supplemented as both low potassium and magnesium may be arrhythmogenic.

3. Strategies to limit infarct size (beta-blockade, ACE-inhibitors, reperfusion).

Beta-blockade. Metoprolol i.v. 1-2 mg at a time repeated at 1-2 min. intervals to a maximum dose of 15-20 mg under continuous ECG and BP monitoring. Aim at a pulse rate of 60 bpm and systolic BP 100-110 mmHg.

ACE-inhibitors. After receiving aspirin, beta-blockade (if appropriate), and reperfusion, patients with STEMI should receive an ACE-inhibitor within the first 24 hours of presentation.

Reperfusion.

Primary percutaneous coronary intervention (PCI) is the current gold standard reperfusion strategy for the treatment of STEMI and demonstrates superior outcome in comparison with thrombolysis. In settings where primary PCI cannot be performed within 120 min of first medical contact by an experienced team, thrombolysis should be considered, particularly if it

can be given pre-hospital (e.g. in the ambulance) and within the first 120 min of symptom onset. As an adjunct to thrombolysis, rescue PCI should be reserved for patients who remain symptomatic post thrombolysis or develop cardiogenic shock.

Thrombolysis (fibrinolysis). Fibrinolytic therapy (Table 5) is recommended within 12 h of symptom onset if primary PCI cannot be performed within 90 min of being able to administer fibrinolysis and within 120 min from first medical contact and there are no contraindications (Table 6). The later the patient presents (particularly after 6 h), the more consideration should be given to transfer for primary PCI (in preference to fibrinolytic therapy) as the efficacy and clinical benefit of fibrinolysis decrease over time, which, in later presentations, has the effect of increasing the acceptable time delay before transfer for primary PCI.

Table 5. Dose and administration of thrombolytic agents

Streptokinase (SK)	Give as 1.5 million units in 100 mL normal saline over 1 hour.
Recombinant tissue-type plasminogen activator (rt-PA, alteplase)	Give 15 mg bolus i.v., then 0.75 mg/kg over 30 min. (not to exceed 50 mg), then 0.5 mg/kg over 60 min (not to exceed 35 mg). This should be followed by i.v. heparin
Reteplase (r-PA)	Give two i.v. bolus of 10 units 30 minutes apart
Tenecteplase (TNK-tPA)	Give as injection over 10 seconds at 30-50 mg according to body weight (500-600 mcg/kg). Maximum dose is 50 mg
APSAC (anistreplase)	Give as i.v. bolus of 30 mg over 2-5 minutes

Streptokinase is the first-generation fibrinolytic agent which is an indirect plasminogen activator and therefore relatively nonspecific for fibrin. In comparative trials, it had the lowest rate of intracranial hemorrhage. streptokinase is antigenic and allergic reactions occur on 5 to 6 % of patients.

Alteplase represents a second-generation fibrinolytic. Of all current fibrinolytics, it has the shortest half-life (4 to 8 minutes) and therefore is administered as a bolus followed by an infusion over 90 minutes or longer.

Reteplase and tenecteplase are the third-generation fibrinolytics. They are the mutants of alteplase with a longer half-life and offer the convenience of bolus administration.

Table 6. Contraindications for use of thrombolytic agents in acute MI

<p>Absolute contraindications</p> <ul style="list-style-type: none"> - previous hemorrhagic stroke at any time; any other cerebrovascular events within 1 year; - known intracranial neoplasm; - active internal bleeding (not including menses); - suspected aortic dissection
<p>Relative contraindications</p> <ul style="list-style-type: none"> - severe, uncontrolled hypertension (BP>180/110 mmHg); - history of cerebrovascular accident or known intracerebral pathologic condition not covered in contraindications; - current use of anticoagulants in therapeutic doses (INR>2); known bleeding diathesis;

- recent trauma (within 2-4 weeks), prolonged CPR (>10 min.), or major surgery (within 3 weeks);
- noncompressible vascular punctures;
- recent internal bleeding (within 2-4 weeks);
- pregnancy;
- active peptic ulcer disease;
- for streptokinase or anistreplase: prior exposure to either agent or prior allergic reaction

4. Additional therapies

Heparin. Unfractionated heparin (UFH) should be used routinely with rt-PA and its derivatives for 24-48 hours for a target aPTT (activated partial thromboplastin time) 50-70 sec or 1.5-2.0 times control (to be monitored at 3, 6, 12 and 24 h). Low molecular weight heparin (LMWH) can be used as an alternative to UFH.

Clopidogrel (loading dose of 600 mg orally followed by a maintenance dose of 75 mg/day) should be administered to all patients undergoing primary PCI. If coronary stents are used, patients should remain on clopidogrel for at least 1 month in bare-metal stents and 12 months in coated stents.

Glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatide, tirofiban) are recommended routinely in the context of STEMI treated with primary PCI.

NSTEMI/UA

Timing of angiography and revascularization should be based on patient risk profile. The GRACE risk score provides the most accurate stratification of risk both on admission and at discharge due to its good discriminative power. However, the complexity of the estimation requires the use of computer or personal digital assistant software for risk calculations, which can also be performed online:

Cardiac catheterization followed by revascularization has been shown to prevent recurrent ischaemia and/or improve short- and long-term outcomes. Several risk factors (troponin elevation, diabetes, ST-segment depression, renal insufficiency, etc.) have been identified to predict the long-term benefit of an invasive strategy. Depending on the acuteness of risk, the timing of angiography can be tailored, according to four categories:

- **invasive** (<72 h);
- **urgent invasive** (<120 min);
- **early invasive** (<24 h);
- primarily **conservative**.

Urgent invasive strategy (<120 min after first medical contact)

This should be undertaken for **very high risk** patients. These patients are characterized by:

- refractory angina (indicating evolving MI without ST abnormalities);

- recurrent angina despite intense antianginal treatment, associated with ST depression (2 mm) or deep negative T waves;
- clinical symptoms of heart failure or haemodynamic instability ('shock');
- life-threatening arrhythmias (ventricular fibrillation or ventricular tachycardia).

Early invasive strategy (<24 h after first medical contact)

Most patients initially respond to the antianginal treatment, but are at increased risk and need angiography followed by revascularization. High risk patients as identified by a GRACE risk score >140 and/or the presence of at least one primary high risk criterion should undergo invasive evaluation within 24 h. High risk criteria include:

- relevant rise or fall in troponin;
- dynamic ST- or T-wave changes (symptomatic or silent);
- diabetes mellitus;
- renal insufficiency (eGFR < 60 mL/min/1.73 m²);
- early postinfarction angina;
- recent PCI;
- prior CABG;
- intermediate to high GRACE risk score

Invasive strategy (<72 h after first medical contact)

In lower risk subsets with a GRACE risk score of <140 but with at least one high risk criterion, the invasive evaluation can be delayed without increased risk but should be performed during the same hospital stay, preferably within 72 h of admission. Thus, such patients should undergo elective invasive evaluation at the first opportunity depending on the local circumstances.

Conservative strategy (no or elective angiography)

Patients that fulfill all of the following criteria may be regarded as low risk and should not routinely be submitted to early invasive evaluation:

- No recurrence of chest pain.
- No signs of heart failure.
- No abnormalities in the initial ECG or a second ECG (at 6–9 h).
- No rise in troponin level (at arrival and at 6–9 h).
- No inducible ischaemia.

In other low risk patients without recurrent symptoms a non-invasive assessment of inducible ischaemia should be performed before hospital discharge. Coronary angiography should be performed if the results are positive for reversible ischaemia.

Medical management

All patients should be treated with adequate analgesia, i.v. nitrates, beta-blockers and statins (if not contraindicated). Other agents can also be added depending on the clinical picture.

1. Anti-ischaemic agents

Anti-ischaemic drugs either decrease myocardial oxygen demand (by decreasing heart rate, lowering blood pressure, reducing preload, or reducing myocardial contractility) or increase myocardial oxygen supply (by inducing coronary vasodilatation).

Beta-blockers competitively inhibit the myocardial effects of circulating catecholamines and reduce myocardial oxygen consumption by lowering heart rate, blood pressure, and contractility. Beta-blockers should be started on presentation, initially using a short-acting agent (e.g., metoprolol 12.5-50 mg t.i.d) which, if tolerated, may be converted to a longer-acting agent. Aim for HR of \approx 50-60 bpm.

Nitrates

E.g., glyceryl trinitrate (GTN) infusion (50 mg in 50 mL 1 M saline at 1-10 mL/h). Tolerance to continuous infusion develops within 24 hours, therefore the lowest efficacious dose should be used.

The use of nitrates in unstable angina is largely based on pathophysiological considerations and clinical experience. The therapeutic benefits of nitrates and similar drug classes such as sydnonimines are related to their effects on the peripheral and coronary circulation. The major therapeutic benefit is probably related to the venodilator effects that lead to a decrease in myocardial preload and LV end-diastolic volume, resulting in a decrease in myocardial oxygen consumption. In addition, nitrates dilate normal as well as atherosclerotic coronary arteries and increase coronary collateral flow.

Nitrates should not be given to patients on phosphodiesterase-5 inhibitors (sildenafil, vardenafil, or tadalafil) because of the risk of profound vasodilatation and critical blood pressure drop.

Calcium channel blockers

Calcium channel blockers are vasodilating drugs. In addition, some have direct effects on atrioventricular conduction and heart rate. There are three subclasses of calcium blockers, which are chemically distinct and have different pharmacological effects: dihydropyridines (such as nifedipine), benzothiazepines (such as diltiazem), and phenylethylamines (such as verapamil). The agents in each subclass vary in the degree to which they cause vasodilatation, decrease myocardial contractility, and delay atrioventricular conduction. Atrioventricular block may be induced by non-dihydropyridines. Nifedipine and amlodipine produce the most marked

peripheral arterial vasodilatation, whereas diltiazem has the least vasodilatory effect. All subclasses cause similar coronary vasodilatation. Therefore, calcium channel blockers are the preferred drugs in vasospastic angina. Diltiazem and verapamil show similar efficacy in relieving symptoms and appear equivalent to beta-blockers.

E.g., diltiazem 60-360 mg orally, verapamil 40-120 mg orally t.i.d. Amlodipine/felodipine 5-10 mg PO can also be used.

Other antianginal drugs

Nicorandil, a potassium channel opener, reduced the rate of the primary composite endpoint in patients with stable angina, but was never tested in ACS patients. Ivabradine selectively inhibits the primary pacemaker current in the sinus node and may be used in selected patients with β -blocker contraindications.

Ranolazine exerts antianginal effects by inhibiting the late sodium current. It was not effective in reducing major cardiovascular events in a clinical trial, but reduced the rate of recurrent ischaemia.

Statins (e.g., atorvastatin 80 mg qd) have been shown to reduce mortality and recurrent MI in the acute setting.

2. Antiplatelet agents

Platelet activation and subsequent aggregation play a dominant role in the propagation of arterial thrombosis and consequently are the key therapeutic targets in the management of ACS. Antiplatelet therapy should be instituted as early as possible when the diagnosis of NSTEMI-ACS is made in order to reduce the risk of both acute ischaemic complications and recurrent atherothrombotic events. Platelets can be inhibited by three classes of drugs, each of which has a distinct mechanism of action.

Aspirin (acetylsalicylic acid) targets cyclo-oxygenase (COX-1), inhibiting thromboxane A_2 formation and inducing a functional permanent inhibition in platelets. However, additional complementary platelet aggregation pathways must be inhibited to ensure effective treatment and prevention of coronary thrombosis. ADP binding to the platelet P2Y₁₂ receptor plays an important role in platelet activation and aggregation, amplifying the initial platelet response to vascular damage. The antagonists of the P2Y₁₂ receptor are major therapeutic tools in ACS.

The prodrug thienopyridines such as clopidogrel and prasugrel are actively biotransformed into molecules that bind irreversibly to the P2Y₁₂ receptor. A new class of drug is the pyrimidine derivative ticagrelor, which without biotransformation binds reversibly to the P2Y₁₂ receptor, antagonizing ADP signalling and platelet activation. I.v. GP IIb/IIIa receptor antagonists (abciximab, eptifibatid, and tirofiban) target the final common pathway of platelet aggregation.

Aspirin

A daily maintenance dose of 75–100 mg should be continued indefinitely. It has the same efficacy as higher doses and carries a lower risk of gastrointestinal intolerance.

P2Y₁₂ receptor inhibitors include thienopyridines (clopidogrel, prasugrel) and triazolopyrimidine (ticagrelor). Of note, ticlopidine was the first thienopyridine investigated in ACS, but was replaced by clopidogrel because of side effects. Today ticlopidine may still be used in patients who are allergic to clopidogrel, although cross-reactions are possible. A loading dose of **clopidogrel** 300-600 mg followed by 75 mg daily maintenance for 9–12 months in addition to aspirin should be given to all patients with NSTEMI-ACS. The 600 mg loading dose of clopidogrel has a more rapid onset of action and more potent inhibitory effect than the 300 mg dose. Clopidogrel should be withheld for 5-7 days in patients requiring CABG to reduce hemorrhagic complications.

Alternative regimens:

prasugrel loading dose of 60 mg followed by a maintenance dose 10 mg daily

ticagrelor loading dose of 180 mg followed by a maintenance dose 90 mg b.i.d.

Glycoprotein IIb/IIIa receptor inhibitors

The three GP IIb/IIIa receptor inhibitors approved for clinical use are i.v. agents belonging to different classes: abciximab is a monoclonal antibody fragment; eptifibatid is a cyclic peptide; and tirofiban is a peptidomimetic molecule.

these agents should be used in conjunction with aspirin, clopidogrel and LMWH or UFH.

Eptifibatid or tirofiban should be used in high-risk patients with ongoing ischemia and elevated troponins in whom invasive strategy is not planned/available (<24 hours). In patients with an early invasive strategy, all GP IIb/IIIa receptor inhibitors can be used. Infusion is generally continued for 12 hours post-PCI.

Administration regimens:

Abciximab (ReoPro) - bolus of 0.25 mg/kg i.v. over 1 minute followed by i.v. infusion 0.125 mcg/kg/min (maximum 10 mcg/min) for 12 hours;

Eptifibatid (Integrilin) - bolus 180 mcg/kg followed by i.v. infusion 2 mcg/kg/min;

Tirofiban (Aggrastat) - 400 ng/kg/min for 30 minutes followed by i.v. infusion 100 ng/kg/min.

3. Anticoagulants

Several anticoagulants, which act at different levels of the coagulation cascade, have been investigated or are under investigation in NSTEMI-ACS:

Indirect inhibitors of coagulation (need antithrombin for their full action)

Indirect thrombin inhibitors: UFH

LMWHs

Indirect factor Xa inhibitors: LMWHs

fondaparinux

Direct inhibitors of coagulation

Direct factor Xa inhibitors: apixaban, rivaroxaban, otamixaban

Direct thrombin inhibitors (DTIs): bivalirudin, dabigatran

All patients should be given a LMWH or fondaparinux or UFH.

LMWH should be used in conjunction with aspirin and clopidogrel and continued for 2-5 days after the last episode of pain and ischemic ECG changes.

E.g., enoxaparin 1 mg/kg bid (100 U/kg twice daily).

Fondaparinux is the only selective activated factor X (factor Xa) inhibitor available for clinical use. Fondaparinux is a synthetic pentasaccharide structurally similar to the antithrombin-binding sequence common to all forms of heparin. In ACS, a 2.5 mg fixed daily dose of fondaparinux is recommended.

UFH should be used as an alternative to LMWH and fondaparinux in conjunction with aspirin and clopidogrel. A weight-adjusted dose of UFH is recommended, at an initial bolus of 60–70 IU/kg with a maximum of 5000 IU, followed by an initial infusion of 12–15 IU/kg/h, to a maximum of 1000 IU/h. The therapeutic window is narrow, requiring frequent monitoring of aPTT, with an optimal target level of 50–75 s, corresponding to 1.5–2.5 times the upper limit of normal. At higher aPTT values, the risk of bleeding complications is increased, without further antithrombotic benefits.

In the PCI setting, UFH is given as an i.v. bolus either under activated clotting time (ACT) guidance (ACT in the range of 250–350 s, or 200–250 s if a GP IIb/IIIa receptor inhibitor is given) or in a weight-adjusted manner (usually 70–100 IU/kg, or 50–60 IU/kg in combination with a GP IIb/IIIa receptor inhibitors).

Bivalirudin plus a provisional GP IIb/IIIa receptor inhibitor showed similar efficacy to heparin/LMWHs plus systematic GP IIb/IIIa receptor inhibitors, while significantly lowering the risk of major haemorrhagic complications. However, no significant difference in short- or long-term outcomes was observed between these two anticoagulation strategies. Bivalirudin is currently approved for urgent and elective PCI at a dose of 0.75 mg/kg bolus followed by 1.75 mg/kg/h. In NSTEMI-ACS patients, bivalirudin is recommended at a dose of 0.1 mg/kg i.v. bolus followed by an infusion of 0.25 mg/kg/h until PCI. Bivalirudin plus provisional GP IIb/IIIa receptor inhibitors are recommended as an alternative to UFH plus GP IIb/IIIa receptor inhibitors in patients with an intended urgent or early invasive strategy, particularly in patients with a high risk of bleeding.

At discharge from hospital, the following measures are necessary:

1. **Aspirin:** continue life long;
2. **P2Y₁₂ inhibitor:** continue for 12 months (unless at high risk of bleeding);
3. **Beta-Blocker:** if LV function is depressed;
4. **ACE inhibitor/ARB:** if LV function is depressed. Consider for patients devoid of depressed LV function;
5. **Aldosterone antagonist/ eplerenone:** if depressed LV function (LVEF \leq 35%) and either diabetes or heart failure, without significant renal dysfunction;

6. **Statin:** titrate to achieve target LDL-C levels <1.8 mmol/L (<70 mg/dL)
7. **Lifestyle:** risk-factor counselling, referral to cardiac rehabilitation / secondary prevention programme.

Comatous states

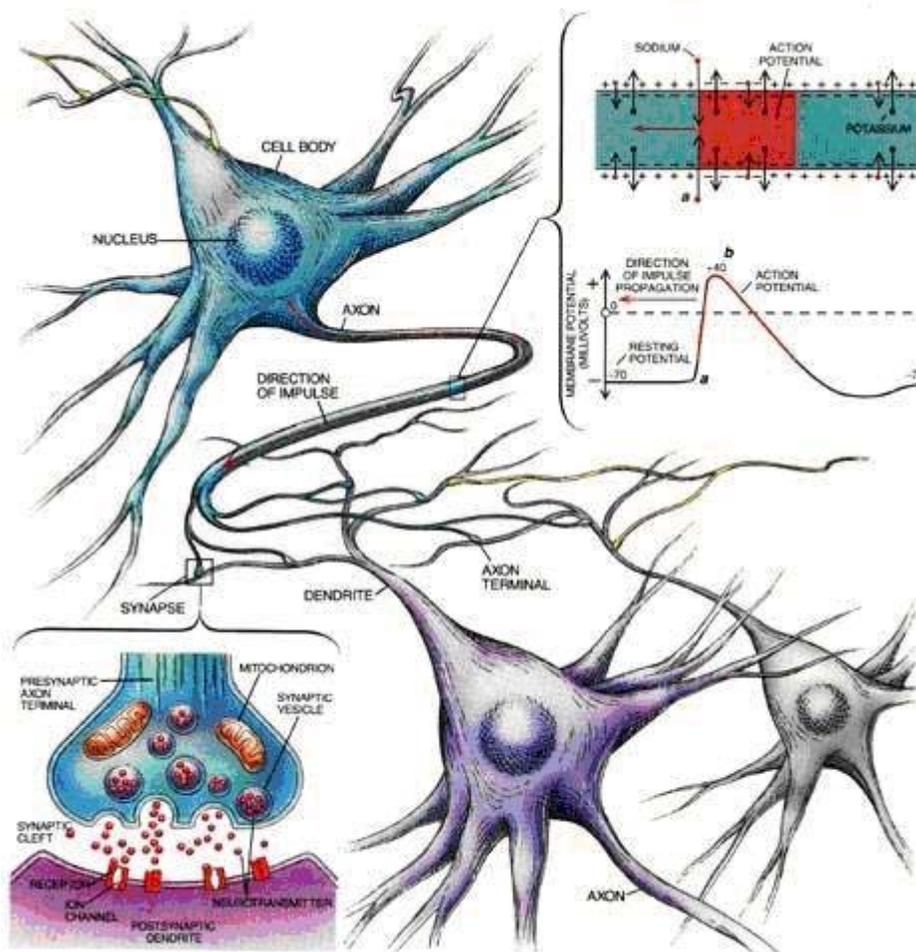

1 Anatomy and physiology of central nervous system.

Nervous system consists of two parts: central nervous system and peripheral nervous system.

The brain (central nervous system, higher vegetative centres and endocrine regulation centres) is located in the skull - reliable bony container, which protects it from the most dangerous environment factors.

As a central regulator of all body functions brain requires a very high level of metabolic processes. Its weight is just 2 % of the body weight (nearly 1500 grams), however it takes nearly 14-15% of circulating blood volume (700-800 ml) every minute. Brain consumes 20% of total oxygen, which gets to the organism every minute. However its main limitation factor is glucose, because it is the only source of energy for the brain (75 milligrams per minute or 100 grams per day).

home.iprimus.com.au

Thus, physiologically functions of the central nervous system depend on an adequate perfusion (oxygen and glucose supply) and adequate blood outflow (wastes transportation) from the cranial cavity.

Serious self-regulation system provides uninterrupted brain functioning and even during massive blood loss brain gets its amount of oxygen through the mechanism of blood flow centralization (of course this causes ischemic injury of visceral organs, but their affection evolution quite reasonably considered less harmful). There is also a mechanism which protects brain in case of hypoglycaemia: blood flow increases and thus increases amount of glucose getting to the nervous cells. On the other hand hyperventilation (hypocapnia) decreases blood flow and hypoventilation (hypercapnia) increases it to eliminate acid metabolites.

When brain tissue is much damaged and regulation fails, brain is not able to change its volume according to the needs. So when blood flow and outflow get into the imbalance the protective cranial “bone box” (the skull) actually becomes brain’s main enemy, because it can’t be extended. For example 5% increasing of blood volume (haematoma, tumour, overhydration, liquor hypertension, etc.) causes unconsciousness. Excessive blood flow brings liquor hyperproduction and this causes brain compression and results in brain tissue

edema and functional disorders.

Brain injuries, vascular disorders, cerebral oedema, increase of intracranial pressure, liquor circulation violations result in cellular hypoxia of central nervous system. Alerted level of consciousness is the first sign of cerebral hypoxia.

5.2 Classification, clinic and diagnostics of coma.

Coma is a complete depression of consciousness with lack of pain sensitivity and reflexes, general muscular relaxation and violated vital functions.

Classification of consciousness levels according to Bogolepow, 1982.

Conscious (normal)

Confused

Stuporous

Soporose

Comatose: moderate

deep

terminal

Each level has its own diagnostic criteria; you can find them in the table below.

Levels of consciousness	Main symptoms	General symptoms
Conscious	Alert, absolutely oriented to self, place and time patients.	Attention is active, speech is fluent, answers are correct and full, commands are obeyed, eyes are opened spontaneously.
Confused	Moderate somnolence or euphoria, partial disorientation with the place and time, but complete self orientation.	Thinking and attention are impaired. Verbal contact is slowed; questions should be repeated to receive answers. Commands are obeyed, however slowly, especially complex commands.
Stuporous	Deep somnolence, time and place disorientation, only simple commands are obeyed after awakening.	Most of the time patient sleeps, sometimes however there are periods of restlessness and agitation. Answers are curt. Defensive reaction to pain stimuli is maintained. Pelvic organs control is deficient.
Soporose	Pathologic somnolence; time, space and self disorientation.	Opens eyes in response to painful stimuli, localizes painful stimuli; reflexes of cerebral nerves and vital functions are preserved.
Moderate comatose	Unconscious	No reaction to external stimuli. To painful stimuli answers with withdrawal. Corneal and pupillar reflexes are overactive, abdominal

		reflexes are reduced. There are pathologic plantar reflexes. Pelvic organs control is violated. Vital functions are preserved.
Deep comatose	Unconscious	Extension to painful stimuli. Skin, tendon, corneal and pupillar reflexes are reduced or absent. Skeletal muscles are rigid or hypotonic. There are respiratory and cardiac disorders.
Deepest comatose	Unconscious	Areflexia, bilateral fixed midriasis, muscle atony; great violations of vital functions. Blood pressure less than 60 mmHg.

Classification of coma according to etiology and pathogenesis.

1. Coma of central genesis (epileptic, traumatic, apoplectic).
2. Coma caused by visceral organs dysfunctions and endocrine glands disorders (diabetic, hypoglycaemic, thyrotoxic, myxedemic, hypopituitary, hypocorticoid, hepatic, uremic, hypochloremic, anaemic, alimentary-distrophic).
3. Infectious coma (in case of pneumonia, malaria, neuronal infections, etc.).
4. Acute toxic coma (poisonings with alcohol and its surrogates, medicinal poisonings, carbon monoxide poisonings).
5. Coma caused by physical factors (caused by electric injury, hypothermic and hyperthermia coma, radiation coma, etc.).

Sometimes it is very hard to find the reason of the coma, so detailed anamnesis

(interview relatives and witnesses) and clinical observations are very important.

First of all ask about the duration of unconsciousness and was it lost suddenly or there were other levels of altered consciousness. Ask about the events prior to incident: did the patient fell and was there a chance of head injury? Did he have fever, flu or jaundice? Are there any sings of chronic diseases like diabetes, epilepsy, hypertonic disease? Have the patient ever suffered from similar unconsciousness episodes? Were there any suicide attempts? If the comatose condition was not sudden, have the patient complained of vomiting, convulsions? Pay attention to the personal things of the patient: you can find medical documents, medicine packages, diabetic bracelets or necklaces, etc.

If the anamnesis failed to reveal the coma etiology, concentrate on objective symptoms.

Skin colour: extreme paleness can be a sign of great blood loss, circulatory collapse, blood diseases. Cyanosis is a symptom of hypercapnic coma caused by respiratory failure or asphyxia (hanging, drowning, convulsions). Hyperaemic face allows you to think about atropine and carbon monoxide poisonings, hyperglycaemic coma or infectious disease.

Head position: tilted back head is a sign of meningitis, tetanus, hysteria; head turned aside can be the symptom of stroke.

Pathological types of breathing are also helpful in coma diagnostics: Cheyne-Stokes breathing (periods of apnoea, which are followed with chaotic frequent breathing) and Biot's breathing (periods of apnoea which are followed with breathing of equal amplitude) show deep affection of central nervous system. Kussmaul breathing (deep and laboured) proves accumulation of acid metabolites (metabolic acidosis) of exogenous (in case of poisonings) or endogenous (diabetic ketoacidosis) nature. Fever and rapid deep breathing are probable signs of infectious coma. Remember that per each excess body temperature degree there are 5-7 excess breathes and 10 excess heart beats.

Generally when you are coming to the patient with consciousness disorders try to do this from the side of patient's head (nape): this way you can easily improve airways patency if necessary (thrust the jaw forward for example) and avoid accidental injuries from the patient if his moves are uncontrolled.

You can always identify simulation or hysteric coma by opening the eyes of the patient: in case of simulating conscious patients or hysteric patients you will feel the resistance of the eyelids. Unconscious patients never resist when you try to open their eyes.

Pressing the eyeballs toy can evaluate their tone: "soft" eyeballs with decreased tone are the symptom of hypovolemia (bleeding, dehydration) or shock condition. However they can also be part of hyperglycaemic coma clinic.

The depth of coma is assessed with the reflexes reduction. If patient reacts to the

external stimuli - it's a moderate coma. If corneal reflexes are preserved with depressed other reflexes – it's a deep coma. Lack of photoreaction is a symptom of terminal coma.

Pupil's diameter varies: pupils are narrowed in case of sleeping pills overdose or organophosphate poisonings; terminally narrow pupils you can see in patients after drugs admission; pupils are dilated in case of hypoxia, neuroleptic poisonings, antihistamine medicines intoxications; the widest pupils you can observe in atropine poisoning.

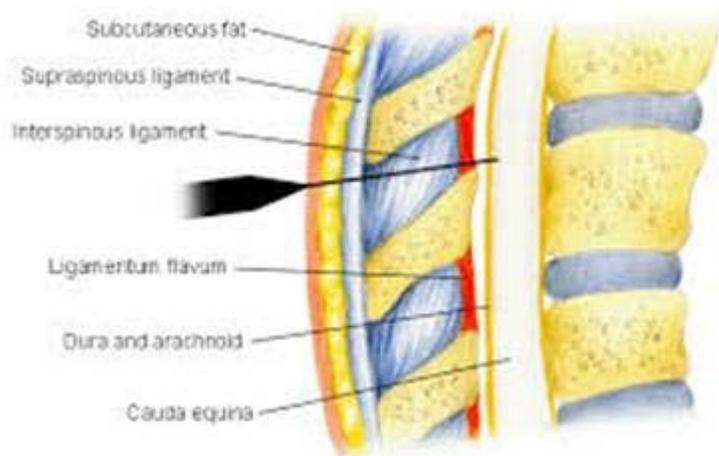

Anisocoria (pupils of different size) is a symptom of local CNS injuries. In most cases you notice this sign when a trauma causes intracranial haematoma. Examine those patients carefully: look for bruises and scratches on the head (including parts covered with hair). Sometimes you can even notice eyeballs deviation to the side of injury. Lack of patellar and heelstring reflexes proves deep CNS affection. Pathological Babinski's reflex shows organic CNS injury. Muscular tone asymmetry is a sign of stroke, tumour, haematoma, etc.

Don't forget to assess other systems and organs, because brain reaction can be only the response to a serious visceral pathology. For example unconsciousness can be a consequence of cardiac arrhythmia (Morgagni-Adams-Stokes syndrome). And on the contrary: CNS violations can cause rhythm disorders.

Localization of the brain pathology	Cardiac symptoms
Damage of frontal lobes and orbital zones	Bradycardia, complete AV block, auricular extrasystole
Damage of midbrain	Extrasystole, atrioventricular block, VF
Medulla oblongata pathology	Node and ventricular extrasystole, fluttering arrhythmia
Hypothalamic zone damage	Extrasystole, paroxysmal tachycardia
Affection of vascular center	Severe vascular tone decrease, hypotension, bradycardia, cardiac arrest.

Pericardial murmur and pleural rub can indicate uraemic coma. Changes of liver size are features of hepatic coma. Enlarged spleen is a symptom of bone marrow or liver diseases.

In case of comatose patients use all your laboratory and instrumental possibilities: perform head X-ray, CT, liquor tests, encephalography, angiography, usual blood tests, etc.

Pic. 5.1 Lumbar puncture.

For assessment of central nervous system condition Glasgow Coma Scale was proposed in 1974.

Clinical signs	Points
Eyes opening	
Spontaneous	4
In response to voice	3
In response to pain	2
Does not open the eyes	1
Verbal response	
Converses normally	5
Confused, disoriented answers	4
Inappropriate words	3
Incomprehensible sounds	2
No sounds	1
Motor response	
Obeys commands	6

Localizes painful stimuli	5
Withdrawal to painful stimuli	4
Abnormal flexion to painful stimuli	3
Extension to painful stimuli	2
No movements	1

Count the points and assess the result according to this:

13-14 points – moderate confusion

11-12 points – deep confusion

8-10 points – sopor

6-7 points - moderate coma

4-5 points - deep coma

3 points - deepest coma

Immediate aid for comatose patients:

- turn the patient aside
- thrust the jaw forward
- assess respiration (skin and mucous membranes colour, respiration rate and character, pathological noises during breathing act, intercostal spaces breathing retraction);
 - in the inspiration is difficult or oral cavity is filled with gastric contents, saline or blood provide airways patency (remove foreign bodies or liquids);
 - in case of ineffective respiration begin artificial ventilation;
 - check the pulse over peripheral and central arteries;
 - check photoreaction by raising the eyelids;
 - call for help (actually this is your primary task, but try to use help of witnesses and don't leave patient alone, especially if you are uncertain about his breathing ability).

To place patient into “recovery position” you should:

- a. place the arm nearest to you at a right angle, flex the opposite knee

b. turn patient aside by pulling the flexed knee and shoulder on the same side; then press the hand of the upper arm to the chick; make sure breathing is not difficult.

Some comatose patients can be hyperreflexive, hyperkinetic and disposed to cramps.

In case of cramps you should:

- lay patient in a supine position on a flat surface (to avoid injuries);
- prevent tongue biting inserting the gag or any available items (like stick or spoon wrapped with cloth);
- keep the airways open (usual methods described above) and hold the head in order to prevent trauma and asphyxia;
- provide oxygenation with the mask;
- between the attacks get an i/v access and give the patient 10-20 ml of 25% magnesium sulphate solution, 2 ml of 0,5% Diazepam solution;
- clean the oral cavity from blood, saliva, gastric contents;
- if patient's breathing is inadequate provide artificial ventilation.

5.3 Diabetic comas.

Diabetic ketoacidosis.

Diabetic ketoacidosis is a type of hyperglycaemic diabetic coma. It appears in case of diabetes decompensation, which can be caused by inadequate insulinotherapy (wrong dosage), violations of diet (overeating, alcohol abuse), other diseases (usually of infectious etiology – pneumonia for example). Sometimes coma is a first symptom of diabetes.

One more time pay attention to the detailed anamnesis: ask the relatives about the onset of the episode. Did the patient feel unwell few days before decompensation?

Was he complaining of weakness, thirst, nausea, vomiting, frequent urination, acetone-like breath odor?

The biochemical foundation of diabetic coma is within the mechanisms of cellular glucose consumption: when cells are not able to absorb glucose it is being accumulated in the blood and thus increases blood osmolarity. Due to osmotic pressure laws fluid will flow from the tissues to the vessels according to the gradients of concentration. This is the mechanism of thirst in case of diabetic patients. When glucose concentration is over 10 mmol per liter kidneys fail to reabsorb it completely from the urine and thus it begins to exude with the urine. The water follows glucose according to the already mentioned osmosis rules and this is the reason of diabetic polyuria and dehydration of diabetic patients. Simultaneously cells are suffering from the lack of energy caused by glucose consumption disorders. In order to maintain their vitality cells begin to use other than glucose energetic metabolites: proteins, fatty acids, etc. This ends up with ketosis (accumulation of ketone bodies) and acidosis. Cells begin to lose potassium and this brings hypokalaemia (potassium is not returning from the urine to the blood).

Your clinical and laboratory findings can be next:

- dehydration symptoms: body weight loss; dry skin and mucous membranes; decrease of skin turgor, eyeballs tone, blood pressure and central venous pressure, urinary output;
- metabolic acidosis signs: acetone-like breath odour, Kussmaul breathing (deep noisy breathing), face hyperaemia (acid substances in blood cause dilatation of small vessels and they become overfilled with blood- hyperaemia appears);
- nausea and vomiting: caused by accumulation of acids within the gastrointestinal tract - increased concentration of acid metabolites in the blood induces compensatory mechanisms of organism protection, among them mucous membranes secretion is one of the most effective;
- laboratory tests: glucose over 6,6 mmol/l, sometimes even more than 30-40 mmol/l; pH is 7,2 and less (uncompensated acidosis); hyperkalemia is caused by cellular potassium lost (with corresponding cellular deficiency of this cation); urine contains ketone bodies; blood tests prove dehydration (hemoconcentration signs: increase of hematocrit, haemoglobin, protein, red blood cells);

First aid: provide general methods of comatose patients treatment – control airways patency, adequacy of ventilation, call for help.

Intensive treatment.

1. Provide oxygenation with the oxygen mask or nasal catheter. If it is necessary perform the intubation and begin artificial ventilation.
2. Get an i/v access, insert urinary catheter and gastric probe; if you have enough time take care about the central venous line.
3. Begin the infusions: saline 1 000 ml during first hour, then 500-1000 ml per hour. Patients with coexistent cardiac diseases should be controlled very carefully: check their central venous pressure and diuresis (should not be less than 40 ml/hour).
4. Insulinotherapy: initial bolus of 10-20 Units of simple insulin (or 0,2-0,3 U/kg/hour in prolonged infusion); supportive dose is 0,1 U/kg/hour. If in 3-4 hours glucose concentration is not 30 % less dose should be doubled; if in 4-5 hours glucose concentration is not 50% less – dose is doubled again. But the speed of glycemia reduction should not be too high: make sure it is not over 5,5 mmol/l. During first 10 hours don't try to reduce to the level less than 14 mmol/l. When glucose concentration will reach 14 mmol/l reduce the insulin infusion to 0,05-0,1 U/kg/hour or change the way of insulin admission into subcutaneous injections every 3-4 hours. Usually 5-10 % solutions of glucose are used with insulin infusions to stop pathological fatty acids metabolism.
5. Control the potassium level according to the blood tests results: in case of hypokalemia add 40 mmols of potassium per each liter of solutions you give i/v, but not faster than 20 mmol/hour.
6. In case of prolonged treatment use antibiotics for infectious diseases prevention. In case if diabetes was decompensated by infection this will be your aetiological treatment of coma.
7. Take care about DIC-syndrome prophylactic: 5000 U of heparin s/c under the coagulation tests control or low molecular weight heparins s/c (0,6ml of fraxiparine once a day).
8. If acid-base disorders are serious (pH<7,1) use 100 ml of 4% sodium bicarbonate solution during first hour and control acid-base balance.

You can calculate the necessary volume of sodium bicarbonate according to the formula:

$$V_{\text{NaHCO}_3} (\text{mmol}) = 0,3 * \text{BE} * \text{BW},$$

BE- base excess (with “-”)

BW – body weight

9. Symptomatic treatment: if necessary use nootropics, heart medicines and hepatic protectors.

10. Control vital functions carefully and don't forget that decompensation of diabetes probably had curable external reason. So your task is to find it and provide proper treatment.

Parameters	Ketoacidotic coma	Hypoglycemic coma
Cause	Undiagnosed diabetes, irregularity of food intake and treatment, infections, traumas	Overdosage of insulin or peroral glucose-reducing drugs. Understated carbohydrates intake after insulin introduction, excess physical activity
Onset	Gradual (a day and more)	Acute (minutes, hours)
Arterial pressure	Reduced	At first increased, then reduced
Color of skin and mucosa membranes	Pale	Hyperemia at the beginning
Respiration	Infrequent, deep, loud	Normal
Skin humidity	Very dry	Wet
Skin turgor	Decreased	Normal
Muscle tonus	Reduced	At first increased, then reduced
Tendon reflexes	Areflexia	Inhibited at first, then increased, areflexia in coma
Glycemia	Increased	Decreased abruptly
Smell of expired air	Acetone	Non specific
Ketonemia	Significantly increased	Normal

Hyperosmolar nonketotic coma.

Hyperosmolar coma is a type of hyperglycaemic coma, caused by high glycemia without ketosis. This complication appears as a consequence of dehydration in elderly patients (in case of diarrhoea, vomiting, burns, excessive perspiration or diuresis). Hyperosmolar coma is diagnosed through the laboratory tests showing plasma hyperosmolality (check chapter 9 for details). If plasma osmolality is over 320 mOsm/l hyperosmolar coma is proved.

Intensive treatment is much alike the therapy of usual hyperglycaemic coma, however rehydration with hypotonic solutions is the main key to success in this situation (use 0,45% saline solution or 2,5% glucose solution). Us usual schemes for insulin therapy and treat the reason of dehydration. Remember: you should never use 4% sodium bicarbonate solution: its osmotic concentration is 3 times higher than the plasma osmotic concentration!

Hyperlactacidemic coma

Hyperlactacidemic coma is a diabetic coma, which appears in decompensated diabetic patients who suffer from hypoxia (disorders of respiration or oxygen transportation). In case of oxygen deficiency intracellular respiration is blocked and acid metabolites (including lactic acid) are accumulated. This brings acidosis and diabetic decompensation.

The most common reasons of hypoxia are pneumonia, shocks and anaemia.

Intensive treatment includes usual steps of hyperglycaemia therapy, but main accent is made over the liquidation hypoxia:

- check the efficiency of respiration and improve it if necessary (mask oxygenation or even artificial ventilation);
- provide shock treatment if the it is the reason of patient's comatose condition;
- transfuse blood components if the cause was anaemia;
- inhibit excessive metabolic reactions (normalize body temperature, use sedative medicines or neuroleptics if patient has psychomotor excitement and agitation);
- use antihypoxants (cytochrome c for example).

Hypoglycaemic coma

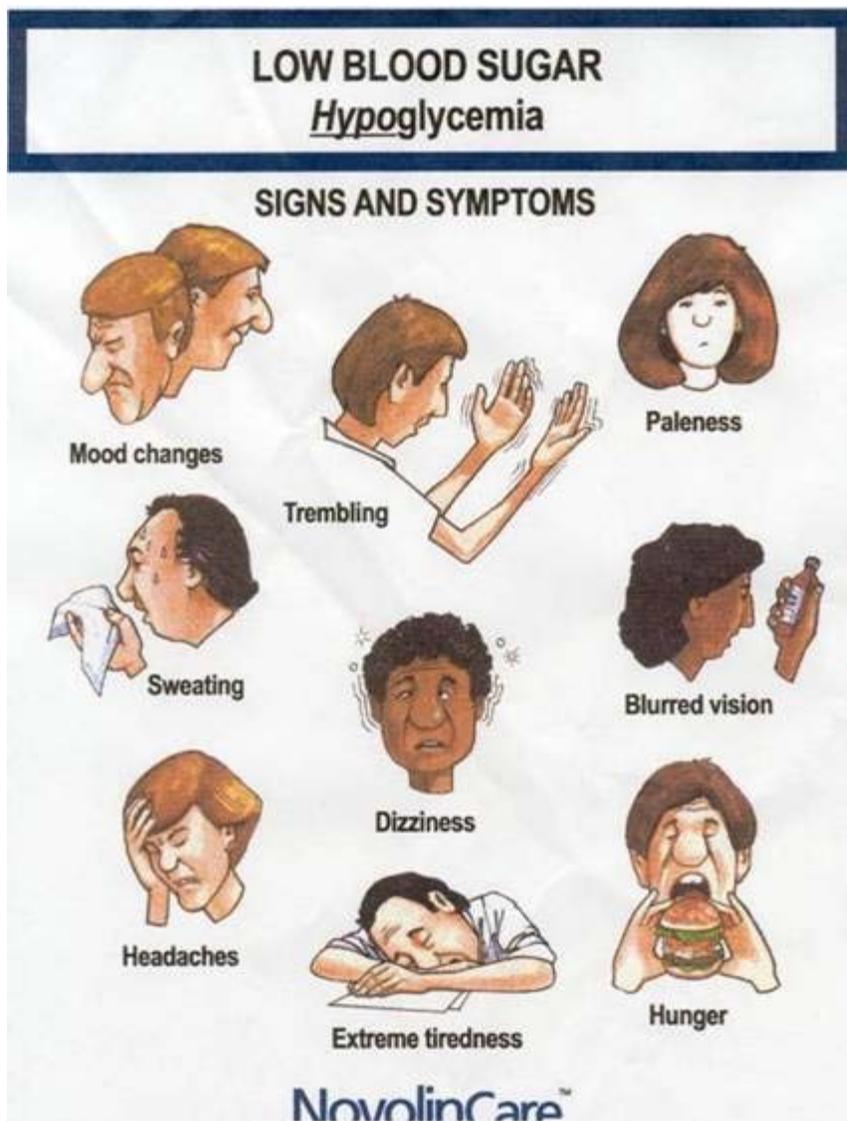

As you can see from the name hypoglycaemic coma is a condition of low glucose concentration in the blood. Unlike most of the previous types of diabetic coma it develops really quickly: within 30-60 minutes. The most common reason for this coma is improper insulin admission or diet violations (insulin overdose or lack of meal after insulin injection). Among the other reasons are: overdose of oral hypoglycaemic drugs (sulfonylurea), physical exercises without insulin dose correction, chronic alcoholism (violated glycogenolysis), hepatic diseases, postoperative gastric diseases (influence speed of glucose absorption).

Your clinical findings will be mostly connected with brain energetic deficiency: weakness, dizziness, coordination violations, dysphoria and inadequate behaviour, unconsciousness and cramps appear as a result of neuroglycopenia (as you remember glucose is the only energetic substrate for neurons, unlike other organs brain is 100% dependable on this monosaccharide).

Hypoglycaemia is classified according to the severity of the symptoms as mild (consciousness preserved, patient is able to take care of himself and hypoglycaemia is liquidated by oral admission of simple carbohydrates), moderate (patient needs help, but his condition is improving after oral admission of simple carbohydrates) and severe (patient is unconscious, needs help and his hypoglycaemia is liquidated only with parenteral glucose infusion).

When glucose concentration is 3,33-2,77 mmol/l you observe only mild hypoglycaemic symptoms. When it diminishes to the level 2,77-1,66 mmol/l the clinical picture is complete (except the unconsciousness). Glucose concentration less than 1,66 mmol/l induces coma. Hypoglycaemia lasting 4-6 hours can end up with irreversible cellular damages and even brain death.

Clinical picture is characterized with: pale skin wet from sweat; hemodynamics (central venous pressure, blood pressure) and other systems might be not involved in the initial stages; eyeballs tone and skin turgor are normal, mucous membranes are moist. Breathing is normal, not pathological Kussmaul breathing of ketoacidosis. There is no acetone-like breath odour. Urinary output is normal.

Those clinical features are quite typical, but to prove hypoglycaemia you should wait laboratory results (blood tests will show low glucose concentration).

Immediate aid.

In case of mild hypoglycaemia patient should eat 10-20 grams of simple carbohydrates (1-2 slices of bread, 2-4 candies, 200 ml of juice). If glucose level is not normalized within 20 minutes patient should take 10-20 grams of complex carbohydrates (few spoons of cereal for example) to prevent hypoglycaemic ricochet. Moderate hypoglycaemic should be treated simultaneously with simple and complex carbohydrates (10-20 grams of each).

Intensive therapy.

In case of severe hypoglycaemia use usual algorithms:

- provide oxygenation and adequate ventilation;
- get an i/v access as soon as possible;
- give 20-40-60-80-100 ml of 40% glucose solution (actually lately it is recommended to use 20% solutions because they cause less irritation of the peripheral veins); the precise dose you will choose according to clinical improvement of CNS condition (but not more than 120 ml);
 - in glucose solutions are not effective prescribe 1 mg of glukagon s/c; 1 ml of 0,1% adrenaline solution s/c, 3060 mg of prednisolone solution i/v;
 - additionally you can use: 100 mg of cocarboxylase i/v, 5 ml of 5% ascorbic acid solution,- or any required symptomatic medicines;
 - in case of brain oedema use 15% mannitol solution (0,5-1,0 g/kg) i/v;
 - even after clinical improvement patients should stay in the ITU for a

while, because his condition is still unstable and encephalopathy is still probable.

In children: when you are out of hospital use glukagon subcutaneously (0,5 mg with children under 5 years and 1 mg with elder kids). When you are in the ITU use i/v infusions of 20% glucose (1 ml/kg) during first 3 minutes, then 10% solution of glucose (2-4 ml/kg), check the glycemia and if you will not see the CNS improvement continue with 10-20% solutions of glucose and keep glucose concentration at the level of 7-11 mmol/l. Check glycemia level every half an hour or hour.

Control tests.

1. According to the GCS deep coma is characterized with:
 - A. 4-5 points
 - B. 13-14 points
 - C. 11-12 points
 - D. 3 points
 - E. complete lack of reaction to external stimuli
2. What is the condition of normal CNS functioning?
 - A. getting of 20-25 % of circulation blood volume every minute;
 - B. glycemia level not less than 3 mmol/l;
 - C. normal concentration of blood proteins and lipids;
 - D. brain should get at least 10% of total blood oxygen;
 - E. plasma osmolality should be 185-210 mOsm/l
3. Hyperglycaemic ketoacidotic coma is not characterized with:
 - A. metabolic acidosis;
 - B. overhydration;
 - C. low central venous pressure;
 - D. respiratory alkalosis;
 - E. severe paleness.
4. Hypoglycaemic coma is characterized with:
 - A. critically low blood pressure;
 - B. decreased tone of eyeballs;
 - C. wet skin;

- D. acute cardiac failure;
- E. noisy frequent breathing.

Task 1.

Andrew, the doctor, is examining Patience, the patient of 52. Patience is unconscious. His breathing is noisy and frequent; he has acetone-like breath odor; his skin and mucous membranes are dry; his blood pressure is low.

1. What symptoms will help Andrew to make a proper diagnosis?
2. Write the algorithm of Andrew's actions: clinical examination and laboratory diagnostics.

Task 2.

Choose the symptoms typical for:

- a. hyperglycaemic coma;
- b. hypoglycaemic coma.

1. Acetone-like breath odour. 2. Paleness. 3. Dry skin and mucous membranes. 4. Wet skin. 5. Hyperaemic face. 6. Tachycardia. 7. Normal heart rate. 8. Decreased tone of eyeballs. 9. Normal eyeballs tone. 10. Usual breathing rate. 11. Deep breathing. 12. Normal blood pressure. 13. Hypotension. 14. Normal urine output. 15. Oliguria. 16. Hyperkalemia. 17. Normal potassium concentration. 18. Hypokalemia. 19. Increased hematocrit. 20. Unchanged hematocrit. 21. Hyperglycaemia. 22. Hypoglycemia. 23. Central venous pressure over 4 cm H₂O. 24. Central venous pressure 6-10 cm H₂O.

Task 3. What medicines are not allowed for patients with hyperosmolar nonketotic coma and why?

a. Insulin; b. saline solution; c. 2,5 % glucose solution; d. 4% sodium bicarbonate solution; e. 10% calcium chloride solution; f. 0,45% sodium chloride solution; g. mannitol solution; h. heparin; i. spironolactone; j. prednisolone.

Task 4.

Andrew, the student of medicine, is a witness of such situation: in the street man suddenly felt and in few seconds cramps began.

What should Andrew do? What is the probable reason of this situation?

Task 5.

Patience, the patient of 50, was found unconscious by the ambulance workers at 4 o'clock in the morning. During the admission to the hospital: patient is not reacting to

pain stimuli. Respiration is normal, however in supine position airways loose patency. Alcohol odour is quite evident. Pupils are asymmetric, right is wider than the left, photoreaction is inhibited. Haemodynamics is stable. Abdomen is soft, peristalsis is active. Urination is not controlled.

What is the probable diagnosis? What treatment should be prescribed?

Acute poisonings.

Acute poisoning is a chemical injury, which occurs when chemical substance gets to the organism and violates its vital functions. If the substance is aggressive enough and proper treatment is not provided on time poisoning will bring death.

Although there are over 500 toxic substances which may cause acute poisoning, clinical picture is made up of quite similar syndromes. Proper diagnostics of these syndromes allows avoiding life-threatening complications and gets the chance to make correct preliminary conclusions about the nature of poisoning.

8.1 Main clinical syndromes of poisonings.

Affection of central nervous system manifests as excitation or depression of patient's mental activity. Depression of CNS has different stages: confusion, stupor, spoor

and toxic coma. One of the coma's deepness criteria is reaction of the patient to the painful stimuli (you can also check reaction to smell of ammonium chloride). Lack of reaction is a sign of coma. Don't live such patient without observation, because his condition is severe and at any moment life-threatening complications may appear: those patients have tendency to bradypnoea up to complete respiratory arrest. Also you should not forget that decreased tone of soft palate and tongue in a supine position will violate patency of the airways and patient can die of asphyxia. In addition comatose condition influences reflexes and lack of swallowing can lead to entrance of saline and gastric contents into the airways (and thus to development of aspiration pneumonia).

Usually CNS depression is caused by excessive alcohol consumption or admission of its surrogates, overdose of neuroleptics, sleeping pills, drugs, sedative medicines, antidepressants and carbon monoxide poisoning. You can remind intensive treatment of comatose patients in the chapter 5.

Some poisoning are followed with acute intoxication psychosis (mental disorders, hallucinations, time and space disorientation, inadequate behavior). This clinical picture you can observe in case of atropine poisoning (and also atropine-like agents: tincture of dope, henbane, amanita) or cocaine, tubazid, antihistaminic drugs and organophosphates poisoning.

In case of psychosis you will have to immobilize patient in the bed for his own good and safety (to avoid injuries both patient's and those of the stuff). You will also have to do this in order to maintain i/v lines for antidotes and sedative infusions (aggressive patient will try to remove everything he or she considers irritating). Constantly observe the patient's vital functions.

Toxic affection of the respiratory system can progress as the violation of:

a. external respiration - neurogenic form, aspirations and obstructions of the airways which bring hypoxic hypoxia;

b. hemoglobin's function – aniline and nitrobenzene create methemoglobin, carbon monoxide connected with hemoglobin creates carboxyhemoglobin and neither the first nor the second is capable of normal oxygen transportation; heavy metal, organic acids and arsenic poisonings lead to destruction of the red blood cells and emission of the free hemoglobin into the plasma;

c. oxygen transportation due to the decrease of circulating blood volume – exotoxic shock;

d. cellular respiration – tissue hypoxia occurs when cytochromes are blocked with toxins like cyanides.

Practically all severe poisonings earlier or later lead to hypoxia, because they violate oxygen supply, transportation and consumption.

Your immediate therapy actions in this situation will be:

- to assess of respiratory system (described above);
- to provide of airways patency (cleaning of the oral cavity, aspiration of the saline and gastric contents, conicotomy if necessary, etc.);
- to begin oxygen supply (face mask, nasal catheter);
- to start artificial ventilation if necessary;
- to prescribe antidotes if they are available (methylene-blue in case of nitro compounds poisonings, unithiolum in case of heavy metals and arsenic poisonings, cytochrome c in case of tissue hypoxia);
- to start hyperbaric oxygenation in case of carbon monoxide poisoning;
- to begin infusion therapy in order to stabilize the hemodynamics;
- to start general detoxification;
- to prescribe symptomatic treatment and provide prevention of the complications (for example prescription of antibiotics).

Affection of the cardiovascular system manifests as inability of the heart and vascular bed to provide adequate blood supply of the organs, which leads to metabolic disorders and in the worst case to death. Severe toxic damage of cardiovascular system brings acute cardiovascular failure: primary toxic collapse, exotoxic shock, secondary somatogenic collapse.

Primary toxic collapse appears in case of massive poison admission, when compensatory mechanisms are not quick enough to resist the chemical aggression. Immediately or minutes after poisoning patients begin to suffer from reduced cardiac output and thus from decreased blood flow in the tissues. Peripheral pulse is weak or absent, blood pressure critically lowers and cardiac arrest can appear. In most cases of primary toxic collapse ambulance is not able to save the life of the patient due to the fulminant development of life-threatening complication. However you should remember that such collapse occurs only in 5 % of the cases.

Exotoxic shock is the reason of death for 70 % of poisoning victims. Violations of hemodynamics on one hand are caused by direct heart and vessels damage and on the other hand by compensatory sympathetic and adrenal reactions. On the background of CNS and gastrointestinal system violations you will observe disorders of systemic hemodynamics and

microcirculation: arrhythmias, decrease of blood pressure, central venous pressure, cardiac output and diuresis. The peripheral vascular tone changes: toxins induce spasm or dilation of arterioles with the ischemia of one and hyperemia of other tissues. Depending on the body reaction on intensive treatment shock can be compensated, decompensated reversible and decompensated irreversible.

In case of toxic shock you should:

- get an i/v line (preferably several, including central venous access);
- start infusions of colloids (albumin, rheopolyglucin, hydroxyethylstarch solutions) and crystalloids (saline, glucose solutions, polarizing solution) in order to normalize blood pressure, heart rate and diuresis; sometimes infusion dose is up to 100-150 ml/kg, (7-10 l/day);
- constantly control patient's condition: monitor the heart action, blood pressure and central venous pressure;
- provide antidote treatment and detoxification; remember that extracorporeal detoxification is possible only after the stabilization of the hemodynamics (systolic blood pressure >90 mm Hg).

Secondary somatogenic collapse is the reason of death in 25% of the cases. It can occur few days after poisoning, when the toxin is already eliminated from the body, however the tissue changes (in the lungs, liver, kidneys, heart) are irreversible. Necessary treatment: hemodynamics stabilization, improvement of microcirculation, intensive therapy of functional disorders and organic changes (artificial lung ventilation, hemodialysis, cardiac support, etc.).

Toxic affection of gastrointestinal tract.

Usually poisoning provokes usual protective reactions: nausea, vomiting, diarrhoea. Chemically aggressive agents can cause "corrosive" effects: concentrated acids and bases can burn the mucous membrane of oral cavity, oesophagus and stomach (vomit is coloured with blood). Profuse vomiting and diarrhoea bring dehydration, electrolytes loss and acid-base imbalance. Especially rapid those complications appear in children.

After recovery patients with chemical burns of gastrointestinal mucous membranes may suffer from cicatrization and stenosis of digestive tract.

Be aware of the fact, that intensive usage of narcotic pain killers and sleeping pills can lead to inhibition of peristalsis and thus to constipation and slow elimination of toxins.

Immediate aid actions:

- clean the stomach. If the patient is conscious stimulate vomiting with the pressing on the root of the tongue or with 2-4 liters of slightly salted fluid. Don't you ever do this in case of chemical burns!
- if you have the skills and possibility insert the stomach probe and evacuate gastric contents with the help of 10-15 liters of water; if necessary give also antidotes through the probe; you can also use probes with several channels;
- after the gastric lavage in order to bind toxins use enterosorbents (activated charcoal for example);
- stimulate stool with saline laxatives (150-200 ml of 33% magnesium sulfate solution) in order to remove connected with the toxin sorbent from the intestines;
- cleansing enemas also help to eliminate toxins from the body.

Toxic affection of liver and kidneys.

This syndrome is caused by primary toxic damage of the liver and kidneys (nephrotoxic and hepatotoxic poisons) or by the secondary disorders of their functions due to violations of blood flow and oxygenation.

Liver is the main detoxification and biotransformation center of the organism, so it takes the "main blow" during intoxication. Intensive detoxification increases metabolic activity and oxygen consumption of the liver several times. Hepatocytes become very sensitive to hypoxia.

Light forms of toxic and hypoxic affections can develop without clinical manifestation. However they will be noticeable in laboratory tests (elevation of transaminases, bilirubin, phosphates). Severe poisoning will bring to toxic hepatitis and even hepatic coma.

Among the hepatotoxic substances are: heavy metals salts, dichloroethane, ethylene glycol, deadly amanita toxins.

To protect the liver you should:

- eliminate the toxic substance from the gastrointestinal tract;
- give antidotes if they exist (unithiol for heavy metals salts, lipoic acid for deadly amanita);
- prescribe cleansing enemas 2-4 times a day (to prevent intoxication with the wastes accumulated in the intestine);
- use extracorporeal detoxification (hemisorbtion, plasmapheresis, artificial liver);

- provide adequate oxygenation and blood supply of the liver;
- prescribe symptomatic treatment.

Kidneys are very important for the elimination of the poisons circulating in the blood. So in many cases they are also the “target” of the toxin. They can be damaged primary (poison affect their tissues directly) and secondary through the violations of vital functions (for example hemodynamics in case of exotoxic shock). Their condition you can control with the help of urine output per hour, which normally is not less than 0,5 ml/kg.

To prevent the renal failure you should:

- eliminate the poison as soon as possible (gastric lavage and enemas for gastrointestinal tract; hemodialysis, hemosorbition, plasmapheresis for blood);
- give antidotes if they exist (unithiol for heavy metals salts, sodium bicarbonate for hemolytic poisons, ethylic alcohol for ethylene glycol and methanol);
- treat disorders of hemodynamics (therapy against exotoxic shock);
- stimulate the urine output with the diuretics on the background of previous rehydration: this will allow you to eliminate diluted in the plasma toxins faster and to prevent renal failure; kidney is an organ which functions normally only if works intense;

Clinical observations tell us, that incredibly massive infusions (10-20-30 l/day) with diuresis stimulation really help patient to dilute and eliminate the toxin without kidneys damage.

In case of acute renal failure you should treat the patient according to the principles described in chapter 6.

8.2. Ethylic alcohol poisoning.

This type of poisoning appears in case of excessive alcohol consumption. It is one of the most common poisonings, as well as one of the lightest and prognostically the most favourable (organic damage is rare). However combined with comorbidities and complications it becomes one of the first reasons of death in toxicology, so don't underestimate it.

Alcohol poisoning, unlike drunkenness, has the characteristic signs of intoxication: vomiting, inhibition of CNS, disorders of cardiovascular system and breathing. Patients usually are in comatose condition. Pay attention to their appearance: clothes are untidy, you can notice sings of involuntary urination or defecation. There is alcohol breathing odour. Skin of the face is hyperaemic and dry. Cyanosis is a sign of respiratory insufficiency, grey

shade of skin is a symptom of cardiac disorders. Wet skin might be the symptom of hypoglycaemic coma, hypercapnia or organophosphate poisoning, which are “covered” with the obvious clinic of alcohol poisoning. In case of moderate coma vital functions are usually not involved. Pupils are narrowed or dilated, photoreaction is preserved. Objective criterion of alcohol poisoning is alcohol concentration of the blood:

- less than 1,5‰ – light inebriation
- 1,5‰-3,5‰ – moderate inebriation
- 3,5‰ and more – severe inebriation

Lethal concentration of alcohol is 5-6‰.

The most common complications of alcohol poisoning are next:

- obstruction of the airways with the tongue, soft palate or biological fluids (vomit, saline, sputum, blood) in supine position;
- regurgitation of the gastric contents and development of aspiration pneumonia; lethality is nearly 70%;
- head traumas with brain injuries: patients usually fell and hurt themselves; the problem with such injuries is that the clinic of hematoma (subdural, epidural, intracerebral) is quite often “covered” with alcohol intoxication and this is why you should always remember about the differential diagnostics. To make a correct diagnosis in case of coma you should check the specific symptoms such as anisocoria (there is no poisoning which causes pupil’s asymmetry!), signs of head injury (scratches, bruises, skull deformations, oto-liquorrhea and nasal liquorrhea, nasal and ear bleeding), asymmetric tendon reflexes and muscle tone, disparity between the amount of alcohol and deepness of coma, prolonged unconsciousness (alcohol coma even without proper treatment lasts only 3-4 hours);
- other traumatic injuries (rib fractures which violate external breathing, spleen or liver ruptures with haemorrhagic shock, ruptures of hollow organs with peritonitis; limb fractures);
- compartment syndrome appears when certain enclosed space within the body for several hours suffers from the decreased blood flow (for example when patients spends few hours in one inconvenient position); even when blood supply will be restored necrotic products will continue pathological process through toxic affection of the life-important organs (for example free myoglobin can cause renal failure).

There is always possibility of chronic diseases exacerbations on the background of alcohol poisoning (stroke, myocardial infarction). Remember about the necessity of complete examination (inspection, palpation, percussion and auscultation of undressed

patient) of such alcohol victims – it is the only way to find all the “diagnostic mysteries” patients hide!

Intensive treatment:

- evaluate CNS condition (deepness of the coma);
- provide airways patency and adequate respiration (described above; if necessary – intubate the patient and begin artificial ventilation);
- check the cardiovascular system: heart rate, pulse, blood pressure;
- in case of severe hemodynamic disorders provide infusion therapy;
- insert the stomach probe and remove its contents using lavage with water;
- take blood samples and check blood alcohol level (obligatory!);
- prescribe intravenously: 60-80 ml of 40% glucose solution, 60-80 ml of 4% sodium bicarbonate solution, 5-10 ml of 5% ascorbic acid, 1-2 ml of vitamin B₁ solution;
- if there are no comorbidities add analeptic solutions i/m (2-3 ml of caffeine or 2 ml of cordiamin);
- in case of severe intoxication begin forced diuresis.

8.3 Poisonings with alcohol surrogates.

Patients can be poisoned with: home-distilled vodka, Cologne water, denatured alcohol, methyl alcohol, lotion, brake fluid, etc. The peculiarity of such poisonings is complex effect of the alcohol and other toxic components of the “drink”.

The most toxic are methyl alcohol and antifreeze (ethylene glycol) – their lethal dose is 60-100 ml. Lower doses cause neuritis of optical nerve and thus blindness (methyl alcohol), acute renal and liver failures (ethylene glycol).

In case of these poisonings detailed anamnesis and blood identification of the poison (gas chromatography) play the most significant role in the diagnostics. However for the prognosis volume of the poisonous fluid, duration of its influence, functional condition of the liver and effectiveness of the antidote therapy and detoxification are the most important.

In the body methanol and ethylene glycol are metabolised according to so called “lethal-synthesis”: during the breakdown of the poison in the liver there are created substances much more toxic than the parent compounds.

Intensive therapy:

1. Gastric lavage with potassium permanganate (oxidizes methyl alcohol).
2. Give antidote: 50 ml of 40% ethylic alcohol solution every 3 hours orally or 100 ml of 5% ethanol solution intravenously slowly combined with glucose solution during 2 days. Antidote will block the process of their biotransformation in the liver until the poisons will not be eliminated from the body.
3. Actively eliminate the poison from the body through repeated gastric lavages, forced diarrhoea, extracorporeal methods of detoxification (hemodialysis, hemosorbtion, plasmapheresis).
4. In order to treat optic neuritis you should perform retrobulbar inject of steroids.
5. Symptomatic treatment.

8.4 Drug poisonings.

In civilized countries these poisoning are the main reason (65-70% of cases) of hospitalization in toxicology units. Usually patients overdose sleeping pills, narcotic painkillers, antihistamine drugs, hypotensive medicines. Among the reasons are suicide tries, drug abuse, toxicomania and accidental overdose due to hectic pace of modern life, etc.

Clinical picture is usually connected with CNS affection. There are phases of somnolence, sleep and coma. Depending on involvement of other systems coma can be complicated or uncomplicated. Usually respiratory complications appear: inspiration centre depression, violations of airways patency due to soft tissues (tongue, soft palate) or biologic fluids (blood, sputum, saline), pneumonia. In 15-20% of cases the poisoning development is complicated with the exotoxic shock. The peculiarities of this shock are next: circulatory disorders with blood stagnation in the pulmonary circuit, toxic affection of the myocardium and decrease of energy metabolism of the organism.

To indicate the poison you should ask relatives and witnesses and check things of the patient (for example you can find medicine packages). Evaluate the size of the pupils: extremely narrowed pupils ("poppy seeds") are the effect of narcotics admission; narrowed pupils might be the sign of sleeping or sedative medicines overdose; dilated pupils are the symptom of clofelin, antidepressants or neuroleptics administration; wide pupils covering the whole iris are usually the sign of atropine poisoning (or a poisoning with atropine-like substances: dope, henbane, amanita).

Principles of the intensive treatment in the toxicology unit:

- clean the gastrointestinal tract as soon as possible (gastric and intestinal lavage, enterosorbption, cleansing enemas) and as often as necessary;
- provide adequate respiration (check airways patency);
- in case of comatose patients intubate the trachea and begin artificial ventilation (sometimes it is necessary for weeks);
- control hemodynamics and treat its violations (infusion therapy and adrenergic agonists or antagonists if necessary);
- stimulate diuresis: patients with barbiturate poisoning should be treated with alkaline forced diuresis in order to eliminate the toxin (add to the infusion 400-600 ml of 4% sodium bicarbonate solution and prescribe diuretics);
- use antidotes: naloxone for opiates, pharmacological antagonists for anticholinergic and cholinomimetic agents; don't you ever prescribe central analeptics for comatose patients with drugs poisoning – cordiamin, caffeine, bemegride, cytiton, lobelinum can cause “cerebral blood flow stealing effect” and thus they deepen the hypoxia of brain cells!
- provide extracorporeal detoxification to eliminate toxins (hemodialysis, hemosorbption, plasmapheresis);
- prescribe antibiotics for infectious diseases prevention (for example in case of prolonged artificial ventilation);
- symptomatic treatment.

8.5 Alkali and acid poisonings.

These poisonings are among the most severe and difficult to treat. Accidentally or intentionally (suicide) victim can take mineral acids (hydrochloric, sulphuric, nitric acids), organic acids (acetic or oxalic acid), alkali (ammonium chloride, battery fluid, etc.).

When corrosive substance gets into the body along its way inside chemical burn appears: mucous membranes of oral cavity, throat, oesophagus, stomach are injured. Together they make nearly 14-15% of the body surface. Patients suffer from unbearable pain, eating and drinking are disabled. In case of acid burn coagulation necrosis appears; alkali burn is more severe, because colliquative necrosis penetrates deeper into the tissues ruining the vessels and causing bleedings. Organic acids easily get into the blood. Sometimes chemical substances or their vapours also get into the airways and thus oedema and risk of asphyxia appear.

Usually part of aggressive substance is spilled over the chin and you can notice

the burn. Systemic disorders are characterized with exotoxic shock which develops as burn shock (unbearable pain, dehydration, toxic affection of the heart, decrease of cardiac output, spasm of arterioles and microcirculation block). Organic acids also provoke hemolysis of red blood cells: free haemoglobin transforms into hydrochloric haematin and obturates renal tubules, causing acute renal failure.

Intensive treatment principles:

- evaluate patient's condition: external respiration, consciousness, cardiovascular system;
- adequate pain relief with narcotic painkillers and non-steroidal anti-inflammatory drugs (1-2 ml of 1% morphine solution; 2 ml of 50% analgin solution);
- liquidate the spasm of gastric cardia and oesophagus (1 ml of 0,1% atropine solution i/m, 5 ml of baralgin solution);
- clean the stomach during first 10 hours after poisoning; insert the stomach probe (cover it thickly with Vaseline and don't push too hard); use water for lavage and don't try to perform chemical inactivation of the poison, because during the reaction carbon dioxide can exude and acute expansion of the stomach leads to its rupture;
- provide treatment of shock (sometimes up to 10-12 liters/day of infusions);
- in case of organic acids poisonings (acetic acid, oxalic acid get into the blood) give 1500-2000 of 4% sodium bicarbonate solution intravenously slowly with diuretics; these actions will help to remove hemoglobin (released due to red blood cells hemolysis) and thus to prevent acute renal failure;
- in case of obstructive breathing disorders (mucous membrane edema) use steroids (90-120 mg of prednisolone), antihistamine drugs (2 ml of 1% dimedrol solution intravenously), sedative medicines (2 ml of 0,5% diazepam solution); perform tracheostomy or conicotomy if necessary;
- prescribe antibiotics for infectious diseases prevention (for example in case of prolonged artificial ventilation);
- symptomatic treatment.

During the recovering period patient may need surgeries for restoration of gastrointestinal tract: the most common practice is the bouginage of the oesophagus or, if necessary, oesophagus plastic.

8.6. Poisonings with toxic gases.

Among the toxic gases are carbon monoxide, car exhausts, propane and butane, ammoniac gases. The last one is the most toxic: few inhales are enough to cause unconsciousness.

The foundation of the pathology lies within the atypical haemoglobin – carboxyhaemoglobin – combination of normal haemoglobin and toxic gas. Oxygen transportation is violated (in case of severe poisonings there are nearly 70-80% of changed haemoglobin) and thus haemic hypoxia appears. In addition within the tissues cytochromes are connected with toxic substances and this leads to tissue hypoxia.

Clinical findings in case of carbon monoxide poisoning depend on the severity of the poisoning. In case of mild intoxication they are: headache, nausea, vomiting. Moderate intoxication shows unconsciousness for 12-16 hours and severe intoxication is characterized with coma, central disorders of breathing, toxic affection of heart and other organs, etc.

If intoxication advances changes of central nervous system become irreversible (brain death is possible).

Intensive treatment.

In case of mild and moderate poisonings you should carry the patient out of the toxic atmosphere as soon as possible. In hospital conditions you should provide oxygen supply, get an intravenous line for crystalloids infusion and prescribe vitamins.

In case of severe intoxication begin artificial ventilation with high oxygen flow. Luckily there is an antidote for carbon monoxide poisoning: hyperbaric oxygenation. Connection with oxygen is more natural for haemoglobin and when the pressure of

oxygen is higher than its usual partial pressure carbon monoxide is replaced from the haemoglobin. Usually in case of comatose patients 40-50 minutes sessions every 6-12 hours are enough.

To normalize tissue metabolism prescribe antihypoxants: 20% solution of sodium oxybutirate (20-40 mg/kg i/v) and cytochrome c (2-3 ml i/v) every 4-6 hours. To improve microcirculation dilute the blood with crystalloid infusions (check the level of hemodilution with hematocrit – stop when it will reach 0,3-0,35 l/l).

Prevent the infectious complications and brain oedema with standard methods.

8.7 Organophosphate poisonings.

These are the poisonings with insecticides, acaricides, herbicides, fungicides, rodenticides, desiccants, defoliants and with chemical warfare agents such as sorin, soman, V-x.

Organophosphate substances are fats and water soluble and thus they penetrate easily through the skin and mucous membranes (gastrointestinal tract, airways, etc.). In the blood they block an enzyme – cholinesterase – responsible for the breakdown of acetylcholine. As you remember acetylcholine is a universal synaptic mediator of nervous impulses and thus its accumulation on the post-synaptic membranes will cause continuous stimulation of vegetative nervous system and cross-striated muscles.

Clinically you will see: nausea, vomiting, cramps; unconsciousness in severe cases. Sometimes in the place of penetration you can see muscle fasciculation (if the poison was administered orally – tongue twitching). Stimulated parasympathetic nervous system shows wet skin, increased salivation and bronchial secretion (sometimes you can even see white phlegm in the mouth – don't mistake it with the pink phlegm of pulmonary oedema), narrowed pupils, bradycardia (heart rate 40-30 beats per minute). In addition to the obvious clinic you can always check the environment of the patient for the signs of organophosphate poisons (specific smell, containers with toxins, etc.).

One third of patients suffer from exotoxic shock, which primary causes hypertension and then hypotension, unconsciousness and depression of respiration.

Immediate aid:

- take patient out of the dangerous environment (if you suspect that the mechanism of poisoning is inhalation);
 - clean the stomach with large amounts of cold water; repeat it several times, because these substances are excreted through the mucous membranes of gastrointestinal tract;
 - give saline laxative;

- if the poison affected skin – wash it with alkaline solution.

Antidotes:

a. use peripheral m-anticholinergic drug – atropine: during the first few hours 2-3 ml of 0,1% atropine solution (up to 30-35 ml during the whole period of intensive atropinization); pay attention to the signs of atropine administration as they are the measure of your antidote treatment effectiveness: termination of excessive bronchial secretion, dilation of the pupils, tachycardia (90-110/min). During next 3-5 days continue atropine prescription (from 10-15 mg to 100-150 mg/day – period of supportive atropinization). Control clinically the level of atropinization.

b. use cholinesterase reactivators: 1-2 ml of 15% dipiroxim solution i/m, up to 600 mg; 3 ml of 40% izonotrozin solution i/m up to 3-4 grams. However remember, that cholinesterase reactivators can be used only 24 hours after poisoning. Later administered reactivators will ne not only ineffective, but also toxic for the patient.

You should also provide usual treatment as soon as possible: infusion therapy, forced diuresis, hemosorbtion, plasmapheresis, hemodialysis and antibiotics for infection preventions.

In case of ineffective external respiration and comatose patient's condition intubate the patient and start artificial respiration. Convulsions in case of organophosphate poisoning are treated with sodium oxybate (75-100 mg/kg i/v every 4 hours). Cardiac glycosides, calcium chloride, euphillinum are forbidden in case of organophosphate poisonings, because they induce toxic heart affection.

Be aware of the possibility of “second poisoning wave”: even 4-8 days after the stabilization of the patient's condition clinical picture of the poisoning might return and this time hemodynamics will decompensate quickly.

8.8 *Mushroom poisoning.*

There are edible, non-edible and relatively edible mushrooms. Non-edible or poisonous mushrooms can contain toxins harmful for central nervous system, liver, kidneys and gastrointestinal tract (according to A. Lokay, 1 968). The most dangerous poisoning is caused by deadly amanita. The poison of this mushroom – amanitotoxin- is not destroyed during cooking and there is no way to detect it in usual conditions. In case of severe poisoning the lethality is 80%.

Specific feature of amanita poisoning is prolonged latent period. Sometimes 6-12 hours pass before the first symptoms of the poisoning appear. All the other relatively edible mushrooms reveal clinical signs of the poisoning much earlier – 1-2

hours after consumption.

After the latent period is over on the background of complete health nausea, profuse vomiting and diarrhoea appear. Those symptoms begin second phase of the poisoning – gastroenterocolitic phase. Liver enlarges; patients suffer from pain in the right subcostal area, weakness, and consciousness disorders. Stool becomes watery and contains mucous. Patients loose up to 4 liters of the fluid during the day. Unlike bacterial food poisonings, mushroom poisonings are not characterized with high fever.

Liver failure and acute kidneys injury are the third phase of the poisoning, which begins on the second or third day of disease. Those failures are characterized with hepatic encephalopathy, jaundice, gastrointestinal bleedings, hepatic breath odour and oligoanuria. The level of alanine and aspartate aminotransferases is very high. When liver returns to its usual size and consciousness is changed into coma hepatargia is stated and prognosis for the disease becomes rather unfavourable.

The forth stage is a stage of recovery and is characterized with gradual regression of the clinical picture and normalization of the laboratory results during several weeks. However survival is possible only for those patients, who ate small amounts of the poisonous mushroom.

Knowing about the high lethality and severity of the amanita poisoning prevention methods become very important. Mushroomers should know the difference between deadly amanita and other mushrooms: deadly amanita is a gill-bearing mushroom with olive or green cap. Its gills white are not connected with the stem. Stem has a bulbus with white volva from one side and a white annulus from another side, under the cap.

Patients should be treated in a special toxicology units or intensive treatment unit. General principles of intensive therapy are:

- gastric and intestinal lavage, enterosorbition and saline laxatives;
- infusion therapy (necessary to liquidate electrolyte deficiency and provide forced diuresis);
- support of the liver functioning with lipoic or thioctic acid (1000-2000 mg/day), concentrated glucose solutions, steroids (up to 40 mg of dexamethasone per day) and silibin (50 mg/day);
- extracorporeal detoxification (hemodialysis, hemosorbition, plasmapheresis, artificial spleen or liver) as soon as possible;
- antibiotics if necessary (penicillin); vitamins (B,C,E);
- external drainage of thoracic duct (decreases intoxication through

elimination of toxic lymph).

8.9 Medical operations and manipulations.

Gastric lavage

Indications: necessity to remove poisons or toxins from the stomach, to clean it before operation or to liquidate stagnation during period after the operation.

Equipment required: gastric probe (with two channels if possible), Janet syringe, water for lavage (15-20 liters of room temperature water), gloves and watertight apron.

Procedure: gastric lavage of comatose patients is a procedure for doctors. In our country nurses are not allowed to do this without control of the doctor: unconscious patients have inhibited reflexes and thus probe can be easily inserted into the trachea instead of oesophagus. In this situation neither cyanosis nor cough may not appear and everything looks just fine, however feeding or lavage try can end with fatal complications (asphyxia and death).

Put on the gloves, choose the probe of necessary size and oil it with Vaseline. Patient should lie on the left side (ask nurse to hold patient's arms to limit his movements during this unpleasant procedure).

If patient is conscious you can previously use lidocaine spray to anaesthetize mucous membranes. Probe can be inserted through the nose (of course in this case size of the probe is limited) or through the mouse. Don't push too hard, especially when you are using nasal passage: you can cause bleeding. Ask patient to bow his head to the chest – this will increase chances of correct probe insertion (oesophagus, not trachea). The length of probe you insert can be measured in advance as a distance between earlobe, nose and xiphoid.

Confirmations of correct probe placement:

- auscultate the epigastrium and simultaneously infuse some air with the syringe- you will hear typical "bubble" noises;
- if you made a mistake and probe is in the trachea you can notice air released from the distant end of the tube according to the respiratory movements.

One-time water dose is nearly 200 ml: it will flow out when you will lower the probe or you will have to evacuate the water with the syringe. Repeat these actions until the water wash out the stomach will be clean (usually it takes nearly 10 liters of water).

Forced diuresis.

Indications: intoxications of different origin (poisonings, infectious diseases, endogenous intoxications).

Medicines required: normal saline (3-5 liters); detoxification solutions; polarizing solution (400 ml of 10% glucose solution, 10 ml of 7,5% potassium chloride solution, 12 units of insulin), osmotic diuretics (mannitol in the dose 1 g/kg), furosemid solution (40-80 mg)

Procedure: get and i/v line (central or peripheral) and insert urinary catheter. During the first phase of forced diuresis “water” the patient with crystalloids and detoxification solutions (30-40 ml/kg). During the second phase infuse osmotic diuretics and furosemide solution. Excessive urine output brings potassium loss, which you should treat with polarizing solution. Balance the speed of infusion with the speed of diuresis: generally per 5-7 liters of infused solutions you should receive at least 5 liters of urine.

Constantly control hemodynamics and blood electrolytes.

Control tests.

1. What medicine should be used as an antidote in case of severe soporific drugs poisoning?

- A. bemegrade
- B. cordiamin
- C. there is no such medicine
- D. unithiol
- E. cytiton

2. What is the most common death reason in case of alcohol poisoning?

- A. acute liver failure
- B. acute respiratory failure
- C. acute renal failure
- D. acute heart insufficiency
- E. collapse

3. What is necessary for the patient, who took 60 ml of acetic essence?

- A. to give 4% sodium bicarbonate solution i/v
- B. to clean the stomach with alkaline solution in order to neutralize the acid
- C. to use unithiol as an antidote

- D. to stimulate intestinal cleansing with saline laxatives
 - E. central analeptics
4. What is the symptom of organophosphate poisoning?
- A. pale and dry skin
 - B. maximal pupil's dilation
 - C. tachycardia
 - D. muscle fasciculation
 - E. acute liver failure
5. What is used as an antidote in case of severe carbon monoxide poisoning?
- A. cytochrome c
 - B. cordiamin solution
 - C. unithiol
 - D. prednisolone
 - E. antidotes are not used
6. What is typical for deadly amanita poisonings?
- A. first symptoms appear in 2-3 hours after mushroom meal;
 - B. low-grade fever
 - C. latent period of 6-12 hours
 - D. first symptoms are haemostatic disorders (bleeding)
 - E. early unconsciousness
7. What is the necessary aid in case of narcotic painkillers overdose?
- A. artificial ventilation
 - B. cordiamin
 - C. oxygen supply
 - D. immobilization of the patient in order to avoid self-injuries during the excitement-phase;
 - E. cardiac medicines

Task 1.

Patience, the patient of 19 is transported to the ITU by witnesses from the street.

Clinical findings: unconscious, cyanotic wet skin, 6 breathes per minute, respiration shallow, blood pressure 70/40 mm Hg, heart rate 112/minute. Name the reason of vital disorder and write the principles of intensive care (algorithm).

Task 2.

Patience, the patient of 19, was found unconscious in his own apartment by the ambulance workers. Clinical findings: total cyanosis, shallow breathing, respiration rate 5/min, pupils extremely narrowed, photoreaction is absent, blood pressure 80/40 mm Hg. In the elbow area there are noticeable signs of injections. Name the reason of vital disorder and write the principles of intensive care (algorithm).

Task 3.

Patience, the patient of 23 was hospitalized into ITU with the diagnosis: mushroom poisoning. It turned out, that yesterday she was eating cooked champignons. 8 hours later she noticed vomiting and diarrhoea. Clinical findings: scleral icterus, dry coated white tongue; painful abdomen (epigastrium and right hypogastric area), painful and enlarged liver (2 cm); hemodynamics and respiration are not violated.

Write the diagnosis and the phase of the disease.

Task 4.

Patience, the patient of 18, is transported to the toxicology unit with delirium. Clinical findings: hyperaemic face, dry skin, dilated pupils. Blood pressure 140/70 mm Hg, heart rate 127/minute. It is known, that 2 hours ago she took 10 unknown tablets during the suicidal attempt. What is the diagnosis and what are your actions?

Task 5.

Patience, the patient of middle age, was found by the ambulance workers in his own kitchen unconscious. Clinical findings: specific smell of organophosphates in the room, signs of vomit on the clothes, miosis, cold clammy skin with cyanotic shade, foamy white sputum in the mouth, blood pressure 90/50 mm Hg, heart rate 54/minute. What is the diagnosis? What immediate aid should be provided during pre-hospital stage?

Task 6.

Adams family were celebrating the New Year Eve near the fireplace. In the morning came the carol singers and found hosts in a condition of deep sleep. "Dream team", the ambulance workers, who came to the place of the accident, stated: 2 adults and their children in comatose condition, vomit signs on the clothes, rapid breathing, pupils dilated with weak photoreaction; heart rate is 110-120 per minute, rhythmic; blood pressure is high.

Name the reason of the accident and describe the actions of the "Dream team".

Task 7.

Name the poisoning agent for each antidote: a. atropine, b. unithiol, c. naloxone, d. tetacinum, e. ethylic alcohol, f. dipiroximum, g. lipoic acid?

Student should repeat next questions

Among the natural vasoconstrictors (agents, which cause constriction of the blood vessel) are epinephrine, norepinephrine, serotonin, angiotensin II. Stress enhances the secretion of catecholamines, their blood concentration increases and arterioles constrict. Spasm of the arterioles is the basis of blood flow centralization: peripheral flow is disregarded in order to provide brain with the oxygenated blood as long as possible. To the group of vasodilators (agents, which provide dilatation of the vessels) belong “acid” metabolites (lactate, pyruvate, adenylic acid, inosinic acid), bradykinin, acetylcholine, different medicines (neuroleptics, α -adrenergic antagonists, peripheral vasodilators, ganglionic blocking agents, etc.), some exogenous poisons. All of them cause blood flow decentralization: opening of arterioles and distribution of the blood from central vessels to the capillary bed.

Capillaries are the interweaving network of the smallest body vessels with the general length of 90-100 thousands of kilometers. However simultaneously work only 20-25% of them. They provide metabolic exchange bringing oxygen and nutrients to the tissues and take back wastes of metabolism. Periodically, every 30-40 seconds one of them get closed and others open (vasomotion effect). Capillaries contain 12% of the whole circulating blood volume, but different pathological conditions can increase this amount even 3 and more times.

“Used” blood from the capillaries flows to the venous system. Veins are the blood reservoir, which contains 70% of the total circulating blood volume. Unlike arteries they are capable of volume control and thus they influence the amount of blood, which returns to the heart.

The most important haemodynamic index of venous system is central venous pressure. CVP represents the pressure which blood causes to the walls of cava veins and right atrium. This parameter is an integral index of circulating blood volume, systemic vascular resistance and pump function of the heart. It can be measure with a special device called “phlebotonometer” (pic. 4.9) or with a usual infusion set and a ruler. Normally CVP measured from the sternum point is 0-14 cm H₂O and from midaxillary line is 8-15 cm H₂O.

Central venous pressure decreases (sometimes even to negative) in case of:

- blood loss
- excessive water loss (dehydration)

- distributive shock (decrease of peripheral resistance due to venous and arterial dilatation)

In those conditions decreases volume of blood returning to the heart and thus suffers cardiac output. In case of negative CVP cardiac arrest is highly probable.

Central venous pressure increases in case of:

- heart failure (insufficiency of left or right ventricle)
- hypervolemia (excessive blood infusion, improper infusion therapy)
- obstructions to blood flow (pulmonary embolism, cardiac tamponade, etc.)

When CVP over 15-16 cm H₂O is combined with left ventricle insufficiency the risk of pulmonary edema is very high.

Blood pressure is an integral index of arterial part of systemic haemodynamics. Talking about blood pressure we may refer to systolic, diastolic, pulse and mean arterial pressure. Systolic (P_{syst}) and diastolic (P_{diast}) pressures are measured with the manometer (method with the usage of phonendoscope was invented by M. Korotkoff). Pulse pressure (PP) is a difference between systolic and diastolic blood pressure.

Mean arterial pressure (MAP) is calculated according to the formula:

$$\text{MAP} = P_{\text{dias}} + 1/3 \text{ PP} \quad \text{mm Hg}$$

MAP defines the level of pressure necessary for the metabolic exchange in the tissues. Its measurement allows the evaluation of tissue perfusion level.

Blood pressure depends on different factors, but the most important are cardiac output and vascular resistance (mostly arterioles). This dependence is direct, thus you can increase blood pressure using:

- infusion of vasoconstrictors - solutions of epinephrine, phenylephrine (mesaton), etc. (they will increase the vascular resistance);
- infusion of hydroxyethyl starch solutions or saline (they will increase circulating blood volume)
- infusion of cardiac glycosides or other medicine which stimulate myocardium

General volume of blood in the body of a healthy adult is nearly 7% from the body weight: 70 ml per kilogram for male and 65 ml per kilogram of body weight for female. Of

course circulating blood volume is lower, because part of blood is out of metabolic processes as a reserve. CBV can be measured with the infusion of coloring substance to the blood flow (Evans blue, polyglucin) and later evaluation of its dissolution degree.

Therefore measurement of CVP, BP, cardiac output and circulating blood volume allow to evaluate condition of circulation system of the patients and to provide adequate correction.

4.2 Acute heart failure; shock and collapse.

Acute cardiovascular failure is a state of cardiac and vascular inability to provide adequate supply of tissue metabolic needs with oxygenated blood and nutrients. This, earlier or later, causes cellular death.

The reasons of the failure vary greatly: mechanic injuries, blood loss, burns, dehydration, exogenous and endogenous intoxications, immediate hypersensitivity reaction, ischemic heart disease, neural and humoral regulation disorders of vascular tone.

Acute cardiac failure is a disorder of heart pumping action. It develops due to primary heart problems or secondary, under the influence of extracardiac factors such as infection or intoxication. There are two types of heart failure: left-sided and right-sided.

Left-sided heart failure is an inability of left ventricle to pump blood from the pulmonary circuit to the systemic circuit. The most common reasons of it are myocardial infarction, mitral insufficiency, left AV valve stenosis, aortic valve stenosis, aortal insufficiency, hypertonic disease, coronary sclerosis, acute pneumonia.

Coronary circulation is possible only during the diastole and in those conditions every violation of coronary passability decreases cardiac output. This way during the systole part of the blood is not injected into aorta, but stays in the left ventricle. Diastolic pressure in the left ventricle increases and blood is literally forced to stagnate in the left atrium. At the same time right ventricle functions normally and continues to pump usual amounts of blood to the pulmonary circuit. Thus hydrostatic pressure in the vessels of pulmonary circulation increases, fluid part of the blood moves first to the lung tissue and then, through alveolar-capillary membrane, to the alveolar lumen.

Clinically pulmonary edema begins with dyspnea (during physical activity or rest). Later attacks of dyspnea are connected with persistent cough with white or pink blood-tinged phlegm. During the attack patient tries to sit as in this position breathing is easier. This condition is called "heart asthma". When hydrostatic pressure is over 150-200 mm Hg, fluid part of blood moves to the alveolar lumen causing development of pulmonary edema.

Pulmonary edema is divided into interstitial and alveolar edema.

Interstitial edema is a condition during which serous part of stagnated in the pulmonary circuit blood infiltrates the lung tissue, including peribronchial and perivascular spaces.

During alveolar edema not only the plasma, but also blood components (red and white blood cells, platelets) get out from the vessels. During the respiratory act blood mixes with the air creating large amount of “foam”, which violates gas exchange. This way, in addition to circulatory hypoxia, hypoxic hypoxia appears.

Condition of the patient gets worse quickly. Sitting position is optimal, but not as helping as previously. Respiratory rate is nearly 30-35 breathes per minute, but attacks of breathlessness are constant. Skin is pale with acrocyanosis. Hypoxia of central nervous system usually causes psychomotor agitation. Respiratory acts are noisy; during cough pink blood-tinged phlegm is released. Auscultation allows you to hear different wet rales, sometimes it's even possible to hear them standing aside the patient without phonendoscope.

Pulmonary edema can be also divided according to the blood pressure level: the one with elevated pressure is caused by a hypertonic disease, aorta valve insufficiency or disorders of cerebral perfusion; another one is caused by total myocardial infarction, acute inflammation of myocardial muscle, terminal valve defects, severe pneumonia and is characterized with normal or low blood pressure.

Immediate aid

- make sure patient is sitting with his legs down (orthopnea)
- provide oxygenation through nasal catheter (before placing oil it with glycerin, insert it to the depth of 10-12 cm – distance from the wing of the nose to auricle) or face mask. Do not use Vaseline, because it can burn in atmosphere with high concentration of oxygen.

However if catheter is not deep enough patient will suffer from an unpleasant “burning” feeling, because oxygen flow will dry mucosa layer of the nasal cavity; also in this situation concentration of oxygen will be lower than expected.

- put venous tourniquets on the limbs in order to reduce amount of blood returning to heart: venous bed of limbs can reserve up to 1,7 liters of blood;
- constantly control heart and kidney activity (ECG, SaO_2 , and blood pressure are checked automatically through the monitor; to control diuresis you should insert Foley catheter;
- catheterize central vein, because amount of infusions should be based on central venous pressure;
- use medical “defoamers” if they are available (ethyl alcohol or antiphomsylan solution) combined with oxygen inhalation

Scheme of oxygenation set connected to “defoamer” container

- a. oxygen source (cylinder with oxygen)
 - b. tube with numerous holes sunk into container with defoamer
 - c. tube for humidified oxygen (its opening should be over the level of fluid);
 - d. patient
- medical treatment: 1% morphine solution (decreases intravascular pressure of pulmonary circuit, inhibits respiration center in medulla oblongata preventive dyspnea progress, sedates patient);
 - solutions of diuretics are used to decrease the circulating blood volume (6-12 ml of 1% furosemid solution, solution of ethacrynic acid), however be careful with them in case of low blood pressure; diuretic effect will last up to 3 hours after i/v infusion, the expected diuresis is 2-3 liters
 - if blood pressure allows you can try to use nitroglycerin to reduce intravascular pressure of pulmonary circuit (1 or 2 tablets with 10 minutes interval)
 - cardiac glycosides for improvement of heart action (0,025% digoxin solution, 0,05% strophanthin solution, 0,06% corglicon solution);
 - in case of high pressure (over 150 mm Hg) use ganglionic blocking agents (1 ml of 5% pentamin solution diluted in 150 ml of saline, give i/v slowly; diluted with saline 250 mg of trimethaphan solution), because they reduce pressure in pulmonary circuit and lower the amount of blood getting to right half of the heart, however be careful with the dosage and monitor blood pressure level carefully;
 - never use osmotic diuretics in case of pulmonary edema – they will increase blood volume and thus heart load!!!
 - when everything listed above failed and patient is worsening with every second you should intubate him and start artificial ventilation with positive end expiratory pressure (begin with 4-6 cm H₂O)

Right-sided heart failure is an inability of right ventricular to pump blood from systemic circuit to the pulmonary circuit due to its weakness or an obstruction to the blood flow.

It occurs in case of pulmonary embolism, right ventricular infarction, excessive infusion therapy (especially including citrated blood) for patients with heart insufficiency, lung

diseases (bronchial asthma, emphysema, pneumosclerosis) which cause increase of right ventricular load.

Patients have acrocyanosis, tachycardia, dyspnea, pronounced neck veins, ankle swelling, enlarged liver, ascytis. Central venous pressure is highly increased (up to 20-25 cm H₂O), however pulmonary edema does not appear.

Intensive treatment is mostly pathogenetic:

- limit the infusions (give only life-necessary solutions, check the water balance of the patient and reduce drinking water if necessary);
- in case of citrated blood transfusions use 5-10 ml of 10% calcium gluconate solution per every 500 ml of blood to prevent hypocalcaemia;
- in case of bronchial spasm use bronchial spasmolytics;
- to remove excessive fluid from the body use diuretics (furosemide solution for example);
- metabolic acidosis is corrected with 4% solution of sodium bicarbonate (i/v slowly with acid-base state control);
- in case of pulmonary embolism anticoagulants are used – fraxiparine 0,6 mg subcutaneously; heparin solution – 5000 IU every 4 hours; fibrinolytic drugs (streptokinase, fibrinolysin, urokinase, etc.)

Shock is a pathological state which can be described as a tissue hypoxia caused by hypoperfusion. Pathogenetic basis of shock depends on its reason (trauma, toxins, thermal injury) and at the same time on reactivity of the organism (level of defense mechanisms mobilization).

Stimulation of sympathetic nervous system - production of catecholamines and other vasoactive substances by hypothalamus and adrenal glands are the universal response of the body to the stress. Those mediators interact with the receptors of peripheral vessels causing their constriction and at the same time they dilatate the vascular bed of life-important organs. This is so called “centralization of the flow”: rational decrease of blood flow in less important tissues (skin, organs of abdominal cavity, kidneys) in case of aggressive external influence for protecting life itself (brain, heart, lungs).

However influence of shock agents (pain, hypovolemia, destroyed cells, toxic metabolites), extended microcirculation violations (vascular spasm, microthrombosis and sludge) and caused by them tissue ischemia lead to hypoxic affection and cellular death of the internal organs. Further it can bring multiple organ dysfunction syndrome.

Collapse is a vascular failure. It occurs when body is not able to provide blood flow according to the new level of its needs (either because reaction is not fast enough or because sympathetic activation fails). Vascular bed volume and circulating blood volume are disproportional: too much blood gets to the microcirculation vascular reserve and the amount, which returns to the heart is not enough for the systemic needs (so called “decentralization” of the blood flow). Cardiac output and blood pressure decrease, that causes hypoperfusion of the central nervous system and thus unconsciousness and life-threatening complications.

Collapse definition is a bit nominal, because if such reaction extends in time the state of shock develops. Shock itself can equally run as a vascular failure or as a sudden clinical death.

Pathogenetic classification of shock (according to P. Marino, 1998):

- hypovolemic
- cardiogenic
- distributive
- mixed (two and more factors).

Clinical classification of shock:

- traumatic shock;
- haemorrhagic shock;
- dehydration shock;
- burn shock;
- septic shock;
- anaphylactic shock;
- cardiogenic shock;
- exotoxic shock.

4 Shock caused by dehydration

It is a type of hypovolemic shock, which occurs during excessive body fluid loss (not blood, because hemorrhagic shock is another shock type).

Its reasons vary greatly:

- gastrointestinal diseases (profuse vomiting, diarrhea, loss of intestinal fluid through fistula);
- polyuria (uncontrolled diuretic treatment, diabetes mellitus and insipidus, diuretic phase of acute renal failure);
- fluid loss through skin and wound surface (burns, high fever);
- inadequate infusion treatment of postoperative or comatose patients;
- hyperventilation (rapid breathing, Kussmaul breathing, inadequate artificial ventilation parameters in case of apparatus without air humidification).

However not only the complete fluid loss can be the reason of shock, but also it's pathological distribution into the extracellular space (intestinal cavity in case of intestinal paralysis, abdominal cavity in case of ascites, pleural cavity in case of pleurisy). This way will can also act prolonged heavy tissue inflammations (peritonitis) or massive injuries (crush-syndrome).

In cases described above electrolytes are also lost (cations of sodium, potassium, calcium, magnesium; anions of chlorine, hydrocarbonate). It causes complex osmolar, acid-base and electrolytic disorders.

Stage of dehydration shock is evaluated according to the actual fluid loss:

less than 5% of body weight – mild dehydration

5-10% of body weight – moderate dehydration

over 10% of body weight – severe dehydration

Water deficiency brings lowering of cardiac output, blood pressure and central venous pressure (through decrease of blood volume returning to the heart, which leads to compensatory adrenergic vasoconstriction).

Dehydration causes body weight loss, skin and mucosa dryness, decrease of subcutaneous turgor and eyeballs tone, hypothermia, tachycardia, oliguria, thirst. While dehydration progresses compensatory mechanisms weaken and central nervous system suffers: patients become sluggish, confused; hallucinations, cramps and unconsciousness are also possible. Laboratory tests show blood concentration.

One of the most important things in treatment of dehydrated patients is daily balance of fluid: check it carefully trough measuring of daily received and lost fluids (food, infusions, stool and urine output). In case of fever or tachypnea make necessary corrections. Balance should be calculated every 12-24 hours (special paper forms make this easier).

Daily fluid balance is calculated by adding all the received fluids (both enteral and parenteral ways) and deducting urine output, stool, perspiration and breathing water loss.

You should remember, that perspiration depends on body temperature: in case of normal temperature (36,6°C) patient loses 0,5 ml/kg of water during every hour; 1 degree of temperature elevation adds 0,25 ml/kg to normal value of 0,5 ml/kg.

According to the fluid balance infusion therapy is divided into positive (for dehydrated patients), negative (for overhydrated patients) and “zero” (for patients without balance disorders).

Water deficiency is calculated according to the formula:

$$W_{\text{def}} = (Ht_p - Ht_n) * 0,2 \text{ BW} / Ht_n,$$

W_{def} – water deficiency, l;

Ht_p – hematocrit of the patient, l/l;

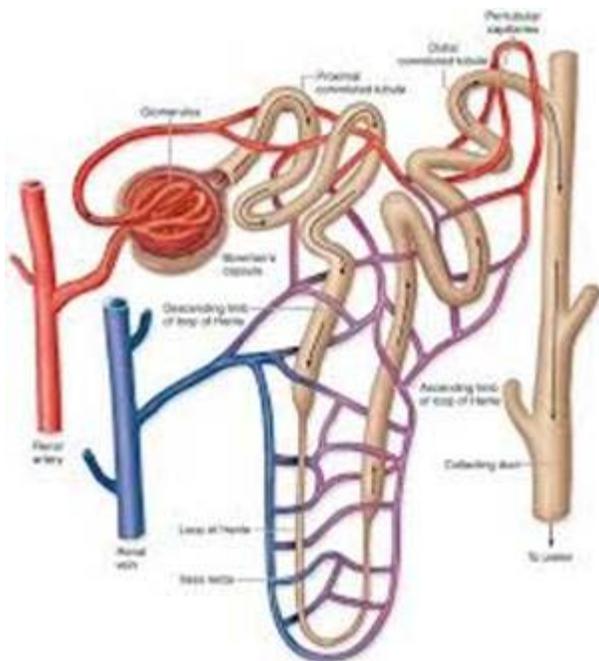

Ht_n - normal hematocrit, l/l;

BW – body weight, kg.

Use crystalloids to treat water deficiency: saline solution, Ringer’s solution, Ringer-lactate solution, electrolytic solutions, 5%, 10, 20% glucose solution. To control potassium concentration (during dehydration this cation is widely lost) prescribe polarizing GIK mixture (pic.9.4), but don’t you ever infuse concentrated potassium solutions quickly – it can cause cardiac arrest (not more than 400 of GIK solution ml per hour).

Acute kidney and hepatic failure

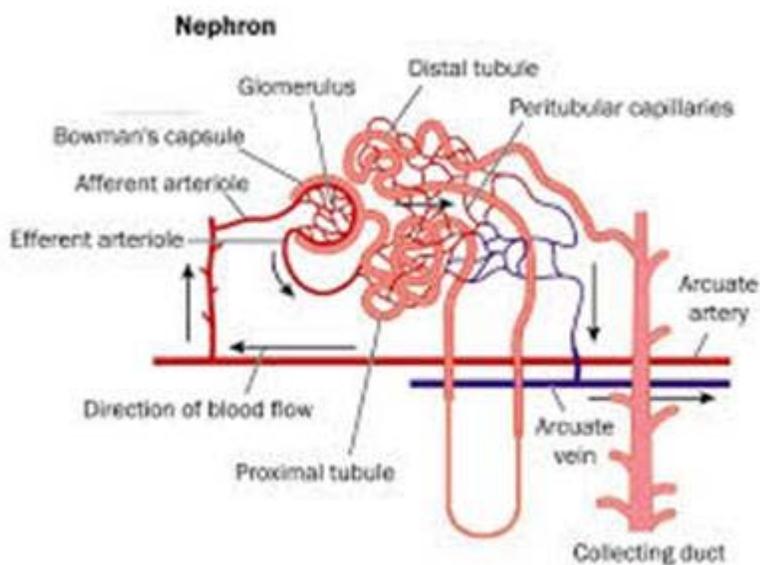

Acute renal failure.

Anatomy and physiology.

Kidneys are the pair organs located in the retroperitoneum (at the level of 12-th rib in the loin region). Their main function is elimination of the metabolic wastes from the organism. They are supplied with blood by paired renal arteries, which are direct arterial branches of abdominal aorta.

Nephron is the basic functional unit of the kidneys. Its structure is quite complicated: it consists of renal corpuscle (Bowman-Shumlanski's capsule and glomerulus), proximal convoluted tubule, loop of Henle, distal convoluted tubule and direct tubule.

Kidneys are exclusively “hard-working” organ. Their total weigh is hardly 0,4% of the total body weight, however they receive 25 % of cardiac output. 10% of total inhaled oxygen are used for their metabolic needs. During the day nearly 150 liters of primary urine are ultrafiltrated out of the blood. Ultrafiltration is possible only when effective filtration pressure is not less than 12 mm Hg. It is defined as a difference between hydrostatic (47 mm Hg), oncotic (25 mm Hg) and intracapsular pressure (10 mm Hg).

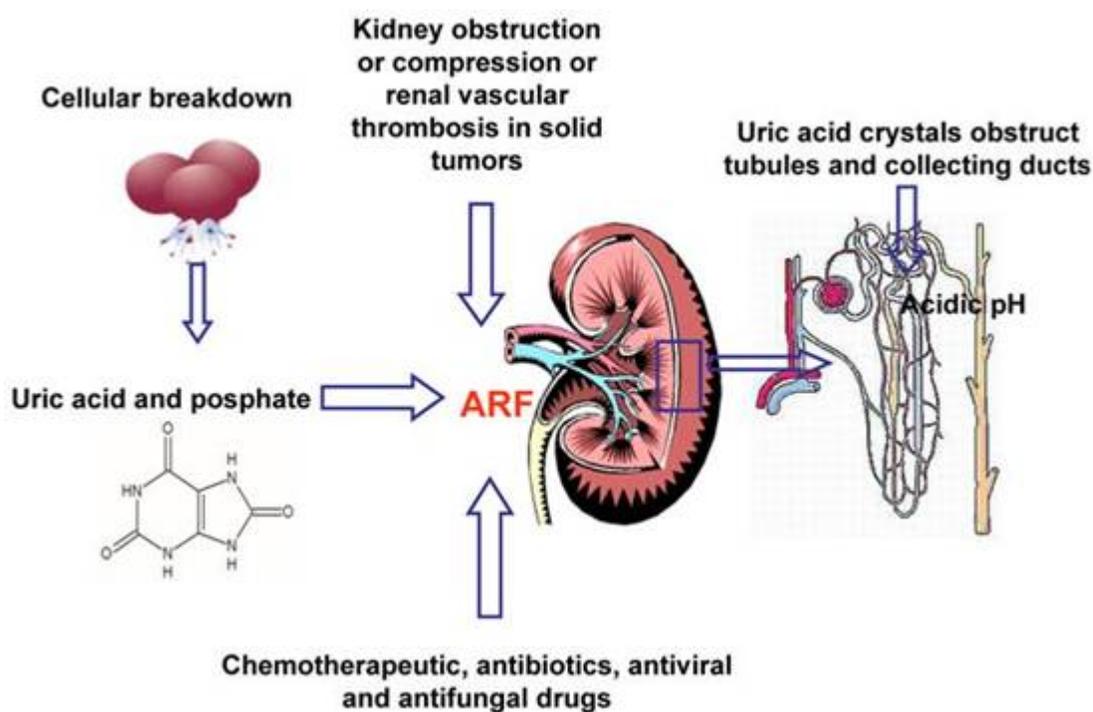

$$EFP = H_p(47) - O_p(25) - I_Cp(10) = 12 \text{ mm Hg}$$

So when hydrostatic pressure (mean arterial pressure) is decreasing or when intracapsular pressure is reaching critical values filtration stops and renal failure appears.

In tubules water, electrolytes and glucose are reabsorbed and metabolic wastes are secreted to the urine. Eventually during one day only 1 % of primary urine is evacuated from the organism in the form of secondary urine with high concentration of toxic substances.

Kidneys participate in haematopoiesis, regulation of fluid balance, electrolytes metabolism and acid-base balance.

Kidneys are also organs of secretion: their parenchyma produces rennin – substance very important for vascular tone regulation.

Etiology and pathogenesis of acute renal failure (acute kidney injury).

Acute kidney injury is a syndrome appearing due to sudden and progressive affection of nephrones, which causes violation of renal function and induces life-threatening homoeostasis disorders.

The reasons of acute kidney injury are divided into 3 groups:

1. Prerenal: pathological conditions, which lower renal blood flow, such as hypovolemia, hypotension, thrombosis, renal artery embolism, renal artery spasm, haemolysis, myolysis (muscle desintegration). Thus the prerenal failure can be connected with the massive blood loss, shock (traumatic, anaphylactic, cardiac), dehydration (burns, pancreatitis, peritonitis, vomiting, diarrhoea), crush-syndrome, transfusion of incompatible blood, acute respiratory failure.

2. Intrinsic: the primary damage is caused to the renal parenchyma by exogenous toxins (alcohol surrogates, acetic acid, ethylene glycol, heavy metal salts), nephrotoxic antibiotics (aminoglycosides), bacterial toxins (in case of sepsis), acute glomerulonephritis, eclampsia.

3. Postrenal: acute renal failure appears due to complications of urine outflow (tumours and calculi of renal pelvis and ureter, prostate, accidental ligation of the ureters during operation).

In 70% of the cases acute renal injury appears as a result of prerenal cause. In stress conditions (massive blood loss, multiple injuries) adrenals intensively produce catecholamines: arterioles of skin, smooth muscles, intestines and kidneys spasm. As you probably remember this helps to save the brain and heart (additional blood for circulating blood volume), however for the rest organs this situation, lasting over 3-4 hours will bring ischemia and even necrosis.

Another mechanism for acute renal failure is connected with the acute vascular insufficiency (collapse, endotoxicosis). Hydrostatic pressure decreases and thus filtration of the blood lowers.

The mechanism of this pathological process is next: hypoperfusion-renal ischemia-hypoxia-coagulation of blood in glomerular vessels-termination of plasma filtration-affectation of tubules membranes- compression of the nephron and capillaries-renal necrosis.

Death of over 75% of nephrons finds its clinical manifestation in acute kidneys injury. All the functions of the kidneys- ultrafiltration, reabsorption, secretion, bioactive substances production – are violated.

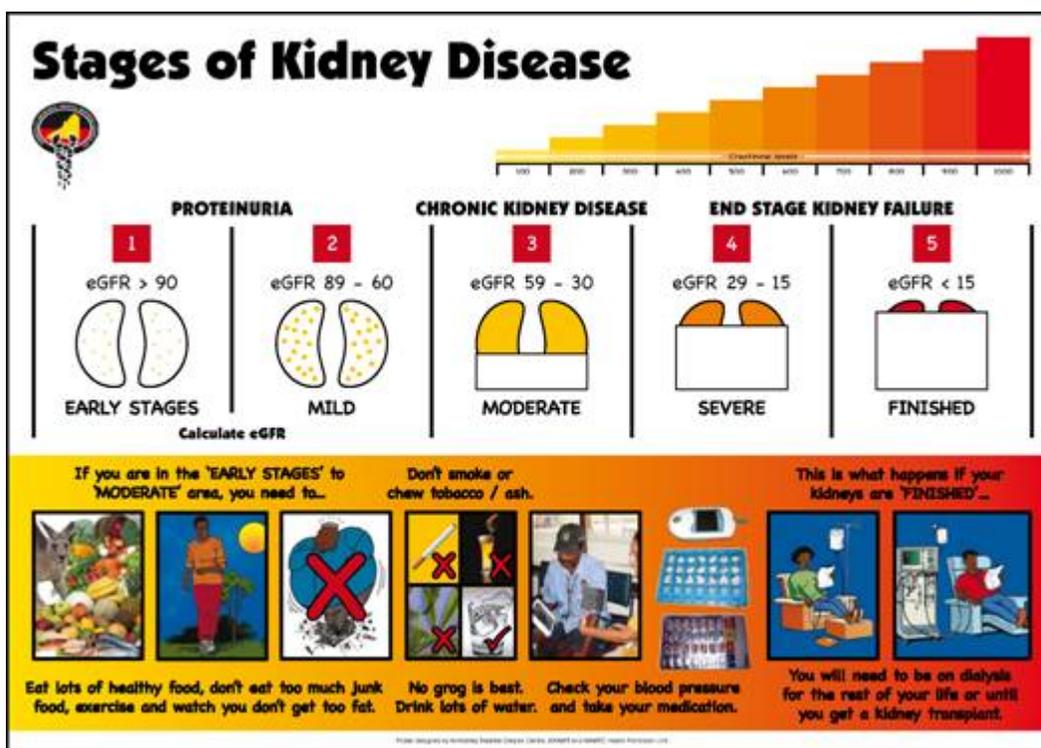

Kidney failure

Acute renal failure (ARF)	A sudden loss of kidney function caused by an illness, an injury, or a toxin that stresses the kidneys (kidney function may recover)
Chronic kidney disease (CKD)	A long and usually slow process where the kidneys lose their ability to function
End-stage renal disease (ESRD)	When the kidneys have completely and permanently shut down

Stages of acute kidneys injury: clinic and treatment.

Clinically in acute kidneys injury we differentiate 5 stages:

I. First stage (initial) is the stage of shock: depends on the initial aggressive agent and duration of its influence. It can last several hours or several days (2-3). Clinic also depends on the causing factor, however first of all you should observe carefully the haemodynamics and urine output, because correct evaluation of patient's condition and proper treatment may prevent the development of next stages.

Warning symptoms are:

- arterial hypotension (systolic blood pressure less than 70 mm Hg if it stays during few hours);
- decrease of urine output;
- hyposthenuria (low specific gravity- less than 1006-1008)

Intensive treatment depends on the primary disease. So you have next possibilities:

1. Hypovolemic shock: profuse bleeding, plasma loss, dehydration.

a. restore the circulating blood volume (blood components transfusions, colloids and crystalloids infusions, glucose solutions) – on time provided correction of circulating blood volume (and you will notice it through normalization of blood pressure, pulse, haemoconcentration indexes and especially central venous pressure) – in most cases means restore of the diuresis.

b. if there is no effect of infusion therapy: to liquidate renal arteries spasm and restore microcirculation give α -adrenoceptor antagonists (droperidol, aminazin, ganglionic blockers, epidural anesthesia); stimulate diuresis with 30% mannitol solution 1 g/kg i/v with the speed 80-100 drops per minute (with 40% glucose solution), 1% furosemid solution (beginning with 2-4 ml every 7-10 minutes and up to 40-50 ml); use additionally spasmolytics (10 ml of 2% euphillin solution i/v with saline). This “triple shot” combined with infusions can liquidate the functional renal failure.

2. Acute vascular insufficiency: anaphylaxis, toxic collapse, orthostatic collapse caused by overdose of ganglionic agents or α -adrenoceptor antagonists; “warm phase” of bacterial shock; reflectory cardiogenic shock.

a. stabilize vascular tone and perfusion pressure with adrenomimetics (epinephrine, dopamine, mezaton i/v, best of all with infusion pump).

b. use steroids, colloids and crystalloids, steroids and then – stimulate the diuresis (described above).

3. Hemolysis (reactions after blood transfusions, hemolytic poisonings, true drowning in sweet water, some snakebites and insect bites, myolysis during crash-syndrome):

a. increase the circulating blood volume providing hemodilution through infusion therapy;

b. increase blood pH infusing 4% solution of sodium bicarbonate (however don't forget to control its level);

c. liquidate spasm of renal arteries;

d. stimulate diuresis.

In case of intense hemolysis, injuries with massive muscle disintegration it would be wise to begin preventive hemodialysis.

4. Renal diseases: normalize hemodynamic indexes, give spasmolytics, stimulate diuresis and use antihypoxic treatment.

5. Postrenal reasons of acute kidneys injury demands immediate consultation of

urologist and decision about operative liquidation of urine flow obstruction (insertion of catheters into the bladder, ureters; epicystostomy, prostatectomy, lithotomy, etc.). Do not stimulate urine output with diuretics until the reason of obturation is not removed!!!

Lack of diuretic effects after stimulation states severe organic injury of nephrons and you should make a diagnosis acute renal failure, stage of oligoanuria.

II. Second stage- oligoanuria- lasts from several days to 3 weeks (duration depends on the degree of the damage and regeneration ability of the nephrons). It can manifest as oliguria (urine output less than 500 ml/day) or anuria (urine output less than 50 ml/day).

The severity of this stage is determined with its symptoms:

1. Overhydration: quite often it is caused by iatrogenic reasons – doctors try to “overfill” patient with the water to stimulate diuresis (outdated and dangerous conception!) or simply calculate the daily fluid balance in a wrong way (too “positive” balance). In addition this phase is characterized with intensive catabolism (tissues destruction) and thus excessive endogenous water production (up to 1500 ml/day). Clinical findings: increase of the body weight, circulating blood volume, blood pressure, central venous pressure, peripheral oedema, possibly pulmonary oedema.

2. Electrolytic disorders: hyperkalemia, hypermagnesemia, hypocalcemia. Clinical findings: depression, somnolence, hyporeflexia, respiratory and cardiac disorders.

3. Metabolic acidosis is caused by accumulation of hydrogen ions due to disorders of their renal secretion. Clinical findings: noisy rapid deep breathing (compensatory Kussmaul breathing), vomiting, evident haemodynamic disorders.

4. Uraemic intoxication. Clinical findings: consciousness disorders (up to coma), ammonia breath odour, uraemic polyserositis (pleuritis, pericarditis), ulceration of oesophageal mucous membrane and gastric mucous membrane, diarrhoea.

5. Disorders of synthetic renal function. Clinical findings: anaemia due to erythropoietin deficiency and hypertension (connected with renin-angiotensin disorders).

Intensive treatment.

Your therapeutic tactic will differ a lot in comparing with the previous phase.

1. Fight with overhydration. First of all medical staff should control carefully body weight gain: ideally correct treatment excludes increase of the weight. Everyday patient loses 400-500 ml of water with respiration. Don't forget to count water loss with vomiting and diarrhea. Infusion therapy should not exceed this total fluid loss and the only solutions you should use are normal saline and 20-40% glucose solutions (with insulin).

2. Control and treat electrolyte disorders: prescribe calcium chloride or calcium gluconate solutions (40-50 ml of 10% solution intravenously). Calcium acts as potassium and magnesium antagonist and thus lowers their plasma concentrations.

3. Treat metabolic acidosis with 4% sodium bicarbonate solution (up to 400-500 ml per day with acid-base control tests). Normalization of blood pH also normalizes potassium level.

4. Catabolism inhibition: to prevent tissues destruction use anabolic hormones (Nerobol, Retabolil) which prevent muscle disintegration and breakdown of the proteins. This helps to reduce endogenous water production and toxins production. For this purpose we are also using concentrated glucose solutions.

5. To eliminate the wastes from the body there are different methods: enterosorbption (enterodez, polisorb, activated charcoal, etc.), intestinal lavage (cleansing enemas 4-6 times a day), extracorporeal detoxification methods (hemodialysis, plasmapheresis, hemosorbption), peritoneal dialysis.

6. Symptomatic treatment: prescribe hypotensive medicines if necessary, preparations for cardiac support, transfuse washed red blood cells. Prevent infectious complications.

Don't forget, that in case of acute kidneys injury withdrawal of many drugs is delayed or interrupted and thus accumulation effects are possible!

Hemodialysis is the process of extracorporeal waste products removal with the help of “artificial kidney”. The principle of its work is quite simple: special pump pushes the blood through the tubes to the dialyzer. Dialyzer itself is a system of capillaries, made of semipermeable membrane (kuprofan, cellophane), which are “immersed” into the dializing solution (something chemically very close to plasma). When blood passes through the capillaries dialysis, osmosis and ultrafiltration take place. During this process toxic wastes (creatinine, urea, uric acid, phosphates, potassium and hydrogen ions) and excessive water move to the dializing solution. Simultaneously ions of sodium and calcium move from the dializing solution into the blood.

According to the method of blood taking and blood return dialysis is conducted

through arterial-venous access or venous-venous access. Aseptic conditions are obligatory; anticoagulants are used in most cases (heparin solution). Average blood speed of 200-250 ml/minute determines duration of dialysis up to 4-5 hours.

Absolute indications to haemodialysis are:

- overhydration (CVP over 15 cm H₂O);
- hyperkalaemia (potassium more than 7 mmol/l);
- creatinine more than 0,3 mmol/l;
- decompensated metabolic acidosis (pH<7,2);
- daily growth of urea > 5 mmol/l, urea level over 35 mmol/l.

Contraindications to haemodialysis:

- unstable haemodynamics (blood pressure less than 90 mm Hg);
- haemorrhagic syndrome;
- decompensated cardiac and respiratory insufficiencies;
- CNS damages (stroke, intracranial haematoma).

III. Third stage is a stage of diuretic function restoring. It begins when the daily urine output becomes more than 500 ml and lasts for 3-5 days. Due to regeneration of the glomeruli blood filtration is gradually restored. Tubules epithelium regenerates a bit slower and thus water reabsorption is still inadequate. Diuresis grows every day and at the end of this phase reaches 1500-2000 ml per day. However urine has low specific gravity and contains large amount of red blood cells and protein. Hyperkalaemia and uraemic intoxication are still dangerous, because wastes elimination is not adequate.

So the intensive treatment is quite similar to the previous stage. You can change the volume of infusions (but again – control the fluid daily balance). When daily urine output will reach physiologic point of 2-3 liters next stage starts.

IV. Fourth stage is a diuretic stage (polyuria). It lasts up to 2 weeks. Daily diuresis increase is 800-1000 ml and daily urine output reaches 7-9 liters. Biochemical blood tests get to the norm (urea, creatinine). Due to excessive diuresis dehydration and electrolyte imbalance develop: potassium and magnesium ions are lost in large amounts and this can bring life-threatening complications.

Intensive treatment is changed: now your task is to restore the circulating blood volume and lost electrolytes reserves. Correction is made according to the laboratory tests and special formulas.

Gradually concentrating ability of kidneys is returned and diuresis is normalized (specific gravity is normalized, electrolytes are reabsorbed).

V. The fifth stage is a stage of recovery. It takes few months or few years to gain complete recovery and for some patients everything will end with a chronic renal failure. In this stage your task is to prescribe symptomatic treatment, proper diet and resort therapy.

Control tests.

1. What is the normal renal blood flow?
 - A. 5-10% of circulating blood volume
 - B. 500 ml/ minute
 - C. $\frac{1}{4}$ of cardiac output
 - D. depends on renal activity
 - E. 40-50% of cardiac output.
2. During the first stage of acute renal failure you should:
 - A. begin hemodialysis;
 - B. provide intensive therapy of shock, normalize microcirculation and stimulate diuresis;
 - C. stop infusions due to overhydration risk;
 - D. perform paranephral block;
 - E. prescribe high doses of furosemide
3. What is a contraindication to hemodialysis?
 - A. potassium level more than 7,0 mmol/l
 - B. CVP>13 cm H₂O
 - C. pH<7,2;
 - D. acute renal failure of III or IV stages;
 - E. prolonged compression of the kidneys
4. Name the symptom atypical for uraemic intoxication:
 - A. metabolic alkalosis
 - B. overhydration
 - C. azotemia;
 - D. anemia;

E. hypocalcaemia

5. In case of III stage of acute renal failure you should:

A. obligatory prescribe furosemide

B. give infusions in the rate 5-10 ml/kg

C. treat respiratory alkalosis

D. first of all begin with the dialysis

E. avoid diuretics

6. The forth stage of acute renal failure:

A. is terminal

B. shows overhydration and hyperkalemia;

C. is characterized with potassium ions loss;

D. needs hemodialysis;

E. shows metabolic acidosis and compensated dyspnea.

Task 1.

What medicines should not be used for treatment of patient with the II stage of acute renal failure?

a. mannitol; b. concentrated glucose solutions; c. heparin; d. plasma; e. panangin; f. normal saline; g. calcium chloride; h. enterodez; i. rheopolyglucin j. magnesium chloride; k.nerobol.

Task 2.

Here are the clinical and laboratory findings of the patient, who is suffering from the lack of urine for 5 days:

Creatinine 0,64 mmol/l; potassium 7,1 mmol/l; urea 41 mmol/l; CVP 14,5 cm H₂O; blood pressure 170/110 mm Hg; heart rate 96/minute.

What treatment should be prescribed?

Task 3.

One week after restore of the diuresis patient with acute renal failure shows such laboratory results: hematocrit 0,5 l/l, plasma sodium 148 mmol/l, plasma potassium 3 mmol/l, chlorine 98 mmol/l. What is the reason for these changes? What changes should be done in the prescriptions?

Violations of homeostasis and their correction.

The importance of the water to the organism.

Life on earth was born in the water environment. Water is a universal solvent for all the biochemical processes of the organism. Only in case of stable quantitative and qualitative composition of both intracellular and extra cellular fluids homeostasis is remained.

The body of an adult human contains 60% of water. Intracellular water makes 40% of the body weight, the water of intercellular space makes 15% of body weight and 5% of body weight are made by the water in the vessels. It is considered that due to unlimited diffusion of water between vessels and extra vascular space the volume of extracellular fluid is 20% of body weight (15%+5%).

Physiologically insignificant amounts of water are distributed beyond the tissues in the body cavities: gastrointestinal tract, cerebral ventricles, joint capsules (nearly 1% of the body weight). However during different pathologic conditions this “third space” can cumulate large amounts of fluid: for example in case of ascites caused by chronic cardiac insufficiency or cirrhosis abdominal cavity contains up to 10 liters of fluid. Peritonitis and intestinal obstructions remove the fluid part of blood from the vessels into the intestinal cavity.

Severe dehydration is extremely dangerous for the patient. Water gets to the body with food and drinks, being absorbed by the mucous membranes of gastro-intestinal tract in total amount of 2-3 liters per day. Additionally in different metabolic transformations of lipids, carbohydrates and proteins nearly 300 of endogenous water are created. Water is evacuated from the body with urine (1,5-2 liters), stool (300 ml), perspiration and breathing (those two reasons are combined as “perspiration loss” and make from 300 to 1000 ml per day).

Water balance is regulated through complicated, but reliable mechanisms. Control over water and electrolytes excretion is realized by osmotic receptors of posterior hypothalamus, volume receptors of the atrial walls, baroreceptors of carotid sinus, juxtaglomerular apparatus of the kidneys and adrenal cortical cells.

When there is a water deficiency or electrolytes excess (sodium, chlorine) thirst appears and this makes us drink water. At the same time posterior pituitary produces antidiuretic hormone, which decreases urine output. Adrenals reveal into the blood flow aldosterone, which stimulates reabsorption of sodium ions in the tubules and thus also decreases diuresis (due to osmosis laws water will move to the more concentrated solution). This way organism can keep precious water.

On the contrary, in case of water excess endocrine activity of glands is inhibited and water is actively removed from the body through the kidneys.

Importance of osmolarity for homoeostasis.

Water sections of the organism (intracellular and extracellular) are divided with semipermeable membrane – cell wall. Water easily penetrates through it according to the laws of osmosis. Osmosis is a movement of water through a partially permeable membrane from the solution with lower concentration to a solution with higher concentration.

Osmotic concentration (osmolarity) is the concentration of active parts in one liter of solution (water). It is defined as a number of miliosmoles per liter (mOsm/l). Normally osmotic concentration of plasma, intracellular and extracellular fluids is equal and varies between 285mOsm/l. This value is one of the most important constants of the organism, because if it changes in one sector the whole fluid of the body will be redistributed (water will move to the environment with higher concentration). Over hydration of one sector will bring dehydration of another. For example, when there is a tissue damage concentration of active osmotic parts increases and water diffuses to this compartment, causing oedema. On the contrary plasma osmolarity decreases, when there is a loss of electrolytes and osmotic concentration of the cellular fluid stays on the previous level. This brings cellular oedema, because water moves through the intracellular space to the cells due to their higher osmotic concentration.

Cerebral oedema appears when the plasma osmolarity is lower than 270 mOsm/l. Activity of central nervous system is violated and hyposmolar coma occurs. Hyperosmolar coma appears when the plasma osmolarity is over 320 mOsm/l: water leaves the cells and fills the vascular bed and this leads to cellular dehydration. The sensitive to cellular dehydration are the cells of the brain.

Plasma osmolarity is measured with osmometer. The principle of measurement is based on difference in freezing temperature between distilled water and plasma. The higher is the osmolarity (quantity of molecules) the lower is freezing temperature.

Plasma osmotic concentration can be calculated according to the formula:

$$\text{Osmotic concentration} = 1,86 * \text{Na} + \text{glucose} + \text{urea} + 10,$$

Plasma osmolarity (osmotic concentration) – mOsm/l

Na- sodium concentration of plasma, mmol/l

Glucose- glucose concentration of the plasma, mmol/l

Urea- urea concentration of the plasma, mmol/l

According to this formula sodium concentration is the main factor influencing plasma osmolarity. Normally sodium concentration is 136-144 mmol/l. Water and electrolytes balance can be violated with external fluid and electrolytes loss, their excessive inflow or wrong distribution.

9.3 Fluid imbalance and principles of its intensive treatment.

Water imbalance is divided into dehydration and overhydration.

Dehydration is caused by:

- excessive perspiration in conditions of high temperature;
- rapid breathing (dyspnea, tachypnea) or artificial ventilation without humidification of the air;
- vomiting, diarrhoea, fistulas;
- blood loss, burns;
- diuretics overdose;
- excessive urine output;
- inadequate enteral and parenteral nutrition or infusion therapy (comatose patients, postoperative care);
- pathological water distribution (“third space” in case of inflammation or injury).

Dehydration signs: weight loss, decrease of skin turgor and eyeballs tone, dry skin and mucous membranes; low central venous pressure, cardiac output and blood pressure (collapse is possible); decreased urine output and peripheral veins tone; capillary refill over 2 seconds (microcirculation disorders) and low skin temperature; intracellular dehydration is characterized with thirst and consciousness disorders. Laboratory tests show blood concentration: hematocrit, hemoglobinconcentration, protein level and red blood cells concentration increase.

Overhydration appears in case of:

- excessive water consumption, inadequate infusion therapy;
- acute and chronic renal failure, hepatic and cardiac insufficiency;
- disorders of fluid balance regulation;
- low protein edema.

Clinical findings in case of overhydration are: weight gain, peripheral oedema, transudation of the plasma into the body cavities (pleural, abdominal), high blood pressure and central venous pressure. In case of intracellular overhydration appear additional symptoms: nausea, vomiting, signs of cerebral edema (spoor, coma). Laboratory tests prove hemodilution.

According to the osmotic concentration of plasma dehydration and overhydration are divided into hypotonic, isotonic and hypertonic.

Isotonic dehydration is caused by equal loss of electrolytes and fluid from the extracellular space (without cellular disorders). Blood tests show hemoconcentration; sodium level and osmotic concentration are normal.

To treat this type of water imbalance use normal saline solution, Ringer solution, glucose-saline solutions, etc.. The volumes of infusions can be calculated according to the formula:

$$V_{H_2O} = 0,2 * BW * (H_{tp} - 0,4) / 0,4 ,$$

V_{H_2O} – volume of infusion, l

H_{tp} – patient's hematocrit, l/l,

BW – body weight, $0,2 * BW$ – volume of extracellular fluid,

0,4- normal hematocrit, l/l,

Hypertonic dehydration is caused by mostly water loss: first it appears in the vascular bed, than in the cells. Laboratory tests show hemoconcentration: elevated levels of proteins, red blood cells, hematocrit. Plasma sodium is over 155 mmol/l and osmotic concentration increases over 310 mOsm/l.

Intensive treatment: if there is no vomiting allow patients to drink. Intravenously give 0,45% saline solution and 2,5 % glucose solution, mixed with insulin. The volume of infusions is calculated according to the formula:

$$V_{H_2O} = 0,6 * BW (N_{ap} - 140) / 140,$$

V_{H_2O} – water deficiency, l

Na_p – plasma sodium, mmol/l

BW – body weight, 0,6*BW volume of general body fluid

140 – physiological plasma sodium concentration

Hypotonic dehydration is characterized with clinical features of extracellular dehydration. Laboratory tests show decrease of sodium and chlorine ions. Those changes cause intracellular movement of the water (intracellular overhydration). Hemoglobin, hematocrit and protein levels are increased. Sodium is lower than 136 mmol/l, osmolarity is lower than 280 mOsm/l.

To treat this type of water imbalance use normal or hypertonic saline and sodium bicarbonate solution (depends on blood pH). Do not use glucose solutions!

The deficiency of electrolytes is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 \text{ BW},$$

Na_d – sodium deficiency, mmol

Na_p – plasma sodium, mmol/l

BW – body weight, 0,2 BW – volume of extracellular fluid

Isotonic overhydration is caused by excess of the water in the vascular bed and extracellular space; however intracellular homeostasis is not violated. Hemoglobin is less than 120 g/l, protein level is less than 60 g/l, plasma sodium is 136-144 mmol/l, osmotic concentration is 285-310 mOsm/l.

Treat the reason of imbalance: cardiac failure, liver insufficiency, etc. Prescribe cardiac glycosides, limit salt and water consumption. Give osmotic diuretics (mannitol solution 1,5 g/kg), saluretics (furosemide solution 2 mg/kg), aldosterone antagonists (triamterene – 200 mg), steroids (prednisolone solution 1-2 mg/kg) albumin solution if necessary (0,2-0,3 g/kg).

Hypertonic overhydration is a state of extracellular electrolytes and water excess combined with intracellular dehydration. Blood tests show decrease of hemoglobin, hematocrit, protein level, however sodium concentration is increased over 144 mmol/l, osmotic concentration is over 310 mOsm/l.

To treat this condition use solutions without electrolytes: glucose with insulin, albumin solutions and prescribe saluretics (furosemide solution), aldosterone antagonists

(spironolactone). If it is necessary perform dialysis and peritoneal dialysis. Do not use crystalloids!

Hypotonic overhydration is a state of extracellular and intracellular water excess. Blood tests show decrease of haemoglobin, hematocrit, proteins, sodium and osmotic concentration. Intensive therapy of this condition includes osmotic diuretics (200-400 ml of 20% mannitol solution), hypertonic solutions (50 ml of 10% saline intravenously), steroids. When it is required use ultrafiltration to remove water excess.

Electrolytes disorders and their treatment

Potassium is a main intracellular cation. Its normal plasma concentration is 3,8-5,1 mmol/l. Daily required amount of potassium is 1 mmol/kg of body weight.

Potassium level less than 3,8 mmol/l is known as kaliopenia. Potassium deficiency is calculated according to the formula:

$$K_d = (4,5 - K_p) * 0,6 \text{ BW}$$

K- potassium deficiency, mmol;

K_p – potassium level of the patient mmol/l;

$0,6 * \text{BW}$ – total body water, l.

To treat this state use 7,5% solution of potassium chloride (1ml of this solution contains 1 mmol of potassium). Give it intravenously slowly with glucose and insulin (20-25 ml/hour). You can also prescribe magnesium preparations. Standard solution for kaliopenia treatment is:

10% glucose solution 400 ml

7,5% potassium chloride solution 20 ml

25% magnesium sulphate solution 3 ml

insulin 12 units

Give it intravenously slowly, during one hour. Forced bolus infusion of potassium solutions (10-15 ml) can bring cardiac arrest.

Potassium level over 5,2 mmol/l is a state called hyperkalemia. To treat this condition use calcium gluconate or calcium chloride solutions (10 ml of 10% solution intravenously), glucose and insulin solution, saluretics, steroids, sodium bicarbonate solution. Hyperkalemia over 7 mmol/l is an absolute indication for dialysis.

Sodium is the main extracellular cation. Its normal plasma concentration is 135-155 mmol/l. Daily required amount of potassium is 2 mmol/kg of body weight.

Sodium concentration which is lower than 135 mmol/l is known as hyponatraemia. This condition is caused by sodium deficiency or water excess. Sodium deficiency is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 \text{ BW},$$

Na- sodium deficiency, mmol;

Na_p – sodium concentration of the patient mmol/l;

0,2*BW – extracellular fluid volume, l.

To treat it use normal saline (1000 ml contains 154 Na mmol) or 5,8% solution of sodium chloride – your choice will depend on osmotic concentration.

Sodium concentration over 155 mmol/l is a state called hypernatremia. This condition usually appears in case of hypertonic dehydration or hypertonicoverhydration. Treatment was described in the text above.

Chlorine is the main extracellular anion. Its normal plasma concentration is 98-107 mmol/l. Daily requirement of chlorine is 215 mmol.

Hypochloremia is a condition of decreased plasma chlorine concentration (less than 98 mmol/l).

Chlorine deficiency is calculated according to the formula:

$$Cl_d = (100 - Cl_p) * 0,2 \text{ BW},$$

Cl_d- chlorine deficiency, mmol

Cl_p – plasma chlorine concentration of the patient, mmol/l

0,2*BW – extracellular fluid volume, l.

To treat hypochloremia use normal saline (1000 ml contains 154 mmol of chlorine) or 5,8% sodium chlorine solution (1 ml contains 1 mmol of chlorine). The choice of solution depends on the osmotic concentration of the plasma.

Hyperchloremia is a condition of increased chlorine concentration (over 107 mmol/l). Intensive therapy of this state includes treatment of the disease, which caused it (decompensated heart failure, hyperchloremic diabetes insipidus, glomerulonephritis).

You can also use glucose, albumin solutions and dialysis.

Magnesium is mostly an intracellular cation. Its plasma concentration is 0,8-1,5 mmol/l. Daily requirement of magnesium is 0,3 mmol/kg.

Hypomagnesemia is a state of decreased magnesium concentration: less than 0,8 mmol/l. Magnesium deficiency is calculated according to the formula:

$$Mg_d = (1,0 - Mg_p) * 0,6BW,$$

Mg_d - magnesium deficiency, mmol

Mg_p – plasma magnesium concentration of the patient, mmol/l

$0,6 * BW$ – extracellular fluid volume, l.

Use 25% magnesium sulphate solution to treat this state (1 ml of it contains 0,5 mmol of magnesium).

Hypermagnesemia is a state of increased magnesium concentration (more than 1,5 mmol/l). This condition appears usually in case of hyperkalemia and you should treat it as you treat hyperkalemia.

Calcium is one of the extracellular cations. Its normal concentration is 2,35-2,75 mmol/l. Daily requirement of calcium is 0,5 mmol/kg.

Calcium concentration less than 2,35 mmol/l is called hypocalcemia. Calcium deficiency is calculated according to the formula:

$$Ca_d = (2,5 - Ca_p) * 0,2 BW,$$

Ca_d – calcium deficiency, mmol

Ca_p – plasma calcium concentration of the patient, mmol/l

$0,2 * BW$ – extracellular fluid volume, l.

To treat this state use 10% calcium chloride (1 ml of the solution contains 1,1 mmol of calcium), ergocalciferol; in case of convulsions prescribe sedative medicines.

Hypercalcemia is a condition with increased calcium concentration (over 2,75 mmol/l). Treat the disease, which caused it: primary hyperparathyroidism, malignant bone tumors, etc. Additionally use infusion therapy (solutions of glucose with insulin), steroids, dialysis and hemosorbtion.

Acid-base imbalance and its treatment.

There are 2 main types of acid-base imbalance: acidosis and alkalosis.

pH is a decimal logarithm of the reciprocal of the hydrogen ion activity. It shows acid-base state of the blood.

Normal pH of arterial blood is 7,36-7,44. Acid based imbalance is divided according to the pH level into:

pH 7,35-7,21 – subcompensated acidosis

pH < 7,2 – decompensated acidosis

pH 7,45-7,55 – subcompensated alkalosis

pH > 7,56 – decompensated alkalosis

Respiratory part of the acid-base imbalance is characterized with pCO₂. Normally pCO₂ of arterial blood is 36-44 mm Hg. Hypercapnia (pCO₂ increased over 45 mm Hg) is a sign of respiratory acidosis. Hypocapnia (pCO₂ less than 35 mm Hg) is a symptom of respiratory alkalosis.

Basis excess index is also a characteristic of metabolic processes. Normally H⁺ ions produced during metabolic reactions are neutralized with buffer system. BE of arterial blood is 0±1,5. Positive value of BE (with +) is a sign of base excess or plasma acid deficiency (metabolic alkalosis). Negative value of BE (with -) is a symptom of bases deficiency, which is caused by acid neutralization in case of metabolic acidosis.

Respiratory acidosis (hypercapnia) is a condition caused by insufficient elimination of CO₂ from the body during hypoventilation. Laboratory tests show:

pH < 7,35,

pCO_{2a} > 46 mm Hg

BE - normal values

However when the respiratory acidosis progresses renal compensation fails to maintain normal values and BE gradually increases. In order to improve this condition you should treat acute and chronic respiratory violations. When pCO₂ is over 60 mm Hg begin artificial lung ventilation (through the mask or tube; when the necessity of ventilation lasts longer than 3 days – perform tracheostomy).

Respiratory alkalosis (hypocapnia) is usually an effect of hyperventilation, caused by excessive stimulation of respiratory centre (injuries, metabolic acidosis, hyperactive metabolism, etc.) or wrong parameters of mechanical ventilation. Gasometry shows:

pH > 7,45,

pCO_{2a} < 33 mm Hg

BE < +1,5 mmol/l.

However prolonged alkalosis brings decrease of BE due to compensatory retention of H⁺ ions. To improve this imbalance treat its reason: normalize ventilation parameters; if patient breathing has rate over 40 per minute – sedate the patient, perform the intubation and begin artificial ventilation with normal parameters.

Metabolic acidosis is characterized with absolute and relative increase of H⁺ ions concentration due to acid accumulation (metabolic disorders, block of acid elimination, excessive acid consumption in case of poisonings, etc.). Laboratory tests show:

pH < 7,35,

pCO_{2a} < 35 mm Hg

BE (-3) mmol/l.

Treat the main reason of acid-base disorder: diabetic ketoacidosis, renal insufficiency, poisoning, hyponatremia or hyperchloremia, etc. Normalize pH with 4% sodium bicarbonate solution. Its dose is calculated according to the formula:

$$V = 0,3 * BE * BW$$

V- volume of sodium bicarbonate solution, ml

BE – bases excess with “-”, mmol/l

BW – body weight, kg

Metabolic alkalosis is a condition of absolute and relative decrease of H⁺ ions concentration. Blood tests show:

pH > 7,45,

pCO_{2a} normal or insignificantly increased (compensatory reaction)

BE 3,0 mmol/l.

To treat this condition use “acid” solutions, which contain chlorides (saline, potassium chloride). In case of kaliopenia give potassium solutions.

Respiratory and metabolic imbalances can mix in case of severe decompensated diseases due to failure of compensatory mechanisms. Correct interpretation of these violations is possible only in case of regular and iterative gasometry blood tests.

Control tasks.

Task 1.

Calculate the total body water volume and its extracellular and intracellular volumes of the Patient, the patient of 48 years and body weight 88 kg.

Task 2.

Patient, the patient of 23 with body weight 70 kg has sodium level 152 mmol/l and hematocrit 0,49 l/l. Name the type of water balance disorder.

Task 3.

Patient, the patient of 54 with body weight 76 kg has sodium level 128 mmol/l. Calculate the volume of saline and 7,5% sodium chloride solution necessary for the treatment of this condition.

Task 4.

Patient, the patient of 60 with body weight 60 kg has sodium level 140 mmol/l and hematocrit 0,55 l/l. Name the type of disorder and prescribe infusion therapy.

Task 5.

Patient, the patient of 42 with body weight 80 kg has potassium level 2,6 mmol/l. Calculate the volume of 4% potassium chloride solution necessary for treatment of this condition.

Task 6.

Patient, the patient of 33 with body weight 67 kg and diagnosis “gastric ulcer, complicated with pylorostenosis” has potassium concentration 3 mmol/l, chlorine concentration 88 mmol/l. pH 7,49, pCO_{2a} 42 mm Hg, BE + 10 mmol/l. Name the type of disorder.

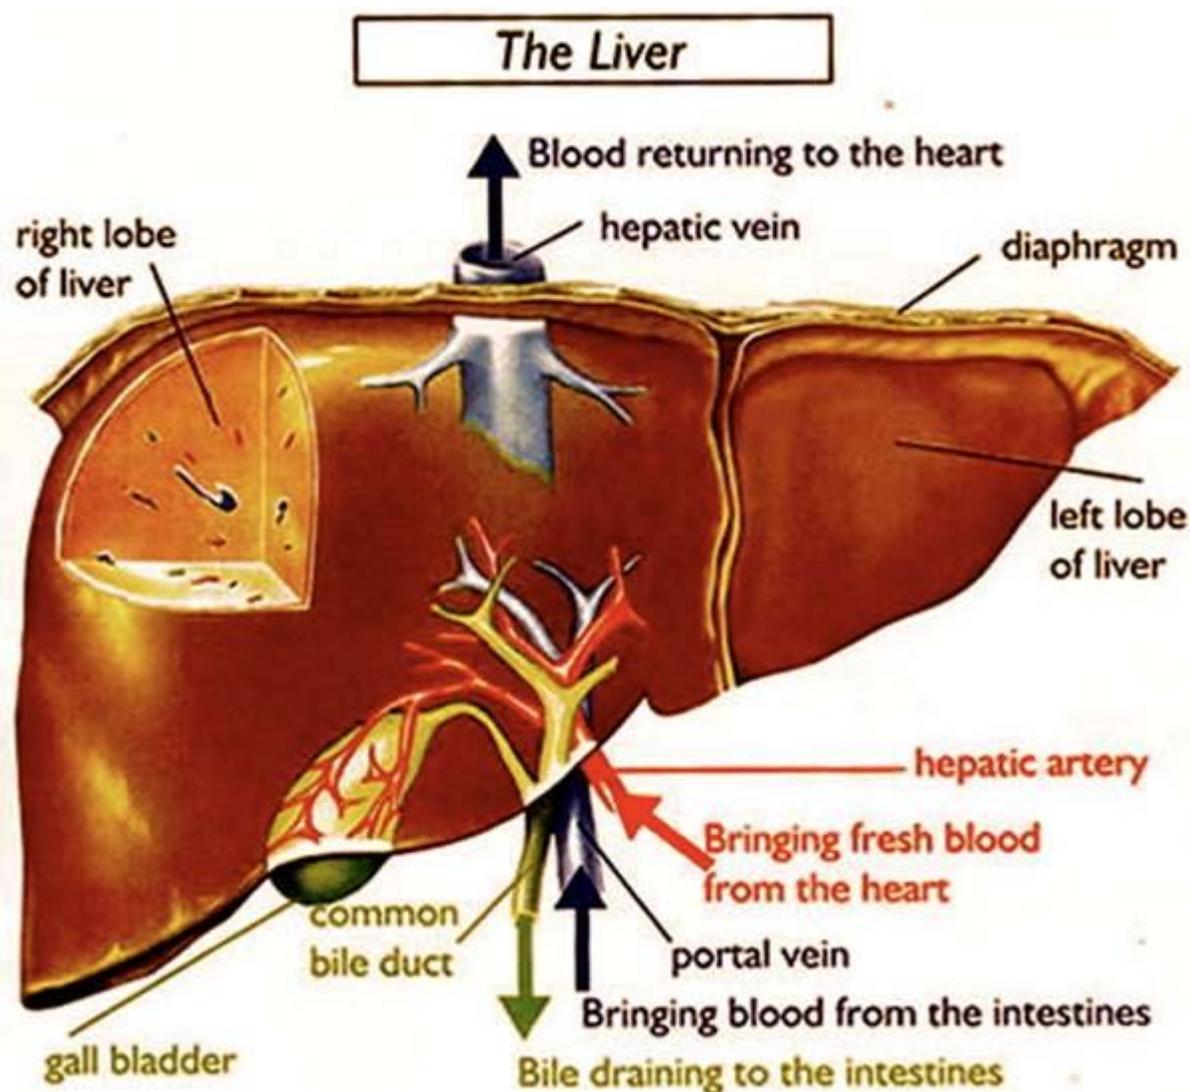

Task 7.

Patient, the patient of 50 with body weight 75 kg, was transported to the admission unit of the hospital with: unconsciousness, cyanotic skin, low blood pressure, shallow breathing. Blood tests show: pH 7,18, pCO_{2a} 78 mm Hg, pO_{2A} – 57 mm Hg, BE -4,2 mmol/l. Name the type of acid-base disorder and prescribe treatment.

Task 8.

Patient, the patient with body weight 62 kg and renal insufficiency has: potassium concentration 5,2 mmol/l, sodium concentration 130 mmol/l, calcium concentration 1,5 mmol/l, pH 7,22, pCO_{2a} 34 mm Hg, BE -9,2 mmol/l. Name the type of disorder.

Acute liver failure.

Anatomy and physiology.

Liver is the largest internal organ, unpaired triangular gland located in the right upper quadrant of the abdominal cavity, below the diaphragm. It is extremely important to the organism because of the variety of activities it performs. Liver is a digestive gland (produces and excretes bile necessary for lipids consumption), a detoxification centre (microsomal oxidation allows detoxification of exogenous and endogenous toxic substances) and a synthetic center, where proteins, lipids and carbohydrates are metabolized. Liver is also an organ of haematopoiesis and a blood reservoir. Additionally it helps to control acid-base balance.

To provide its metabolic needs with the oxygen organism gives nearly 25% of total consumed oxygen; in case of severe intoxication this number growth up to 40% of the total oxygen. Blood flow of the liver is for 25% provided by hepatic arteries and for 80% by the portal vein. Thus the blood liver receives is poorly oxygenated and any hypoxic condition

will bring oxygenation disorders first of all to the tissues of the liver. This evolutionary resulted in unique regeneration abilities of the liver: death of 70% of cells will end up with a failure; however after a certain adaptation period hepatic tissues will restore their quantity and quality.

Cause	Examples	Comment
Drugs and Toxins	<ul style="list-style-type: none"> ❖ Acetaminophen ❖ Amanita phalloides ❖ Isoniazid ❖ Halothane 	Acetaminophen poisoning is the overall leading cause of ALF in the US
Viral Infection	<ul style="list-style-type: none"> ❖ Hepatitis A ❖ Hepatitis B (+/-D) ❖ Hepatitis E ❖ Herpes simplex virus 	Hepatitis C is a very rare cause of ALF
Vascular problems	<ul style="list-style-type: none"> ❖ Shock ❖ Heat stroke ❖ Tumor infiltrating the liver 	Most often seen after cardiac arrest, major blood loss, or iatrogenic ligation of the major blood vessels feeding the liver
Metabolic/Miscellaneous	<ul style="list-style-type: none"> ❖ Wilson Disease ❖ Acute fatty liver of pregnancy ❖ Alpha-1 antitrypsin deficiency ❖ Autoimmune hepatitis 	Family screening is appropriate for many metabolic/genetic causes of ALF
Indeterminate	<ul style="list-style-type: none"> ❖ Unknown 	Approximately 15%-20% of adult ALF cases, and up to 50% of ALF in children, cannot be attributed to a specific cause.

Acute liver failure: aetiology and pathogenesis.

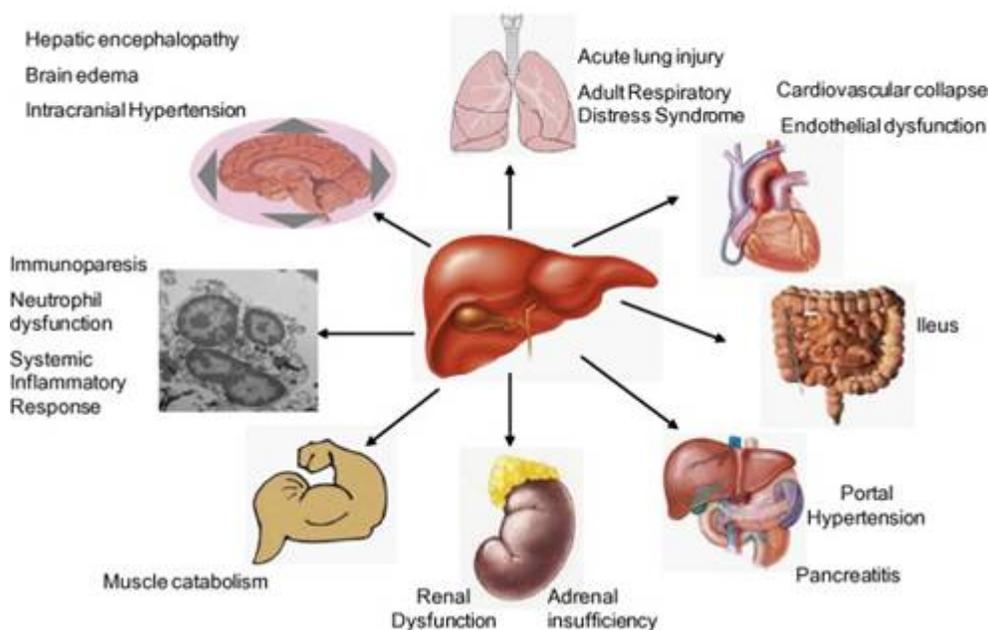

Acute liver failure is a state of hepatic cells dysfunction, caused by unknown earlier liver disease, resulting in general intoxication, coagulation violations, neurological and mental disorders. Its etiology is usually connected with: viral hepatitis (hepatitis B virus, hepatitis A virus), poisonings (mushrooms, dichlorethane, phosphorus, carbon tetrachloride, arsenic), eclampsia, burn disease, anaesthetic gas, antibiotics, sulfanilamides, massive bacterial pneumonia, cirrhosis, hepatic tumours and metastasis.

Advanced liver failure manifests in coma. Hepatic coma is divided into endogenous (“destructive”, hepatocellular) and exogenous (“shunt”, porto-caval). Toxic damage of 70% of liver cells will cause endogenous coma. In case of liver cirrhosis high portal pressure antagonizes portal blood flow and thus most of the blood moves to the caval venous system and is not detoxified – exogenous coma appears. Clinically we usually observe mixed comas.

Central nervous system in case of lever failure is affected in various ways. Ammonia

encephalopathy appears because of violations of uric acid synthesis (it is made from ammonia and without this process ammonia concentration increases several times). Food rich with proteins stimulates ammonia encephalopathy onset, as well as gastrointestinal bleedings, hypnotic medicines and opiates, alcohol, surgeries, infections and metabolic alkalosis. In the CNS tissues false mediators like octopamine, amino acids and their toxic metabolites are accumulated. On the background of hypoproteinemia interstitial edema appears and this brings respiratory hypoxia of tissues. At the same time violated synthesis of enzymes, disordered metabolism of carbohydrates and lipids, metabolic alkalosis with hypokalaemia just advance the encephalopathy.

Systemic Manifestations of Acute Liver Failure

Clinical findings in case of liver failure.

Liver failure has several forms:

1. Excretory form (disorders are mostly connected with bile production, jaundice is the main characteristic).
2. Vascular form (clinically portal hypertension is the most noticeable).
3. Hepatocellular form (most clinical signs are caused by disorders of synthetic metabolism in liver cells).

According to the duration of the process we define acute and chronic liver failure, according to the compensation level - compensated, subcompensated and decompensated failure.

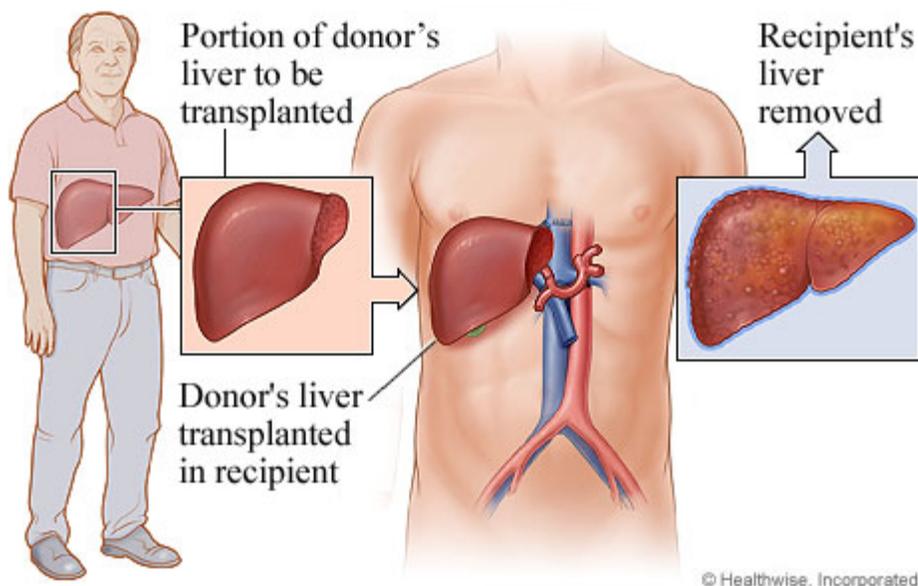

Central nervous system is damaged gradually: it begins with precoma and progresses into moderate and deep coma.

Clinical findings:

- skin: jaundice, vascular spiders, “hepatic” palm, extension of small superficial face vessels;
- fever;
- hepatic breath odour, hepatic smell of sweat and urine (this smell occurs due to transformation of methionine into methyl mercaptan);
- digestion disorders (nausea, hiccups, inappetence, smooth red tongue, abdominal pain, meteorism, defecation disorders);
- obstructive and diffuse respiration disorders – hypoxic hypoxia;
- cardiovascular disorders (arterial hypotension, tachycardia, extrasystoles);
- haemorrhagic syndrome, anemia (due to interruption of coagulation factors synthesis and bleeding of gastric or oesophageal erosions and ulcers);
- frequent additional complications: renal failure, hepatorenal syndrome is prognostically dangerous.

If liver failure progresses CNS damage deepens and you can clinically observe: weakness, headache, sluggishness, apathy, inversion of sleep and awakening. Disorientation develops gradually, there is possibility of excitement periods and cramps. You can also find overactive tendon reflexes, foot clonus, Babinski’s sign. One of the most significant symptoms is flapping: trepidation of limbs and face, especially of hands in prone position (arms extended). In case of deepest coma you will see dilated pupils, eyeballs are fixed, tendon reflexes are absent.

Progressive and quick decrease of liver size is a prognostically bad sign. However when the disease is chronic and fibrous changes took place this symptom is not noticed (liver stays enlarged).

Intensive treatment.

The basic principle of liver failure treatment is etiologically aimed therapy: you should treat the reason of the failure. Two other important components are prevention and treatment of liver failure complications during 10-14 days necessary for the regeneration of the hepatocytes.

Necessary treatment measures:

1. Patient should follow strictly bed regiment in isolated ward. Medical staff should follow aseptic and antiseptic rules.

2. Eliminate animal fats and proteins from the patient's diet to prevent encephalopathy.

3. Liquidate hepatotoxic factors (hypoxia, hypovolemia, haemorrhagic syndrome, intoxication):

- provide oxygen supply (nasal catheter, face mask with the flow 3-4 l/min); sometimes hyperbaric oxygenation and even intestinal oxygenation (0,2-0,3 ml/kg/min) are possible;

- to increase hepatic blood flow restore the circulating blood volume, improve rheological properties of the blood, restore the peristalsis. To achieve this you should: infuse crystalloids and glucose solutions, spasmolytics, 2 % eufhyllin solution (20-30 ml/day). 10% albumin solution (200-300 ml) and mannitol solution (1 g/kg) increase oncotic blood pressure and thus help to prevent interstitial oedema of the liver;

- prevent ulceration of stomach and gastrointestinal bleeding by prescription of famotidine or omeprazole (40 mg twice a day); oesophageal bleedings are stopped with Blackmore probe;

- if you suspect stagnated blood in the intestines – remove it, because otherwise intoxication will get more intense;

- use only “fresh” blood stabilized with heparin for transfusions.

Prevent and treat intoxication with:

- intestinal lavage and enemas;

- antibiotics which are not toxic to the liver (for example ampicillin 1,0 every 4 hours);

- extracorporeal blood detoxification (plasmapheresis, hemosorbition or hemodialysis; usage of artificial liver or artificial spleen);

- prescribe antagonists of ammonium (40-50 ml of 1% glutamic acid solution with glucose 3 times a day; 2,0 of alfa-arginine solution i/v every 8 hours).

4. To stimulate energetic metabolism in hepatocytes prescribe concentrated glucose solutions (10-20% solutions, up to 5g/kg/day). This will also prevent proteins breakdown and thus wastes accumulation.

5. To stabilize the membranes of the hepatocytes prescribe steroids (10-15 mg/kg of hydrocortisone).

6. To stabilize the energetic exchange and stimulate transportation of the lipids prescribe choline chloride (10 ml of 10% solution with 200 ml of glucose solution after previous atropine admission, twice a day).

7. Additionally prescribe vitamins (ascorbic acid, B₁, B₂, B₆, K, E, B₁₂, folic and nicotinic acids in doses 2-3 times higher than daily needs), cardiac glycosides, panangin, antioxidants (cytochrome c, sodium gamma-hydroxybutyrate).

8. Symptomatic treatment helps to stabilize homoeostasis if not to treat failure itself: if necessary use anticonvulsive medicines, antipyretics, etc.

Control tests.

1. The reason of exogenous liver failure is:

A. acute exogenous poisoning

B. exogenous shock

C. hepatitis B

D. hepatic cirrhosis

E. hyperbilirubinemia

2. The reason of endogenous liver failure is:

- A. oesophageal bleeding
- B. acute carbon monoxide poisoning
- C. infectious shock
- D. damage of hepatocytes
- E. endocrinological diseases

Task 1.

What is typical for exogenous (a.) and endogenous (b.) liver failure?

a. unconsciousness; b. rapid noisy breathing; c. bleeding varicose veins of oesophagus; d. ascites; e. anaemia f. elevated transaminases; g. acute exogenous poisonings; h. viral hepatitis i. alcohol abuse.

Task 2.

Patience, the patient with liver failure, receives:

a. enteral nutrition reached with proteins; b. oxygenation; c. albumin infusion; d. blood transfusion; e. sodium thiopental for cramps treatment f. steroids; g. vitamins h. gentamicin i. diuretics.

Acute poisonings.

Acute poisoning is a chemical injury, which occurs when chemical substance gets to the organism and violates its vital functions. If the substance is aggressive enough and proper treatment is not provided on time poisoning will bring death.

Although there are over 500 toxic substances which may cause acute poisoning, clinical picture is made up of quite similar syndromes. Proper diagnostics of these

syndromes allows avoiding life-threatening complications and gets the chance to make correct preliminary conclusions about the nature of poisoning.

8.1 Main clinical syndromes of poisonings.

Affection of central nervous system manifests as excitation or depression of patient's mental activity. Depression of CNS has different stages: confusion, stupor, spoor and toxic coma. One of the coma's deepness criteria is reaction of the patient to the painful stimuli (you can also check reaction to smell of ammonium chloride). Lack of reaction is a sign of coma. Don't live such patient without observation, because his condition is severe and at any moment life-threatening complications may appear: those patients have tendency to bradypnoea up to complete respiratory arrest. Also you should not forget that decreased tone of soft palate and tongue in a supine position will violate patency of the airways and patient can die of asphyxia. In addition comatose condition influences reflexes and lack of swallowing can lead to entrance of saline and gastric contents into the airways (and thus to development of aspiration pneumonia).

Usually CNS depression is caused by excessive alcohol consumption or admission of its surrogates, overdose of neuroleptics, sleeping pills, drugs, sedative medicines, antidepressants and carbon monoxide poisoning. You can remind intensive treatment of comatose patients in the chapter 5.

Some poisoning are followed with acute intoxication psychosis (mental disorders, hallucinations, time and space disorientation, inadequate behavior). This clinical picture you can observe in case of atropine poisoning (and also atropine-like agents: tincture of dope, henbane, amanita) or cocaine, tubazid, antihistaminic drugs and organophosphates poisoning.

In case of psychosis you will have to immobilize patient in the bed for his own good and safety (to avoid injuries both patient's and those of the stuff). You will also have to do this in order to maintain i/v lines for antidotes and sedative infusions (aggressive patient will try to remove everything he or she considers irritating). Constantly observe the

patient's vital functions.

Toxic affection of the respiratory system can progress as the violation of:

a. external respiration - neurogenic form, aspirations and obstructions of the airways which bring hypoxic hypoxia;

b. hemoglobin's function – aniline and nitrobenzene create methemoglobin, carbon monoxide connected with hemoglobin creates carboxyhemoglobin and neither the first nor the second is capable of normal oxygen transportation; heavy metal, organic acids and arsenic poisonings lead to destruction of the red blood cells and emission of the free hemoglobin into the plasma;

c. oxygen transportation due to the decrease of circulating blood volume – exotoxic shock;

d. cellular respiration – tissue hypoxia occurs when cytochromes are blocked with toxins like cyanides.

Practically all severe poisonings earlier or later lead to hypoxia, because they violate oxygen supply, transportation and consumption.

Your immediate therapy actions in this situation will be:

- to assess of respiratory system (described above);
- to provide of airways patency (cleaning of the oral cavity, aspiration of the saline and gastric contents, conicotomy if necessary, etc.);
- to begin oxygen supply (face mask, nasal catheter);
- to start artificial ventilation if necessary;
- to prescribe antidotes if they are available (methylene-blue in case of nitro compounds poisonings, unithiolum in case of heavy metals and arsenic poisonings, cytochrome c in case of tissue hypoxia);
- to start hyperbaric oxygenation in case of carbon monoxide poisoning;
- to begin infusion therapy in order to stabilize the hemodynamics;
- to start general detoxification;
- to prescribe symptomatic treatment and provide prevention of the complications (for example prescription of antibiotics).

Affection of the cardiovascular system manifests as inability of the heart and

vascular bed to provide adequate blood supply of the organs, which leads to metabolic disorders and in the worst case to death. Severe toxic damage of cardiovascular system brings acute cardiovascular failure: primary toxic collapse, exotoxic shock, secondary somatogenic collapse.

Primary toxic collapse appears in case of massive poison admission, when compensatory mechanisms are not quick enough to resist the chemical aggression. Immediately or minutes after poisoning patients begin to suffer from reduced cardiac output and thus from decreased blood flow in the tissues. Peripheral pulse is weak or absent, blood pressure critically lowers and cardiac arrest can appear. In most cases of primary toxic collapse ambulance is not able to save the life of the patient due to the fulminant development of life-threatening complication. However you should remember that such collapse occurs only in 5 % of the cases.

Exotoxic shock is the reason of death for 70 % of poisoning victims. Violations of hemodynamics on one hand are caused by direct heart and vessels damage and on the other hand by compensatory sympathetic and adrenal reactions. On the background of CNS and gastrointestinal system violations you will observe disorders of systemic hemodynamics and microcirculation: arrhythmias, decrease of blood pressure, central venous pressure, cardiac output and diuresis. The peripheral vascular tone changes: toxins induce spasm or dilation of arterioles with the ischemia of one and hyperemia of other tissues. Depending on the body reaction on intensive treatment shock can be compensated, decompensated reversible and decompensated irreversible.

In case of toxic shock you should:

- get an i/v line (preferably several, including central venous access);
- start infusions of colloids (albumin, rheopolyglucin, hydroxyethylstarch solutions) and crystalloids (saline, glucose solutions, polarizing solution) in order to normalize blood pressure, heart rate and diuresis; sometimes infusion dose is up to 100-150 ml/kg, (7-10 l/day);
- constantly control patient's condition: monitor the heart action, blood pressure and central venous pressure;
- provide antidote treatment and detoxification; remember that extracorporeal detoxification is possible only after the stabilization of the hemodynamics (systolic blood pressure >90 mm Hg).

Secondary somatogenic collapse is the reason of death in 25% of the cases. It can occur few days after poisoning, when the toxin is already eliminated from the body, however the tissue changes (in the lungs, liver, kidneys, heart) are irreversible. Necessary treatment: hemodynamics stabilization, improvement of microcirculation, intensive therapy of functional disorders and organic changes (artificial lung

ventilation, hemodialysis, cardiac support, etc.).

Toxic affection of gastrointestinal tract.

Usually poisoning provokes usual protective reactions: nausea, vomiting, diarrhoea. Chemically aggressive agents can cause “corrosive” effects: concentrated acids and bases can burn the mucous membrane of oral cavity, oesophagus and stomach (vomit is coloured with blood). Profuse vomiting and diarrhoea bring dehydration, electrolytes loss and acid-base imbalance. Especially rapid those complications appear in children.

After recovery patients with chemical burns of gastrointestinal mucous membranes may suffer from cicatrization and stenosis of digestive tract.

Be aware of the fact, that intensive usage of narcotic pain killers and sleeping pills can lead to inhibition of peristalsis and thus to constipation and slow elimination of toxins.

Immediate aid actions:

- clean the stomach. If the patient is conscious stimulate vomiting with the pressing on the root of the tongue or with 2-4 liters of slightly salted fluid. Don't you ever do this in case of chemical burns!
- if you have the skills and possibility insert the stomach probe and evacuate gastric contents with the help of 10-15 liters of water; if necessary give also antidotes through the probe; you can also use probes with several channels;
- after the gastric lavage in order to bind toxins use enterosorbents (activated charcoal for example);
- stimulate stool with saline laxatives (150-200 ml of 33% magnesium sulfate solution) in order to remove connected with the toxin sorbent from the intestines;
- cleansing enemas also help to eliminate toxins from the body.

Toxic affection of liver and kidneys.

This syndrome is caused by primary toxic damage of the liver and kidneys (nephrotoxic and hepatotoxic poisons) or by the secondary disorders of their functions due to violations of blood flow and oxygenation.

Liver is the main detoxification and biotransformation center of the organism, so it takes the “main blow” during intoxication. Intensive detoxification increases metabolic activity and oxygen consumption of the liver several times. Hepatocytes become very

sensitive to hypoxia.

Light forms of toxic and hypoxic affections can develop without clinical manifestation. However they will be noticeable in laboratory tests (elevation of transaminases, bilirubin, phosphates). Severe poisoning will bring to toxic hepatitis and even hepatic coma.

Among the hepatotoxic substances are: heavy metals salts, dichloroethane, ethylene glycol, deadly amanita toxins.

To protect the liver you should:

- eliminate the toxic substance from the gastrointestinal tract;
- give antidotes if they exist (unithiol for heavy metals salts, lipoic acid for deadly amanita);
- prescribe cleansing enemas 2-4 times a day (to prevent intoxication with the wastes accumulated in the intestine);
- use extracorporeal detoxification (hemosorbition, plasmapheresis, artificial liver);
- provide adequate oxygenation and blood supply of the liver;
- prescribe symptomatic treatment.

Kidneys are very important for the elimination of the poisons circulating in the blood. So in many cases they are also the “target” of the toxin. They can be damaged primary (poison affect their tissues directly) and secondary though the violations of vital functions (for example hemodynamics in case of exotoxic shock). Their condition you can control with the help of urine output per hour, which normally is not less than 0,5 ml/kg.

To prevent the renal failure you should:

- eliminate the poison as soon as possible (gastric lavage and enemas for gastrointestinal tract; hemodialysis, hemosorbition, plasmapheresis for blood);
- give antidotes if they exist (unithiol for heavy metals salts, sodium bicarbonate for hemolytic poisons, ethylic alcohol for ethylene glycol and methanol);
- treat disorders of hemodynamics (therapy against exotoxic shock);
- stimulate the urine output with the diuretics on the background of previous rehydration: this will allow you to eliminate diluted in the plasma toxins faster and to prevent renal failure; kidney is an organ which functions normally only if works intense;

Clinical observations tell us, that incredibly massive infusions (10-20-30 l/day)

with diuresis stimulation really help patient to dilute and eliminate the toxin without kidneys damage.

In case of acute renal failure you should treat the patient according to the principles described in chapter 6.

Ethylic alcohol poisoning.

This type of poisoning appears in case of excessive alcohol consumption. It is one of the most common poisonings, as well as one of the lightest and prognostically the most favourable (organic damage is rare). However combined with comorbidities and complications it becomes one of the first reasons of death in toxicology, so don't underestimate it.

Alcohol poisoning, unlike drunkenness, has the characteristic signs of intoxication: vomiting, inhibition of CNS, disorders of cardiovascular system and breathing. Patients usually are in comatose condition. Pay attention to their appearance: clothes are untidy, you can notice signs of involuntary urination or defecation. There is alcohol breathing odour. Skin of the face is hyperaemic and dry. Cyanosis is a sign of respiratory insufficiency, grey shade of skin is a symptom of cardiac disorders. Wet skin might be the symptom of hypoglycaemic coma, hypercapnia or organophosphate poisoning, which are "covered" with the obvious clinic of alcohol poisoning. In case of moderate coma vital functions are usually not involved. Pupils are narrowed or dilated, photoreaction is preserved. Objective criterion of alcohol poisoning is alcohol concentration of the blood:

- less than 1,5‰ – light inebriation
- 1,5‰-3,5‰ – moderate inebriation
- 3,5‰ and more – severe inebriation

Lethal concentration of alcohol is 5-6‰.

The most common complications of alcohol poisoning are next:

- obstruction of the airways with the tongue, soft palate or biological fluids (vomit, saline, sputum, blood) in supine position;
- regurgitation of the gastric contents and development of aspiration pneumonia; lethality is nearly 70%;
- head traumas with brain injuries: patients usually fell and hurt themselves; the problem with such injuries is that the clinic of hematoma (subdural, epidural, intracerebral) is quite often "covered" with alcohol intoxication and this is why you should always remember about the differential diagnostics. To make a correct diagnosis in case of coma you should check the specific symptoms such

as anisocoria (there is no poisoning which causes pupil's asymmetry!), signs of head injury (scratches, bruises, skull deformations, oto-liquorrhea and nasal liquorrhea, nasal and ear bleeding), asymmetric tendon reflexes and muscle tone, disparity between the amount of alcohol and deepness of coma, prolonged unconsciousness (alcohol coma even without proper treatment lasts only 3-4 hours);

- other traumatic injuries (rib fractures which violate external breathing, spleen or liver ruptures with haemorrhagic shock, ruptures of hollow organs with peritonitis; limb fractures);

- compartment syndrome appears when certain enclosed space within the body for several hours suffers from the decreased blood flow (for example when patients spends few hours in one inconvenient position); even when blood supply will be restored necrotic products will continue pathological process through toxic affection of the life-important organs (for example free myoglobin can cause renal failure).

There is always possibility of chronic diseases exacerbations on the background of alcohol poisoning (stroke, myocardial infarction). Remember about the necessity of complete examination (inspection, palpation, percussion and auscultation of undressed patient) of such alcohol victims – it is the only way to find all the “diagnostic mysteries” patients hide!

Intensive treatment:

- evaluate CNS condition (deepness of the coma);
- provide airways patency and adequate respiration (described above; if necessary – intubate the patient and begin artificial ventilation);
- check the cardiovascular system: heart rate, pulse, blood pressure;
- in case of severe hemodynamic disorders provide infusion therapy;
- insert the stomach probe and remove its contents using lavage with water;
- take blood samples and check blood alcohol level (obligatory!);
- prescribe intravenously: 60-80 ml of 40% glucose solution, 60-80 ml of 4% sodium bicarbonate solution, 5-10 ml of 5% ascorbic acid, 1-2 ml of vitamin B₁ solution;
- if there are no comorbidities add analeptic solutions i/m (2-3 ml of caffeine or 2 ml of cordiamin);
- in case of severe intoxication begin forced diuresis.

Poisonings with alcohol surrogates.

Patients can be poisoned with: home-distilled vodka, Cologne water, denatured alcohol, methyl alcohol, lotion, brake fluid, etc. The peculiarity of such poisonings is complex effect of the alcohol and other toxic components of the “drink”.

The most toxic are methyl alcohol and antifreeze (ethylene glycol) – their lethal dose is 60-100 ml. Lower doses cause neuritis of optical nerve and thus blindness (methyl alcohol), acute renal and liver failures (ethylene glycol).

In case of these poisonings detailed anamnesis and blood identification of the poison (gas chromatography) play the most significant role in the diagnostics. However for the prognosis volume of the poisonous fluid, duration of its influence, functional condition of the liver and effectiveness of the antidote therapy and detoxification are the most important.

In the body methanol and ethylene glycol are metabolised according to so called “lethal-synthesis”: during the breakdown of the poison in the liver there are created substances much more toxic than the parent compounds.

Intensive therapy:

1. Gastric lavage with potassium permanganate (oxidizes methyl alcohol).
2. Give antidote: 50 ml of 40% ethylic alcohol solution every 3 hours orally or 100 ml of 5% ethanol solution intravenously slowly combined with glucose solution during 2 days. Antidote will block the process of their biotransformation in the liver until the poisons will not be eliminated from the body.
3. Actively eliminate the poison from the body through repeated gastric lavages, forced diarrhoea, extracorporeal methods of detoxification (hemodialysis, hemosorbtion, plasmapheresis).
4. In order to treat optic neuritis you should perform retrobulbar inject of steroids.
5. Symptomatic treatment.

8.4 Drug poisonings.

In civilized countries these poisoning are the main reason (65-70% of cases) of hospitalization in toxicology units. Usually patients overdose sleeping pills, narcotic painkillers, antihistamine drugs, hypotensive medicines. Among the reasons are suicide tries, drug abuse, toxicomania and accidental overdose due to hectic pace of modern life,

etc.

Clinical picture is usually connected with CNS affection. There are phases of somnolence, sleep and coma. Depending on involvement of other systems coma can be complicated or uncomplicated. Usually respiratory complications appear: inspiration centre depression, violations of airways patency due to soft tissues (tongue, soft palate) or biologic fluids (blood, sputum, saline), pneumonia. In 15-20% of cases the poisoning development is complicated with the exotoxicshock. The peculiarities of this shock are next: circulatory disorders with blood stagnation in the pulmonary circuit, toxic affection of the myocardium and decrease of energy metabolism of the organism.

To indicate the poison you should ask relatives and witnesses and check things of the patient (for example you can find medicine packages). Evaluate the size of the pupils: extremely narrowed pupils (“poppy seeds”) are the effect of narcotics admission; narrowed pupils might be the sign of sleeping or sedative medicines overdose; dilated pupils are the symptom of clofelin, antidepressants or neuroleptics administration; wide pupils covering the whole iris are usually the sign of atropine poisoning (or a poisoning with atropine-like substances: dope, henbane, amanita).

Principles of the intensive treatment in the toxicology unit:

- clean the gastrointestinal tract as soon as possible (gastric and intestinal lavage, enterosorbition, cleansing enemas) and as often as necessary;
- provide adequate respiration (check airways patency);
- in case of comatose patients intubate the trachea and begin artificial ventilation (sometimes it is necessary for weeks);
- control hemodynamics and treat its violations (infusion therapy and adrenergic agonists or antagonists if necessary);
- stimulate diuresis: patients with barbiturate poisoning should be treated with alkaline forced diuresis in order to eliminate the toxin (add to the infusion 400-600 ml of 4% sodium bicarbonate solution and prescribe diuretics);
- use antidotes: naloxone for opiates, pharmacological antagonists for anticholinergic and cholinomimetic agents; don't you ever prescribe central analeptics for comatose patients with drugs poisoning – cordiamin, caffeine, bemegrade , cytiton, lobelinum can cause “cerebral blood flow steeling effect” and thus they deepen the hypoxia of brain cells!
- provide extracorporeal detoxification to eliminate toxins (hemodialysis, hemosorbition, plasmapheresis);
- prescribe antibiotics for infectious diseases prevention (for example in case of prolonged artificial ventilation);

- symptomatic treatment.

8.5 Alkali and acid poisonings.

These poisonings are among the most severe and difficult to treat. Accidentally or intentionally (suicide) victim can take mineral acids (hydrochloric, sulphuric, nitric acids), organic acids (acetic or oxalic acid), alkali (ammonium chloride, battery fluid, etc.).

When corrosive substance gets into the body along its way inside chemical burn appears: mucous membranes of oral cavity, throat, oesophagus, stomach are injured. Together they make nearly 14-15% of the body surface. Patients suffer from unbearable pain, eating and drinking are disabled. In case of acid burn coagulation necrosis appears; alkali burn is more severe, because colliquative necrosis penetrates deeper into the tissues ruining the vessels and causing bleedings. Organic acids easily get into the blood. Sometimes chemical substances or their vapours also get into the airways and thus oedema and risk of asphyxia appear.

Usually part of aggressive substance is spilled over the chin and you can notice the burn. Systemic disorders are characterized with exotoxic shock which develops as burn shock (unbearable pain, dehydration, toxic affection of the heart, decrease of cardiac output, spasm of arterioles and microcirculation block). Organic acids also provoke hemolysis of red blood cells: free haemoglobin transforms into hydrochloric haematin and obturates renal tubules, causing acute renal failure.

Intensive treatment principles:

- evaluate patient's condition: external respiration, consciousness, cardiovascular system;
- adequate pain relief with narcotic painkillers and non-steroidal anti-inflammatory drugs (1-2 ml of 1% morphine solution; 2 ml of 50% analgin solution);
- liquidate the spasm of gastric cardia and oesophagus (1 ml of 0,1% atropine solution i/m, 5 ml of baralgin solution);
- clean the stomach during first 10 hours after poisoning; insert the stomach probe (cover it thickly with Vaseline and don't push too hard); use water for lavage and don't try to perform chemical inactivation of the poison, because during the reaction carbon dioxide can exude and acute expansion of the stomach leads to its rupture;
- provide treatment of shock (sometimes up to 10-12 liters/day of infusions);

- in case of organic acids poisonings (acetic acid, oxalic acid get into the blood) give 1500-2000 of 4% sodium bicarbonate solution intravenously slowly with diuretics; these actions will help to remove hemoglobin (released due to red blood cells hemolysis) and thus to prevent acute renal failure;
- in case of obstructive breathing disorders (mucous membrane edema) use steroids (90-120 mg of prednisolone), antihistamine drugs (2 ml of 1% dimedrol solution intravenously), sedative medicines (2 ml of 0,5% diazepam solution); perform tracheostomy or conicotomy if necessary;
- prescribe antibiotics for infectious diseases prevention (for example in case of prolonged artificial ventilation);
- symptomatic treatment.

During the recovering period patient may need surgeries for restoration of gastrointestinal tract: the most common practice is the bouginage of the oesophagus or, if necessary, oesophagus plastic.

8.6. Poisonings with toxic gases.

Among the toxic gases are carbon monoxide, car exhausts, propane and butane, ammoniac gases. The last one is the most toxic: few inhales are enough to cause unconsciousness.

The foundation of the pathology lies within the atypical haemoglobin – carboxyhemoglobin – combination of normal haemoglobin and toxic gas. Oxygen transportation is violated (in case of severe poisonings there are nearly 70-80% of changed haemoglobin) and thus haemic hypoxia appears. In addition within the tissues cytochromes are connected with toxic substances and this leads to tissue hypoxia.

Clinical findings in case of carbon monoxide poisoning depend on the severity of the poisoning. In case of mild intoxication they are: headache, nausea, vomiting. Moderate intoxication shows unconsciousness for 12-16 hours and severe intoxication is characterized with coma, central disorders of breathing, toxic affection of heart and other organs, etc.

If intoxication advances changes of central nervous system become irreversible (brain death is possible).

Intensive treatment.

In case of mild and moderate poisonings you should you should carry the patient out of the toxic atmosphere as soon as possible. In hospital conditions you should provide oxygen supply, get an intravenous line for crystalloids infusion and prescribe

vitamins.

In case of severe intoxication begin artificial ventilation with high oxygen flow. Luckily there is an antidote for carbon monoxide poisoning: hyperbaric oxygenation. Connection with oxygen is more natural for haemoglobin and when the pressure of oxygen is higher than its usual partial pressure carbon monoxide is replaced from the haemoglobin. Usually in case of comatose patients 40-50 minutes sessions every 6-12 hours are enough.

To normalize tissue metabolism prescribe antihypoxants: 20% solution of sodium oxybutirate (20-40 mg/kg i/v) and cytochrome c (2-3 ml i/v) every 4-6 hours. To improve microcirculation dilute the blood with crystalloid infusions (check the level of hemodilution with hematocrit – stop when it will reach 0,3-0,35 l/l).

Prevent the infectious complications and brain oedema with standard methods.

8.7 Organophosphate poisonings.

These are the poisonings with insecticides, acaricides, herbicides, fungicides, rodenticides, desiccants, defoliants and with chemical warfare agents such as sorin, soman, V-x.

Organophosphate substances are fats and water soluble and thus they penetrate easily through the skin and mucous membranes (gastrointestinal tract, airways, etc.). In the blood they block an enzyme – cholinesterase – responsible for the breakdown of acetylcholine. As you remember acetylcholine is a universal synaptic mediator of nervous impulses and thus its accumulation on the post-synaptic membranes will cause continuous stimulation of vegetative nervous system and cross-striated muscles.

Clinically you will see: nausea, vomiting, cramps; unconsciousness in severe cases. Sometimes in the place of penetration you can see muscle fasciculation (if the poison was administered orally – tongue twitching). Stimulated parasympathetic nervous system shows wet skin, increased salivation and bronchial secretion (sometimes you can even see white phlegm in the mouth – don't mistake it with the pink phlegm of pulmonary oedema), narrowed pupils, bradycardia (heart rate 40-30 beats per minute). In addition to the obvious clinic you can always check the environment of the patient for the signs of organophosphate poisons (specific smell, containers with toxins, etc.).

One third of patients suffer from exotoxic shock, which primary causes hypertension and then hypotension, unconsciousness and depression of respiration.

Immediate aid:

- take patient out of the dangerous environment (if you suspect that the mechanism of poisoning is inhalation);

- clean the stomach with large amounts of cold water; repeat it several times, because these substances are excreted through the mucous membranes of gastrointestinal tract;
- give saline laxative;
- if the poison affected skin – wash it with alkaline solution.

Antidotes:

a. use peripheral m-anticholinergic drug – atropine: during the first few hours 2-3 ml of 0,1% atropine solution (up to 30-35 ml during the whole period of intensive atropinization); pay attention to the signs of atropine administration as they are the measure of your antidote treatment effectiveness: termination of excessive bronchial secretion, dilation of the pupils, tachycardia (90-110/min). During next 3-5 days continue atropine prescription (from 10-15 mg to 100-150 mg/day – period of supportive atropinization). Control clinically the level of atropinization.

b. use cholinesterase reactivators: 1-2 ml of 15% dipiroxim solution i/m, up to 600 mg; 3 ml of 40% izonotrozin solution i/m up to 3-4 grams. However remember, that cholinesterase reactivators can be used only 24 hours after poisoning. Later administered reactivators will ne not only ineffective, but also toxic for the patient.

You should also provide usual treatment as soon as possible: infusion therapy, forced diuresis, hemosorbtion, plasmapheresis, hemodialysis and antibiotics for infection preventions.

In case of ineffective external respiration and comatose patient's condition intubate the patient and start artificial respiration. Convulsions in case of organophosphate poisoning are treated with sodium oxybate (75-100 mg/kg i/v every 4 hours). Cardiac glycosides, calcium chloride, euphillinum are forbidden in case of organophosphate poisonings, because they induce toxic heart affection.

Be aware of the possibility of “second poisoning wave”: even 4-8 days after the stabilization of the patient's condition clinical picture of the poisoning might return and this time hemodynamics will decompensate quickly.

8.8 *Mushroom poisoning.*

There are edible, non-edible and relatively edible mushrooms. Non-edible or poisonous mushrooms can contain toxins harmful for central nervous system, liver, kidneys and gastrointestinal tract (according to A. Lokay, 1 968). The most dangerous poisoning is caused by deadly amanita. The poison of this mushroom – amanitotoxin- is not destroyed during cooking and there is no way to detect it in usual conditions. In case

of severe poisoning the lethality is 80%.

Specific feature of amanita poisoning is prolonged latent period. Sometimes 6-12 hours pass before the first symptoms of the poisoning appear. All the other relatively edible mushrooms reveal clinical signs of the poisoning much earlier – 1-2 hours after consumption.

After the latent period is over on the background of complete health nausea, profuse vomiting and diarrhoea appear. Those symptoms begin second phase of the poisoning – gastroenterocolitic phase. Liver enlarges; patients suffer from pain in the right subcostal area, weakness, and consciousness disorders. Stool becomes watery and contains mucous. Patients loose up to 4 liters of the fluid during the day. Unlike bacterial food poisonings, mushroom poisonings are not characterized with high fever.

Liver failure and acute kidneys injury are the third phase of the poisoning, which begins on the second or third day of disease. Those failures are characterized with hepatic encephalopathy, jaundice, gastrointestinal bleedings, hepatic breath odour and oligoanuria. The level of alanine and aspartateaminotransferases is very high. When liver returns to its usual size and consciousness is changed into coma hepatargia is stated and prognosis for the disease becomes rather unfavourable.

The forth stage is a stage of recovery and is characterized with gradual regression of the clinical picture and normalization of the laboratory results during several weeks. However survival is possible only for those patients, who ate small amounts of the poisonous mushroom.

Knowing about the high lethality and severity of the amanita poisoning prevention methods become very important. Mushroomers should know the difference between deadly amanita and other mushrooms: deadly amanita is a gill-bearing mushroom with olive or green cap. Its gills white are not connected with the stem. Stem has a bulbus with white volva from one side and a white annulus from another side, under the cap.

Patients should be treated in a special toxicology units or intensive treatment unit. General principles of intensive therapy are:

- gastric and intestinal lavage, enterosorbition and saline laxatives;
- infusion therapy (necessary to liquidate electrolyte deficiency and provide forced diuresis);
- support of the liver functioning with lipoic or thioctic acid (1000-2000 mg/day), concentrated glucose solutions, steroids (up to 40 mg of dexamethasone per day) and silibin (50 mg/day);

- extracorporeal detoxification (hemodialysis, hemosorbition, plasmapheresis, artificial spleen or liver) as soon as possible;
- antibiotics if necessary (penicillin); vitamins (B,C,E);
- external drainage of thoracic duct (decreases intoxication through elimination of toxic lymph).

8.9 Medical operations and manipulations.

Gastric lavage

Indications: necessity to remove poisons or toxins from the stomach, to clean it before operation or to liquidate stagnation during period after the operation.

Equipment required: gastric probe (with two channels if possible), Janet syringe, water for lavage (15-20 liters of room temperature water), gloves and watertight apron.

Procedure: gastric lavage of comatose patients is a procedure for doctors. In our country nurses are not allowed to do this without control of the doctor: unconscious patients have inhibited reflexes and thus probe can be easily inserted into the trachea instead of oesophagus. In this situation neither cyanosis nor cough may not appear and everything looks just fine, however feeding or lavage try can end with fatal complications (asphyxia and death).

Put on the gloves, choose the probe of necessary size and oil it with Vaseline. Patient should lie on the left side (ask nurse to hold patient's arms to limit his movements during this unpleasant procedure).

If patient is conscious you can previously use lidocaine spray to anaesthetize mucous membranes. Probe can be inserted through the nose (of course in this case size of the probe is limited) or through the mouse. Don't push too hard, especially when you are using nasal passage: you can cause bleeding. Ask patient to bow his head to the chest – this will increase chances of correct probe insertion (oesophagus, not trachea). The length of probe you insert can be measured in advance as a distance between earlobe, nose and xiphoid.

Confirmations of correct probe placement:

- auscultate the epigastrium and simultaneously infuse some air with the syringe- you will hear typical "bubble" noises;
- if you made a mistake and probe is in the trachea you can notice air released from the distant end of the tube according to the respiratory movements.

One-time water dose is nearly 200 ml: it will flow out when you will lower the probe or you will have to evacuate the water with the syringe. Repeat these actions until the water wash out the stomach will be clean (usually it takes nearly 10 liters of water).

Forced diuresis.

Indications: intoxications of different origin (poisonings, infectious diseases, endogenous intoxications).

Medicines required: normal saline (3-5 liters); detoxification solutions; polarizing solution (400 ml of 10% glucose solution, 10 ml of 7,5% potassium chloride solution, 12 units of insulin), osmotic diuretics (mannitol in the dose 1 g/kg), furosemid solution (40-80 mg)

Procedure: get and i/v line (central or peripheral) and insert urinary catheter. During the first phase of forced diuresis "water" the patient with crystalloids and detoxification solutions (30-40 ml/kg). During the second phase infuse osmotic diuretics and furosemide solution. Excessive urine output brings potassium loss, which you should treat with polarizing solution. Balance the speed of infusion with the speed of diuresis: generally per 5-7 liters of infused solutions you should receive at least 5 liters of urine.

Constantly control hemodynamics and blood electrolytes.

Control tests.

1. What medicine should be used as an antidote in case of severe soporific drugs poisoning?

- A. bemegrade
- B. cordiamin
- C. there is no such medicine
- D. unithiol
- E. cytiton

2. What is the most common death reason in case of alcohol poisoning?

- A. acute liver failure
- B. acute respiratory failure
- C. acute renal failure
- D. acute heart insufficiency

E. collapse

3. What is necessary for the patient, who took 60 ml of acetic essence?

A. to give 4% sodium bicarbonate solution i/v

B. to clean the stomach with alkaline solution in order to neutralize the acid

C. to use unithiol as an antidote

D. to stimulate intestinal cleansing with saline laxatives

E. central analeptics

4. What is the symptom of organophosphate poisoning?

A. pale and dry skin

B. maximal pupil's dilation

C. tachycardia

D. muscle fasciculation

E. acute liver failure

5. What is used as an antidote in case of severe carbon monoxide poisoning?

A. cytochrome c

B. cordiamin solution

C. unithiol

D. prednisolone

E. antidotes are not used

6. What is typical for deadly amanita poisonings?

A. first symptoms appear in 2-3 hours after mushroom meal;

B. low-grade fever

C. latent period of 6-12 hours

D. first symptoms are haemostatic disorders (bleeding)

E. early unconsciousness

7. What is the necessary aid in case of narcotic painkillers overdose?

A. artificial ventilation

B. cordiamin

C. oxygen supply

D. immobilization of the patient in order to avoid self-injuries during the

excitement-phase;

E. cardiac medicines

Task 1.

Patience, the patient of 19 is transported to the ITU by witnesses from the street. Clinical findings: unconscious, cyanotic wet skin, 6 breathes per minute, respiration shallow, blood pressure 70/40 mm Hg, heart rate 112/minute. Name the reason of vital disorder and write the principles of intensive care (algorithm).

Task 2.

Patience, the patient of 19, was found unconscious in his own apartment by the ambulance workers. Clinical findings: total cyanosis, shallow breathing, respiration rate 5/min, pupils extremely narrowed, photoreaction is absent, blood pressure 80/40 mm Hg. In the elbow area there are noticeable signs of injections. Name the reason of vital disorder and write the principles of intensive care (algorithm).

Task 3.

Patience, the patient of 23 was hospitalized into ITU with the diagnosis: mushroom poisoning. It turned out, that yesterday she was eating cooked champignons. 8 hours later she noticed vomiting and diarrhoea. Clinical findings: scleral icterus, dry coated white tongue; painful abdomen (epigastrium and righthypogastric area), painful and enlarged liver (2 cm); hemodynamics and respiration are not violated.

Write the diagnosis and the phase of the disease.

Task 4.

Patience, the patient of 18, is transported to the toxicology unit with delirium. Clinical findings: hyperaemic face, dry skin, dilated pupils. Blood pressure 140/70 mm Hg, heart rate 127/minute. It is know, that 2 hours ago she took 10 unknown tablets during the suicidal attempt. What is the diagnosis and what are your actions?

Task 5.

Patience, the patient of middle age, was found by the ambulance workers in his own kitchen unconscious. Clinical findings: specific smell of organophosphates in the room, signs of vomit on the clothes, miosis, cold clammy skin with cyanotic shade, foamy white sputum in the mouth, blood pressure 90/50 mm Hg, heart rate 54/minute. What is the diagnosis? What immediate aid should be provided during pre-hospital stage?

Task 6.

Adams family were celebrating the New Year Eve near the fireplace. In the

morning came the carol singers and found hosts in a condition of deep sleep. “Dream team”, the ambulance workers, who came to the place of the accident, stated: 2 adults and their children in comatose condition, vomit signs on the clothes, rapid breathing, pupils dilated with weak photoreaction; heart rate is 110-120 per minute, rhythmic; blood pressure is high.

Name the reason of the accident and describe the actions of the “Dream team”.

Task 7.

Name the poisoning agent for each antidote: a. atropine, b. unithiol, c. naloxone, d. tetacinum, e. ethylic alcohol, f. dipiroximum, g. lipoic acid?

The essential components of the human cardiovascular system are the heart, blood, and blood vessels. It includes: the pulmonary circulation, a "loop" through the lungs where blood is oxygenated; and the systemic circulation, a "loop" through the rest of the body to provide oxygenated blood. An average adult contains five to six quarts (roughly 4.7 to 5.7 liters) of blood, accounting for approximately 7% of their total body weight.

While it is convenient to describe the flow of the blood through the right side of the heart and then through the left side, it is important to realize that both atria contract at the same time and that both ventricles contract at the same time. The heart works as two pumps, one on the right and one on the left that works simultaneously. The right pump pumps the blood to the lungs or the pulmonary circulation at the same time that the left pump pumps blood to the rest of the body or the systemic circulation. Venous blood from systemic circulation (deoxygenated) enters the right atrium through the superior and inferior vena cava. The right atrium contracts and forces the blood through the tricuspid valve (right atrioventricular valve) and into the right ventricles. The right ventricles contract and force the blood through the pulmonary semilunar valve into the pulmonary trunk and out the pulmonary artery. This takes the blood to the lungs where the blood releases carbon dioxide and receives a new supply of oxygen. The new blood is carried in the pulmonary veins that take it to the left atrium. The left atrium then contracts and forces blood through the left atrioventricular, bicuspid, or mitral, valve into the left ventricle. The left ventricle contracts forcing blood through the aortic semilunar valve into the ascending aorta. It then branches to arteries carrying oxygen rich blood to all parts of the body.

Blood Flow Through Capillaries

From the arterioles, the blood then enters one or more capillaries. The walls of capillaries are so thin and fragile that blood cells can only pass in single file. Inside the

capillaries, exchange of oxygen and carbon dioxide takes place. Red blood cells inside the capillary release their oxygen which passes through the wall and into the surrounding tissue. The tissue then releases waste, such as carbon dioxide, which then passes through the wall and into the red blood cells.

The Circulatory System

The circulatory system is extremely important in sustaining life. Its proper functioning is responsible for the delivery of oxygen and nutrients to all cells, as well as the removal of carbon dioxide, waste products, maintenance of optimum pH, and the mobility of the elements, proteins and cells, of the immune system. In developed countries, the two leading causes of death, myocardial infarction and stroke are each direct results of an arterial system that has been slowly and progressively compromised by years of deterioration.

Arteries

Arteries are muscular blood vessels that carry blood away from the heart, oxygenated and deoxygenated blood. The pulmonary arteries will carry deoxygenated blood to the lungs and the systemic arteries will carry oxygenated blood to the rest of the body. Arteries have a thick wall that consists of three layers. The inside layer is called the endothelium, the middle layer is mostly smooth muscle and the outside layer is connective tissue. The artery walls are thick so that when blood enters under pressure the walls can expand.

Arterioles

An arteriole is a small artery that extends and leads to capillaries. Arterioles have thick smooth muscular walls. These smooth muscles are able to contract (causing vessel constriction) and relax (causing vessel dilation). This contracting and relaxing affects blood pressure; the higher number of vessels dilated, the lower blood pressure will be. Arterioles are just visible to the naked eye.

Capillaries

Capillaries are the smallest of a body's vessels; they connect arteries and veins, and most closely interact with tissues. They are very prevalent in the body; total surface area is about 6,300 square meters. Because of this, no cell is very far from a capillary, no more than 50 micrometers away. The walls of capillaries are composed of a single layer of cells, the endothelium, which is the inner lining of all the vessels. This layer is so thin that molecules such as oxygen, water and lipids can pass through them by diffusion and enter the tissues. Waste products such as carbon dioxide and urea can diffuse back into the blood to be carried away for removal from the body.

The "capillary bed" is the network of capillaries present throughout the body. These beds are able to be "opened" and "closed" at any given time, according to need. This process is called autoregulation and capillary beds usually carry no more than 25% of the amount of blood it could hold at any time. The more metabolically active the cells, the more capillaries it will require to supply nutrients.

Veins

Veins carry blood to the heart. The pulmonary veins will carry oxygenated blood to the heart while the systemic veins will carry deoxygenated to the heart. Most of the blood volume is found in the venous system; about 70% at any given time. The veins outer walls have the same three layers as the arteries, differing only because there is a lack of smooth muscle in the inner layer and less connective tissue on the outer layer. Veins have low blood pressure compared to arteries and need the help of skeletal muscles to bring blood back to the heart. Most veins have one-way valves called venous valves to prevent backflow caused by gravity. They also have a thick collagen outer layer, which helps maintain blood pressure and stop blood pooling. If a person is standing still for long periods or is bedridden, blood can accumulate in veins and can cause varicose veins. The hollow internal cavity in which the blood flows is called the lumen. A muscular layer allows veins to contract, which puts more blood into circulation. Veins are used medically as points of access to the blood stream, permitting the withdrawal of blood specimens (venipuncture) for testing purposes, and enabling the infusion of fluid, electrolytes, nutrition, and medications (intravenous delivery).

Venules

A venule is a small vein that allows deoxygenated blood to return from the capillary beds to the larger blood veins, except in the pulmonary circuit where the blood is oxygenated. Venules have three layers; they have the same makeup as arteries with less smooth muscle, making them thinner.

The double circulatory system of blood flow refers to the separate systems of pulmonary circulation and the systemic circulation in amphibians, birds and mammals (including humans.) In contrast, fishes have a single circulation system. For instance, the adult human heart consists of two separated pumps, the right side with the right atrium and ventricle (which pumps deoxygenated blood into the pulmonary circulation), and the left side with the left atrium and ventricle (which pumps oxygenated blood into the systemic circulation). Blood in one circuit has to go through the heart to enter the other circuit. Blood circulates through the body two to three times every minute. In one day, the blood travels a total of 19,000 km (12,000 miles), or four times the distance across the U.S. from coast to coast.

The Pulmonary Circuit

In the pulmonary circuit, blood is pumped to the lungs from the right ventricle of the heart. It is carried to the lungs via pulmonary arteries. At lungs, oxygen in the alveolae diffuses to the capillaries surrounding the alveolae and carbon dioxide inside the blood diffuses to the alveolae. As a result, blood is oxygenated which is then carried to the heart's left half -to the left atrium via pulmonary veins. Oxygen rich blood is prepared for the whole organs and tissues of the body. This is important because mitochondria inside the cells should use oxygen to produce energy from the organic compounds.

The Systemic Circuit

The systemic circuit supplies oxygenated blood to the organ system. Oxygenated blood from the lungs is returned to the left atrium, then the ventricle contracts and pumps blood into the aorta. Systemic arteries split from the aorta and direct blood into the capillaries. Cells consume the oxygen and nutrients and add carbon dioxide, wastes, enzymes and hormones. The veins drain the deoxygenated blood from the capillaries and return the blood to the right atrium.

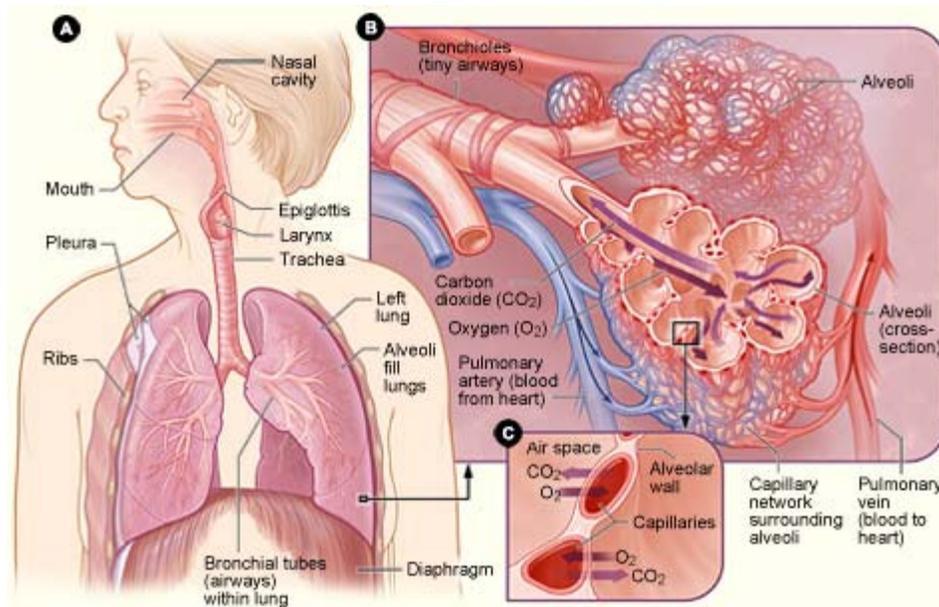

Pic. 4.1 Distribution of blood in the body:

- a. hear cavity itself 0 3% (% of blood volume)
- b. arteries -15%
- c. capillares -12%
- d. venous system – 70%

Cardiac cycle is the term used to describe the relaxation and contraction that occur, as a heart works to pump blood through the body. Heart rate is a term used to describe the frequency of the cardiac cycle. It is considered one of the four vital signs. Usually it is calculated as the number of contractions (heart beats) of the heart in one minute and expressed as "beats per minute" (bpm). When resting, the adult human heart beats at about 70 bpm (males) and 75 bpm (females), but this rate varies between people. However, the reference range is nominally between 60 bpm (if less termed bradycardia) and 100 bpm (if greater, termed tachycardia). Resting heart rates can be significantly lower in athletes, and significantly higher in the obese. The body can increase the heart rate in response to a wide variety of conditions in order to increase the cardiac output (the amount of blood ejected by the heart per unit time). Exercise, environmental stressors or psychological stress can cause the heart rate to increase above the resting rate. The pulse is the most straightforward way of measuring the heart rate, but it can be deceptive when some strokes do not lead to much cardiac output. In these cases (as happens in some arrhythmias), the heart rate may be considerably higher than the pulse. Every single 'beat' of the heart involves three major stages: atrial systole, ventricular systole and complete cardiac diastole. Throughout the cardiac cycle, the blood pressure increases and decreases. As ventricles contract the pressure rise, causing the AV valves

to slam shut.

Acute respiratory failure.

3.1 Anatomy and physiology of respiratory system.

One of the most important conditions of living is continuous gas exchange. Every day a human body consumes nearly 700 l of oxygen and produces 600 liters of carbon dioxide.

Oxygen is responsible for the mitochondrial and microsomal oxidation, peroxidation of unsaturated fatty acids and oxydase reactions. But the most significant role it plays when provides oxidative phosphorylation during energetic metabolism of the cell.

There are two types of breathing: external or lung respiration provides inflow of oxygen and carbon dioxide elimination; internal respiration is a complex process, which consists of haemoglobin transformation (connection and disconnection with oxygen), transportation of oxygenated haemoglobin through circulatory system to the tissues and local cellular metabolism.

External breathing is being regulated by centres in medulla and pons. Increasing of carbon dioxide concentration, as well as acidosis of cerebrospinal fluid, stimulates inspiration. At the end of expiration inspiration centre is being stimulated automatically and thus respiratory act begins again. In addition receptors of aorta arch and carotid sinus are also involved into respiratory act regulation: they respond to the lowering of oxygen concentration in the arterial blood.

The act of ventilation itself is being done through contraction of chest muscles and diaphragm. Muscles, responsible for respiration, enlarge chest and thus create negative pressure inside of it, what makes air move through the airways to the alveoli. Expiration is usually passive: chest falls down to its previous position and “used” air gets back to the atmosphere.

Tidal volume (TV) is 450-800 ml for male and 400-700 for female. It can be measured

by spirometer or volumeter. But not the whole air of one respiratory effort gets to the alveoli: part of it stays in oral cavity, nasal cavity, pharynx, trachea, bronchi and thus does not participate in the act of respiration itself. It is so called “dead space”- volume of airways which are ventilated, but are not involved in gas exchange. Dead space makes nearly 30% of the tidal volume (2,22 ml/kg of body weight).

Normal respiration rate (RR) is 14-20 per minute. Thus minute ventilation is calculated according to the formula:

$$\text{Minute ventilation} = \text{Tidal volume} * \text{Respiratory rate} \quad (\text{ml})$$

However the parameter, which helps to characterize the efficiency of breathing, is alveolar ventilation (AV): it shows the exact amount of the air which gets to the alveoli during the minute. The difference between minute ventilation and alveolar ventilation is the volume of dead space:

$$\text{Alveolar ventilation} = (\text{Tidal volume} - \text{Dead space volume}) * \text{Respiratory rate} \quad (\text{ml})$$

According to this formula breathing with lower frequency and higher tidal volume is more effective. In addition efficiency of breathing is increased through reduction of dead space volume. Thus endotracheal tube or tracheostomy make it two times less.

Oxygen gets to the arterial blood due to the difference of gas partial pressures. If the atmospheric pressure is 740-760 mm of Mercury and the amount of oxygen in the air is 20-21% partial pressure of Oxygen (pO_2) will be 160-150 mm of Mercury. In the airways air is being mixed with “used gases” and water steam, so the partial pressure of oxygen inside the alveoli is 95-85 mm of Mercury. With such values pO_{2a} , 3 ml of oxygen will be dissolved in one liter of blood (plasma).

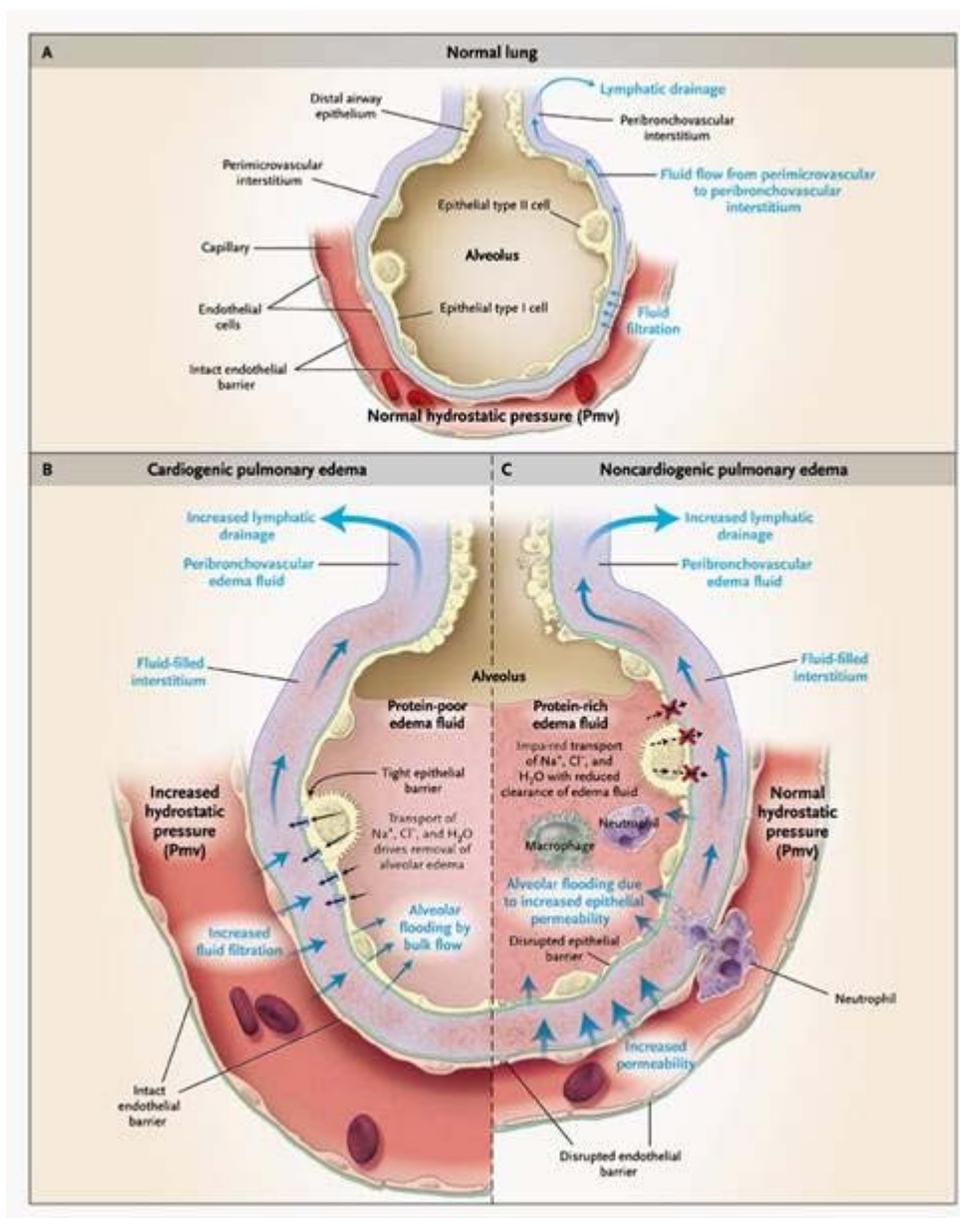

The main amount of oxygen in blood is being bound to the haemoglobin. One gram of haemoglobin bounds 1,34-1,39 ml of oxygen. In normal conditions haemoglobin of arterial blood (HbO_{2a}) is saturated to the extent of 96%. So, with the concentration of haemoglobin 120-140 grams per liter, one liter of arterial blood contains 170-190 ml of oxygen (VO_{2a}).

From every litre of blood only one third of oxygen amount (nearly 50 ml) is being used for the needs of the tissues. Thus venous blood contains nearly 120-140 ml of oxygen (VO_{2v}) and its HbO_{2v} is 70-75% and pO_{2v} 45-55 mm of Mercury.

Partial pressure of carbon dioxide in the arterial blood (pCO_{2a}) is an important index of ventilation adequacy. Normally it is 36-46 mm of Mercury. Worsening of lung ventilation causes increasing of pCO_{2a} over 44 mm of Mercury – hypercapnia appears. Excessive ventilation, on the contrary, helps in elimination of carbon dioxide and appearance of

hypocapnia: $p\text{CO}_{2a}$ is lower than 35 mm of Mercury.

Respiratory insufficiency is a condition in which metabolic needs of the body can not be satisfied with adequate oxygen admission, blood transportation, cellular consumption and carbon dioxide elimination.

Classification of respiratory insufficiency according to L. Usenko (1993):

A. Primary (caused by disorders of external respiration). Reasons:

1. airway patency disorders (obstruction with tongue, vomit, mucus, gastric contents, foreign bodies; laryngeal spasm, etc.)
2. central nervous system disorders (intoxication, brain injuries, haemorrhages, inflammations, etc.)
3. disorders of respiratory muscles activity (myasthenia, botulism, tetanus,

muscle relaxants, etc.)

4. defects of chest structure or functional chest disorders (chest injuries, limited diaphragm mobility – for example due to enteroparesis)
5. disorders of pulmonary compliance (pneumonia, bronchiolitis, atelectasis, “shock lung” syndrome, etc.)
6. disorders of ventilation-perfusion system (irregularity of ventilation and perfusion during artificial ventilation, pulmonary oedema, etc.)

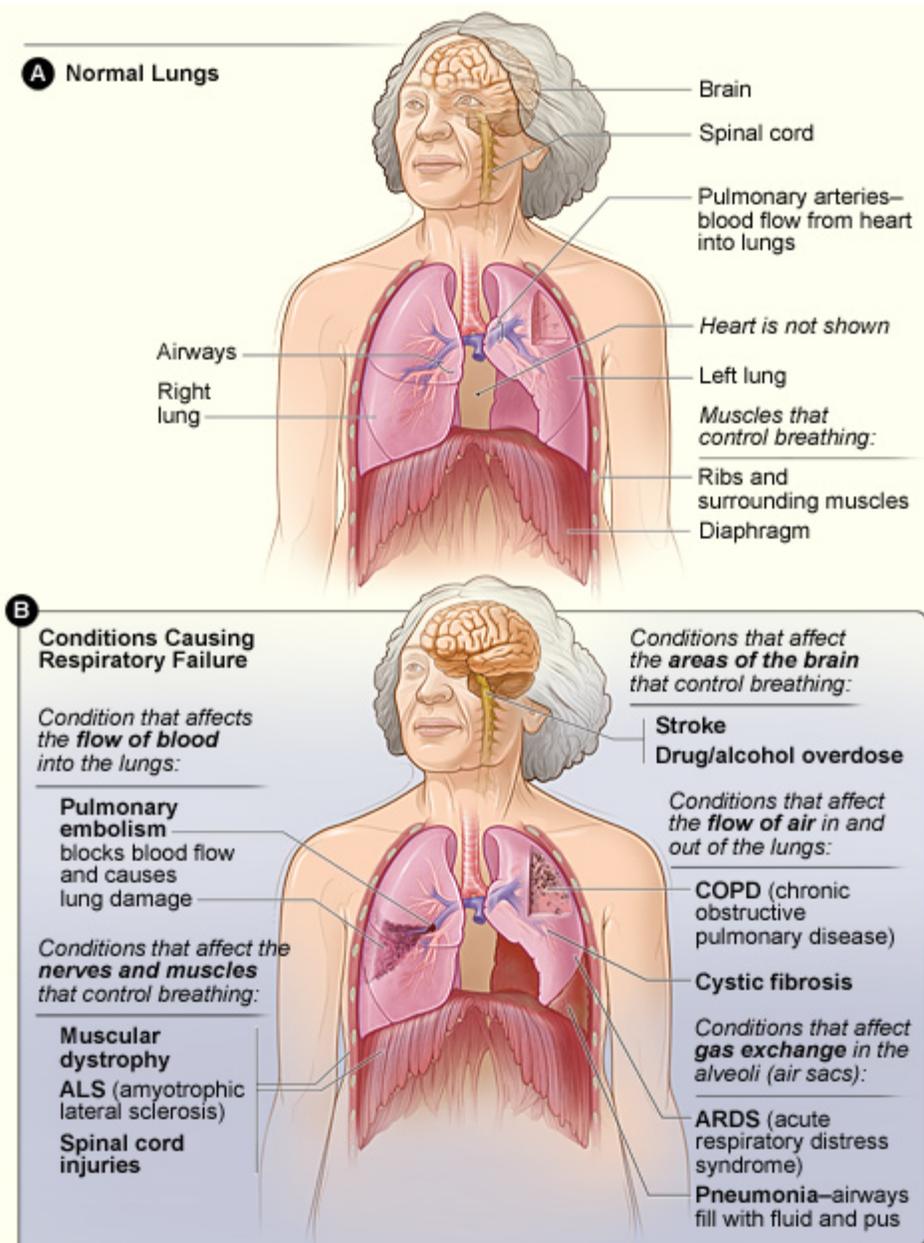

B. Secondary (caused by inability of blood to contain enough oxygen for metabolic needs of tissues or disorders of transportation and cellular consumption).

Respiratory insufficiency is characterized with hypoxia (“lowering of the oxygen”). Hypoxia occurs in case of:

1. Inability of external respiration to provide arterial blood with enough amount of oxygen (hypoxic hypoxia)
2. Lowering of oxygen amount due to anaemia - decreased level of haemoglobin, red blood cells or appearance of their atypical forms (haemic hypoxia).
3. Inability of cardiovascular system to provide systemic and pulmonary circulation enough for metabolic needs of the body (circulatory hypoxia).
4. Disorders of oxidative phosphorylation on cellular level of different organs and systems (tissue hypoxia).

Hypoxia itself can be accompanied with hypercapnia and hypocapnia. In case of tissue hypoxia there is also a possibility of hyperoxia (excessive oxygen amount) as its background.

In clinical conditions we usually deal with mixed gas exchange disorders.

Clinical symptoms of acute respiratory insufficiency

There are two types of respiratory insufficiency according to its duration: acute and chronic. Acute respiratory insufficiency develops in minutes or hours, can be life-threatening and thus needs urgent intensive treatment.

Symptoms of acute respiratory failure are really various.

Central nervous system. Conscious patients can complain of breathlessness (feeling of the air-lack), difficult inspiration or expiration. Due to development of hypoxia patients become restless, anxious, and sometimes euphoric; they can not evaluate critically their condition or environment. Terminal stages of insufficiency show total CNS inhibition – comatose state (hypoxic or hypercapnic). Quite often, especially in children, convulsions appear.

Skin and mucosa are mirror of respiratory insufficiency: their changes are quite

illustrative.

In case of external respiration disorders the amount of oxygenated haemoglobin is decreased and thus quantity of reduced haemoglobin. Arterial blood becomes “venous” (dark): skin and mucosa become cyanotic (blue, purple). First of all their colour change lips, nail plates, earlobes, afterwards face and other body parts. In case of anaemic patients with haemoglobin level 60 grams per litre and lower skin stays pale even in terminal stages of respiratory insufficiency. In case of cyanic and carbon monoxide intoxication skin, nail plates and mucosa turn bright pink, although patients are greatly suffering from hypoxia. Hydrosis is quite significant feature of hypercapnia. Terminal respiratory insufficiency is characterized with dark-grey color cold skin covered with clammy sweat.

Disorders of external respiration are the most obvious symptoms of respiratory insufficiency. Clinically in case of those patients next symptoms might be observed:

complete breathing arrest (apnea);

low respiratory rate – less than 12 per minute (bradypnea);

high respiratory rate – more than 20 per minute (tachypnea);

shallow breathing (respiratory volume less than 5 ml per kilogram of body weight);

respiratory “anarchy” (irregular breathing with pauses and uneven amplitude of respiratory movements);

pathological types of respiration:

a. Cheyne-Stokes breathing (periods of apnea, which are followed with chaotic frequent breathing);

b. Biot’s breathing (periods of apnea which are followed with breathing of equal amplitude);

c. Difficult breathing (noticeable at a distance, correlation between inspiration and expiration is violated, with active participation of additional muscles):

1. inspiratory dyspnea (difficult inspiration) – inspiration is prolonged, intercostals spaces, jugular fossa and subclavian fossa are retracted; sometimes stridorous noise can be heard

2. expiratory dyspnea (difficult expiration) – patients should make a great physical effort in order to exhale; exhalation is prolonged, noisy, heard at a distance; chest is enlarged, becomes barrel shaped

Cardiovascular system at the beginning reacts through compensative hyperdynamic reaction. Cardiac output, heart rate, systolic and diastolic pressure increase. Tissue perfusion

improves, what makes cellular oxygen supply and carbon dioxide elimination more effective. But due to hypoxia development vessel tone decreases and heart action is depressed. Blood pressure critically lowers and in case of inadequate treatment cardiac arrest appears.

Indications for artificial ventilation:

- apnoea
- central nervous system disorders - coma
- gray-cyanotic colour of skin, covered with clammy sweat
- low breathing frequency (less than 6 per minute) or high breathing frequency (more than 40 per minute) in case of normal thermal conditions, which causes great lowering of alveolar ventilation
 - excessive chest excursion, participation of additional muscles
 - pathological types of breathing
 - critical lowering of haemodynamic indexes (systolic blood pressure lower than 60 mm Hg), life-threatening arrhythmias

Decreasing of pO_{2a} to 60 mm Hg and less or increasing of pCO_{2a} mm Hg

Main types of external respiration disorders

Disorders of respiratory centre.

These disorders occur in case of narcotic intoxication, hypnotic and anaesthetic medicine usage. Injuries of the head, haemorrhages, brain strokes, inflammatory processes of the brain and meninges can violate breathing centre directly or through brain oedema. In these cases respiratory centre loses the ability of adequate reaction and thus acidosis, hypercapnia and hypoxia are not any more regulating ventilation.

In those patients we can see shallow, sometimes pathological breathing (Cheyne-Stokes, Biot's), in the most severe cases respiratory arrest occurs. The concentration of oxygen decreases and the level of carbon dioxide increases and thus hypoxia and hypercapnia damage cells on central nervous system, myocardium, other organs and systems, causing cardiac arrest.

Toxic or hypoxic damage of the brain, in turn, causes or deepens the coma and thus brings obstructive respiratory disorders. The muscle tone is decreasing, so the tongue blocks upper airways. In this situation only immediate actions, providing normal air passage, can save the patient's life.

It is quite often observed that in case of unconscious patient's oral cavity and pharynx are overfilled with saline and trachea, bronchi filled with mucus, which normally should be swallowed or spat out. Mucus gets infected quickly and thus inflammatory reactions begin, causing complications such as purulent bronchitis and tracheitis, pneumonia, which may lead coma patient to death.

Respiratory disorders of unconscious patients can be explained with passive outflow of gastric contents from stomach to the oral cavity and its further aspiration into airways (trachea

and bronchi). According to A. Zilber (1989) aspiration of 10-15 ml of acid gastric contents in most cases end with the death of the patient.

Prevention and treatment of this disease belong to the most urgent.

Urgent help:

1. Evaluate central nervous system condition – deepness of coma (chapter 5)
2. To prevent aspiration turn patient into save position (side position with head turned aside and if possible lower upper part of the body – thus gastric contents will probably flow out rather than into trachea).
3. Open the mouth of the patient and clean the oral cavity, if necessary, using your finger or forceps with surgical drape).
4. Titled the head backwards (use roll or small cushion if possible). Thus airways should stay clear.
5. Thrust the jaw forward: place your thumbs over the chin and the rest of your fingers put on the jaw (little fingers on the angles of the jaw), push the jaw forward and up, in a position of malocclusion (lower teeth in front of upper). After this action is done further providing of airways patency is quite simple and can be achieved with one finger.
6. You can also use simple airway adjuncts such as oropharyngeal and nasopharyngeal airways. Guedel tube is inserted between teeth with its curved distal end turned up, than moved toward soft palate and turned 180° and placed over the tongue.

In case of inadequate breathing or complete lack of it artificial ventilation should be provided (mouth to mouth or with apparatus for ventilation).

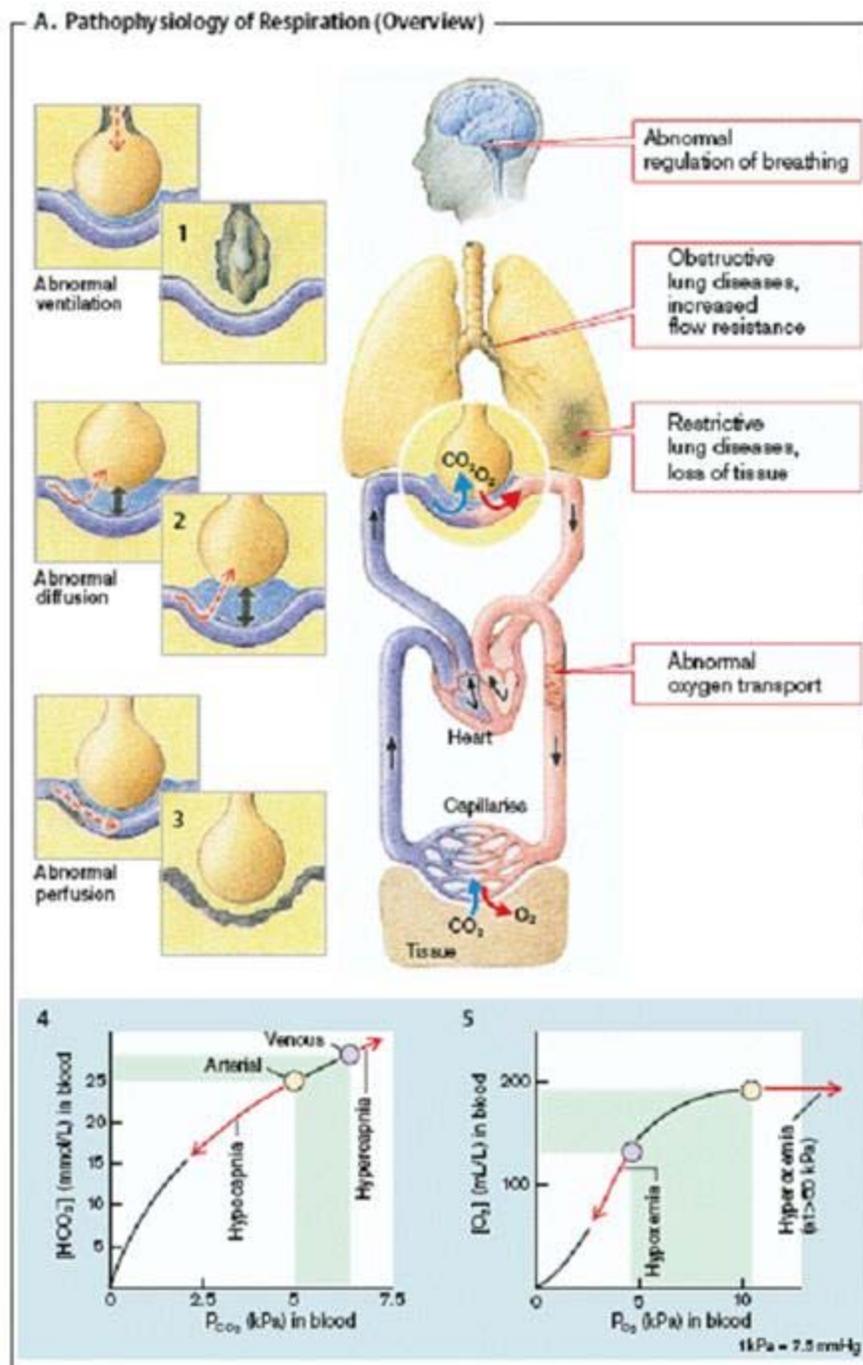

Constantly check patient's condition: control the heart and respiratory rate, blood pressure, body temperature, ECG. When there will be a possibility take biological material for the laboratory tests.

Immediate intensive treatment:

Perform direct laryngoscopy in order to check airways patency.

1. clean the oral cavity, if necessary, from foreign bodies and liquids such as vomit, sputum, blood cloths, gastric contents using electric vacuum suction
2. Provide oxygen supply of the patient: 8-10 liters per minute
3. In case of ineffective breathing begin artificial ventilation with Ambu bag or stationary respiratory apparatus.

4. Get the intravenous access, peripheral or central and start the infusion.
5. In case of further inadequacy of breathing give 0,5 ml of 0,1% of atropine intravenous and intubate the patient, because probably artificial ventilation will be prolonged.
6. Insert gastric sound and aspirate its contents.
7. Write down all the current data about patient's condition and performed treatment actions.
8. Continue observation using laboratory and instrumental techniques.
9. Continue etiological and symptomatic treatment.

Alveolar hypoventilation caused by respiratory muscles violations.

This pathology appears when chest muscles are not able to perform a complete respiratory act. Hypoventilation is the most common reason of vital disorders in case of patients with polyneuropathies, myasthenia, botulism, tetanus, poliomyelitis, organophosphate poisoning. In case of patients after operations this type of hypoventilation may occur due to relaxants used for anaesthesia, hypokalemia or metabolic alkalosis.

Excursion of the chest is reduced and thus volumes of inspiration and expiration are lower. Conscious patients feel breathless and anxious; cyanosis, clammy sweat, tachycardia, hypertension, restlessness appear. If treatment is not provided, CNS is depressed and earlier or

later cardiovascular system fails. Those patients should be ventilated with the help of respiratory apparatus immediately, as in their case oxygenation itself will not help (hypoxia will be corrected, but never the less elimination of carbon dioxide will not be improved and hypercapnia will cause cardiac arrest).

Residual relaxants effect is eliminated with anticholinergic drugs (1-2 ml of 0,05% proserin solution intravenous with previous administration of 0,1% atropine sulphate solution).

For hypokalemia correction special mix glucose, potassium and insulin is used (so called polarizing solution).

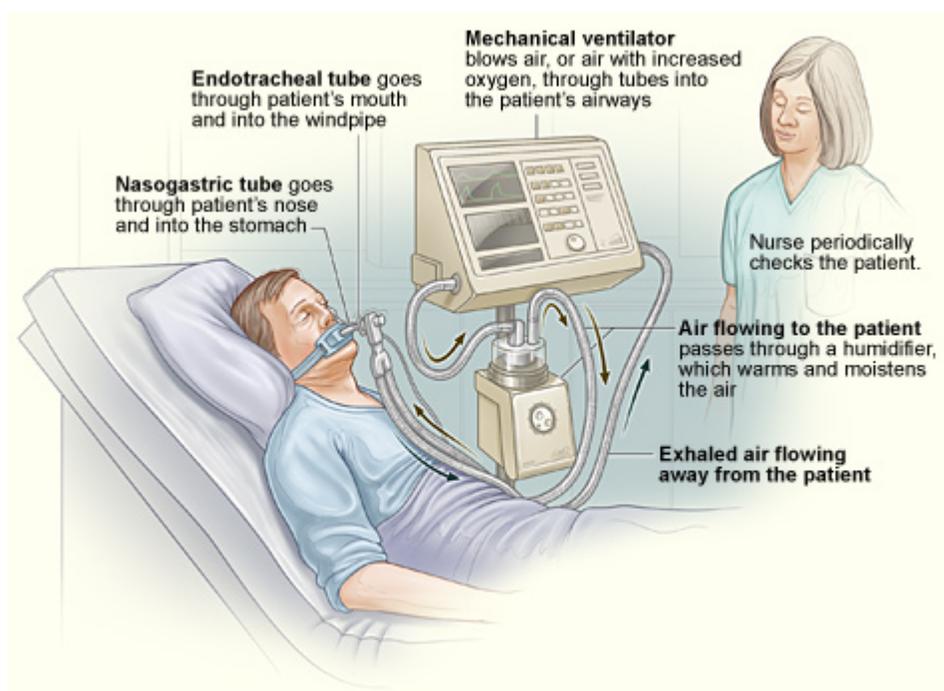

Low cholinesterase activity of plasma is compensated with fresh frozen plasma.

Organophosphate poisonings are treated with special antidotes (8.2); for elimination of convulsions specific medicines are used (5.3).

Brief lung ventilation (up to 30 minutes) can be provided with the mask. Ventilation up to 3 days needs intubation. If self-breathing is still inadequate after this time tracheostomy is recommended.

History of medicine knows cases, when patients were artificially ventilated for 18-20 years.

Team of medical professionals, responsible for treatment of patient with hypoventilation should follow all the asepsis and antiseptic rules and should be very careful and attentive to the patient's condition and apparatus work.

Rules of care: patients on prolonged ventilation

1. Constantly check the condition of the patient (vital functions should be

monitored), record in the papers parameters of ventilation, heart rate, blood pressure and central venous pressure, consciousness, physiologic and pathological liquid loss and medicines administered.

2. All the time control work of the respiratory apparatus (respiratory rate, volumes of respiration, minute ventilation, pressure in the airways during inspiration and expiration). If self-breathing is present, but inadequate it's important to achieve synchronized patient-apparatus breathing (choose the correct mode or sometimes use pharmacological sleep to "turn off" the respiratory centre of the patient if respiratory efforts are exhausting for the organism).

3. Every 30 minutes change parameters of respiration, making tidal volume 40-50% more than the necessary every 5-10 minutes. This way you prevent the development of atelectasis.

4. Every hour carry out oral, tracheal and bronchial suction using plastic catheters with side foramina and blunt end. Catheters generally should not be reused, but if it's necessary you can use them for one patient several times keeping them in antiseptic solution between suction. Procedure: doctor or nurse puts on gloves and face mask, disconnects tube from the apparatus, carefully and at the same time quickly inserts the plastic catheter, previously connected to the vacuum suction, into the tube and turns it clockwise and counterclockwise. For cleaning of principal bronchi try to turn head of the patient and to push catheter deeper, but try not to make single suction try longer than 10-12 seconds. In necessary – continue suction after a ventilation break (during this pause you can carefully clap over the chest of the patient to remove mucus from lower airways to their upper parts). After suction is done clean the catheter and place it into the antiseptic solution.

Cleaning of the trachea through tracheostomy tube has 2 main points:

- inserting the catheter keep the side foramen of it's upper end open
- during the suction shut it with your finger to create negative pressure and aspirate mucus; taking it out don't forget to scroll it.

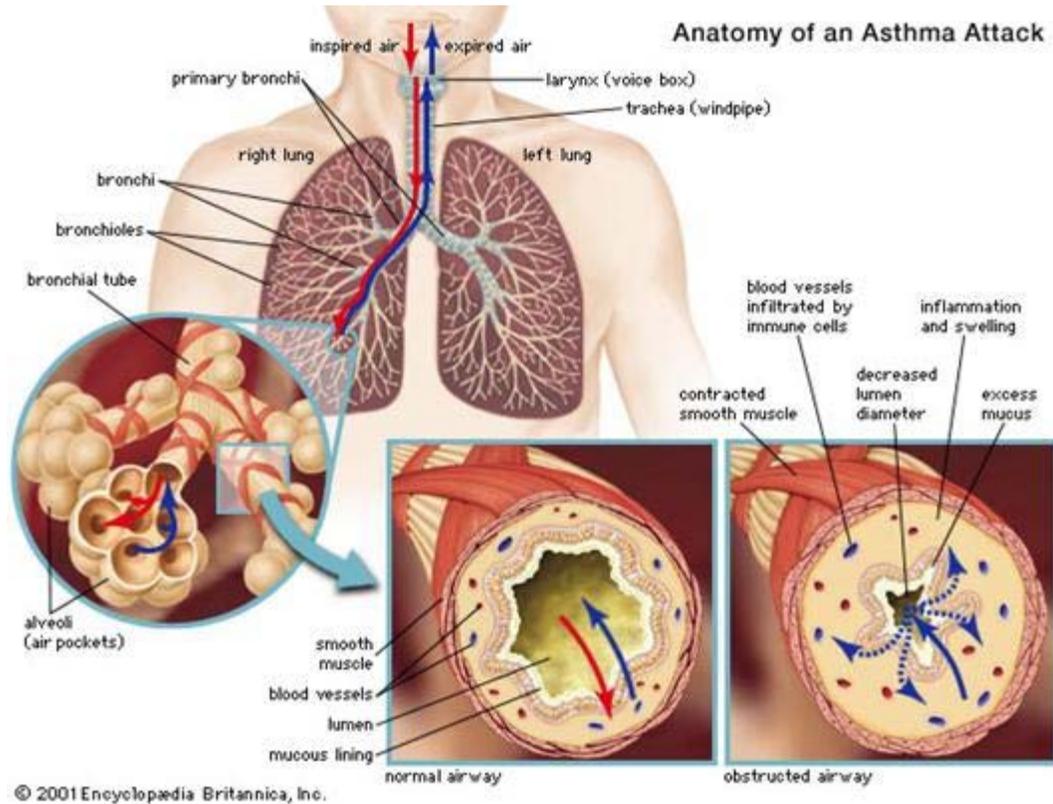

The same technique should be used for oral and nasal cavities (right and left nostril), but not the same catheter. Every catheter container with antiseptic should be signed.

5. Every hour change the position of the patient: make it lateral, supine or prone, Fowler's or Trendelenberg. Changing body position you change perfusion and ventilation correlations in the lungs and thus arterial blood becomes more oxygenated. This way appearance of bedsores is also prevented.

6. Every 12-24 hours change the endotracheal or tracheostomy tube.

7. In case of excessive mucus accumulation (worsening of auscultatory picture, x-ray negative dynamics) or atelectasis suspicion perform therapeutic bronchoscopy.

8. To prevent development of inflammatory reactions pay special attention to humidifying and warming of the ventilation mix, use aerosol inhalations, adequate infusion level, enteral and parenteral nutrition, state of the immune system and choose antibiotics rationally.

Status asthmaticus

Status asthmaticus is an acute exacerbation of asthma that is caused by bronchial spasm and does not respond to standard treatments of bronchodilators and steroids. It occurs when parasympathetic-sympathetic balance is greatly violated. Pathological stimulation of vagus causes spasms of smooth bronchi muscles, what brings increasing of resistance worsening of their patency. In addition excessive secretion and oedema of bronchial walls make airways almost not conductive.

Such exacerbation can be caused by allergens, stress or endocrinological factors.

Main clinical asthma symptom is dyspnea attack, which begins with dry cough. Those attacks are sudden; patients feel more comfortably sitting in bed with their arms based on bed. This position is called orthopnea, it help to use additional muscles (abdominal, muscles of the shoulder girdle) in respiratory act. Extreme wheezing is heard at distance. Inspiration is extremely short and expiration much prolonged and forced. Lack of mucus is rather warning

symptom. In case of complete obturation “silent lung” appears: breathing is asymmetric, there are silent parts of the lungs which do not contain any auscultative phenomena. Patients suffer from hypoxia and hypercapnia which earlier or later result in unconsciousness.

Treatment.

Most asthma attacks are successfully treated with inhalation of short acting β_2 -adrenoreceptor agonists (SABA), such as salbutamol. Anticholinergic medications, such as ipratropium bromide, might be used in addition for severe cases. Steroids are generally considered the most effective treatment available for long term control. When neither steroids, nor adrenomimetics work for treatment of a long and severe attack (or series of attacks)

In case of status asthmaticus spasm of bronchioles, inflammation and edema of bronchial wall and violation of mucus excretion and evacuation (due to abnormal cilia work) create pathogenetic base. Hyperventilation leads to greater water loss, what makes surface of bronchi dry and mucus more thick. This sick mucus can not be evacuated from airways during cough and thus it obstructs small bronchi and bronchioles, making ventilation impossible.

There are two types of status asthmaticus: anaphylactic and metabolic. Anaphylactic type is connected with allergic and immune reactions. It might appear after administration of some medicines (antibiotics, enzymes, aspirin, etc.) and develops very fast. Metabolic type of status asthmaticus is caused by metabolism disorders, which block β -adrenoreceptors. Long-term administration of sympatomimetics (asthmopent, ephedrine) can also cause metabolic type of status asthmaticus.

Status asthmaticus has certain stages:

1 stage: relative compensation. Patients are cyanotic, restless, sitting. Dyspnea has expiratory character with respiratory rate 26-40 per minute. Heart rate is 120 per minute, blood pressure in most patients is elevated. Auscultatory picture shows sibilant rales, prolonged expiration and “mosaic” breathing.

2 stage: decompensation. General condition of the patient is very serious. Patients are exhausted, sometimes excited and aggressive. Skin is cyanotic, wet. Respiratory rate might be 60 per minute, breathing is shallow, noisy at distance and extremely weak during auscultation, sometimes “silent lung” is observed. Heart rate is 120-140 per minute, blood pressure lowers to 80 mm of Mercury. Hypoxemia and hypercapnia cause mixed respiratory and metabolic acidosis.

3 stage: hypoxic coma. General condition of the patient is extremely severe. Patients are unconscious, convulsions are possible. Skin is cyanotic, covered with clammy sweat. Pupils are wide, reflexes are depressed or pathologic reflexes appear. Respiratory rate is over 60 per minute (sometimes acute bradypnea); auscultation picture – “silent lung”. Heart rate is over

140 per minute, blood pressure lowers to critical values. Biochemical blood test results show mixed decompensated acidosis ($\text{pH} < 7,2$) and serious homeostatic disorders. Acute cardiopulmonary insufficiency may lead to death.

Intensive treatment of status asthmaticus.

1. Begin oxygenation as soon as possible; if there is such possibility you should add 20%-30% of helium to the gas mix.

2. Provide constant monitoring of vital functions (ventricular fibrillation is one of possible death reasons of these patients).

3. Get intravenous access and start infusion of warm saline (polarizing solution, etc.). In case of extreme dehydration total infusion volume might reach 5-7 liters per day. In case of metabolic acidosis use 4% solution of sodium bicarbonate (100-150 ml).

4. Use steroids: solution of hydrocortisone (intravenously 150-200 mg every 2-3 hours), solution of prednisolone (60 mg every 4-6 hours), solution of dexamethason (8-16 mg every 6 hours).

5. Add to the treatment spasmolytics, antihistaminic, sedative medicines (10 ml of 2,4% ephillin solution; 2 ml of 2% no-spa solution, 1 ml of 2% dimedrol solution, 2-4 ml of 0,5% solution of diazepam or 10-20 ml of 20% solution of sodium oxybate intravenously slowly). In the past for some cases halothane-nitrous oxide mix was used to fight with bronchi spasm.

7. In case of progressive cardiac insufficiency use heart stimulating medicines such as cardiac glycosides (0,5 ml of 0,05% solution of strophanthin with saline intravenously). 7. If patient's condition is not getting worth and previously used treatment failed perform the intubation and begin artificial ventilation.

Indications for artificial ventilation in case of status asthmaticus:

- unconsciousness
- low blood pressure (< 70 mm Hg)
- tachycardia (over 140 per minute)
- $\text{pCO}_2 > 60$ mm Hg, $\text{pO}_2 < 60$ mm Hg, $\text{pH} < 7,25$

In those cases patients might receive halothane-oxygen narcosis. Therapeutic bronchoscopy should be performed with warm saline lavage (50-100 ml with its further suction, nearly 1,5 liters per one bronchoscopy). During lavage try to change patients position

in order to remove more mucus cloths.

There are many important points in general asthma treatment. Among them: rational antibiotic treatment, elimination of allergens, treatment of comorbidities and adequate asthma attacks treatment, in order to avoid development of status asthmaticus.

Chest injuries

Multiple rib fractures, especially that causing flail chest, violate greatly biomechanics of breathing. Clinically one can see reduction of chest excursion, retraction of certain chest wall parts and asymmetric breathing movements. Patients show decreasing of tidal volume, cyanosis, violations of haemodynamics, microcirculation disorders and depression of central nervous system.

Rib fractures can also cause hemothorax and pneumothorax. One of the most dangerous complications of chest injury is a tension pneumothorax, which end with a severe hypoxia, mediastinum organs dislocation and thus death.

Chest trauma patients should be treated very carefully: use all your diagnostic possibilities, including inspection, palpation, percussion, auscultation and additional laboratory and instrumental tests. Especially important is such approach with unconscious victims.

The choice of treatment depends on specific type of injury and its complications: hemothorax and pneumothorax need to be drained; tension pneumothorax should be punctuated (transformed into open pneumothorax); ineffective spontaneous ventilation should be replaced with artificial; antibiotics and painkillers are generally recommended.

“Coronary Café-syndrome“

This name is used for a sudden asphyxia, which appears when foreign body gets between the vocal cords and obturates the airways.

It is caused by a violation of swallowing and breathing. Imagine a situation in which the victim speaks loudly during the meal and then suddenly stops talking and jumps to his feet. His efforts to inhale are ineffective, hands try to free the neck rending the clothes, face gets cyanotic and swollen, eyes get filled with fear. In 3-4 minutes patient losses the consciousness, convulsions begin and finally clinical death appears (respiratory efforts cease, pulse gets weaker, defecation and urination are possible).

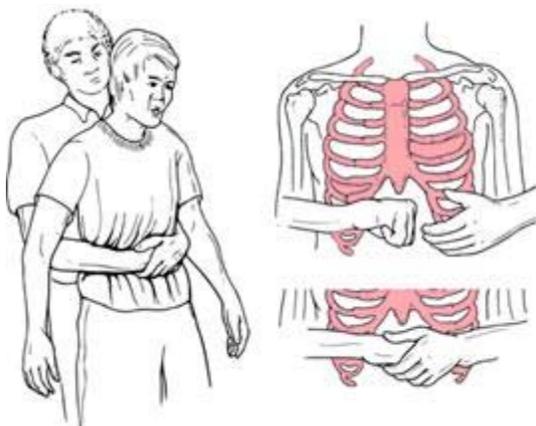

Thus, during acute foreign body obturation of glottis we can see 3 subsequent stages:

- 1- patient conscious, on his feet

- 2- patient unconscious, convulsions develop
- 3- clinical death (lasts from 5-th to 10-th minute)

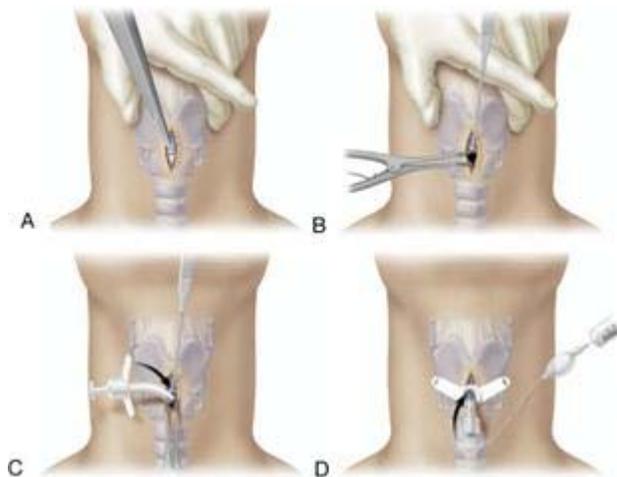

On the first stage doctor or any health care system professional (even skilled witness who has no medical education) should try to perform Heimlich manoeuvre. Stand behind the patient and wrap your arms around the victim's waist (hands on the epigastrium) and start making inwards and upwards thrusts. If the patient is still able to "collaborate" ask him to inhale during the manoeuvre.

Heimlich Manoeuvre

This manoeuvre allows to create a high pressure in the windpipe of the patient and thus exhaled air forces the foreign body to get out from the glottis. If the try will be unsuccessful only urgent conicotomy will save the life of the patient.

Procedure of conicotomy: put a roll (improvised one if necessary) under the neck of the patient, extending his neck as much as possible. In case of convulsions just ask someone to hold the patient. Then cover tightly with the first and third fingers of your left hand the thyroid cartilage and "slide" down with your index finger to the fossa, which divides thyroid and cricoid cartilages. At this place the thickness of the membrane is only few millimetres, so it can be easily pricked with a sharp object (for example kitchen knife). Limit the blade of the knife to 1cm long with the fingers of your right hand and sliding over the nail of your left hand index finger prick or cut the membrane. If it is possible insert a tube into the opening you made to prevent it's closing (you can even use your ball pen for this purpose). The faster this manipulation will be done, the higher are chances of the patient to get fully recovered.

Conicotomy consists of 2 phases:

- A. Cutting of the membrane with a scalpel with limiting its cutting length (with a plaster). It is done to save the posterior wall of trachea from injuring.
- B. Restoring of airways patency with a needle (puncture of the membrane).

If the victim is in a state of clinical death (the third stage) perform the conicotomy immediately and start CPR. You can ventilate the patient through the conicotomy tube.

Advanced medical help includes direct laryngoscopy and extraction of a foreign body with a forceps. If necessary those patients can be treated with a bronchoscopy or tracheostomy.

Laryngospasm

Laryngospasm is a pathological muscular contraction of the laryngeal cords, which manifests itself with a difficult or impossible inspiration. It appears as a consequent of pathological reflex or excessive stimulation of vagal nerve.

Usual reasons for laryngospasm are traumatic operations on reflex zones (vocal cords, trachea bifurcation, epiglottis, eye bulbs, periosteums). Irritation of vocal cords by food, saline, gastric contents, chemical or thermal stimuli as long as allergic reaction are the most common reasons for laryngospasm.

There are two types of laryngospasm: total and partial. Both cases are sudden and characterized by an inspiration dyspnea. Patient tries to inhale, his respiratory muscles contract, retracting intercostals spaces, jugular and supraclavicular fossae. During partial laryngospasm a small amount of air gets through the vocal cords and the sound of this air movement reminds cry of a rooster. Total laryngospasm is silent (aphonic). Within few seconds patient becomes cyanotic, his blood pressure and heart rate rise, later victim becomes unconscious, reflexes are inhibited. In some cases after this muscles of larynx relaxes

spontaneously and thus laryngospasm stops. But if deep hypoxia lasted for a while cardiac arrest still might appear.

Immediate aid

- begin oxygenation through the face mask as without proper oxygen supply partial laryngospasm becomes total

- whatever the reason of laryngospasm was eliminate it (remove the stimulator from the reflex zone if necessary, stop the operation for example)

- give intravenously atropine solution (0,01 mg per kilogram of body weight), ephedrine (5-10 ml of 2,4% solution, diluted in 10 ml of saline). If the initial damage was caused by thermal, chemical or allergic stimuli use antihistamine medicine (2 ml of 2,5% promethazine solution, 2 ml of 2% dimedrol solution) and steroids (60-90 mg of prednisolone).

Intensive treatment

- inhalation of bronchial spasmolytics (salbutamol);

- repeat the medicines mentioned above;

- in case of partial laryngospasm start artificial respiration through the mask with high oxygen speed and large ventilation volume;

- if your previous actions are not successful – use depolarising muscle relaxants (give 10 ml of 2% suxamethonium solution intravenously) and after total muscle relaxation perform direct laryngoscopy and trachea intubation. Of course if you have time and possibilities previously use hypnotics (for example 5-10 ml of propofol solution);

- if there are no conditions for intubation or your tries were unsuccessful, but situation is worsening into life-threatening (extreme bradycardia, unconsciousness, blood pressure less than 70 mm of Hg, general convulsions) perform conicotomy with the equipment you have and insert tube for oxygenation;

- in case of cardiac arrest start CPR according to general standards.

Bronchial spasm

Bronchial spasm is an acute disorder of external respiration caused by spasm of small bronchi smooth muscles. It can be total or partial. The reasons are the same as those for laryngospasm. Treatment for bronchial and laryngeal spasm are much alike, however muscle relaxants and conicotomy are not effective and thus death is almost unavoidable. What could be really useful is prophylactic premedication: before operations on reflex zones use atropine solution (0,01 mg per kg of body weight) in order to avoid pathological reflexes.

3.4 Medical operations and manipulations.

Usage of laryngeal mask.

Laryngeal mask is an elastic plastic tube with mask-shaped distant ending. It was invented in 1982 by British anaesthetist Archie Brain and now is popular worldwide among ambulance rescuers and anaesthesiology specialists.

Indications: providing of airways patency in case other methods failed; artificial ventilation during anaesthesia if intubation is not required.

Required equipment: laryngeal masks of different sizes, syringe (10 or 20 ml); equipment for oral cavity opening and cleaning if necessary (vacuum suction for example).

Procedure: open the mouth and clean the oral cavity if necessary. Staying on the right side of the patient use fingers of your left hand to press the chin down and thus open the mouth. Insert the laryngeal mask to the oral cavity keeping it's mask-shaped end with your index and long fingers. Glide it downwards and backwards along the tongue until you will feel a definitive resistance. After placement fill the inflatable cuff with air using the syringe: this way cuff will surround the laryngeal framework and air will be insufflated directly to the airways. The free end of the LMA can be connected to the AMBU bag or respiratory apparatus. Nowadays laryngeal masks have a variety of modifications: some of them even allow intubation, some are made with non-inflatable cuffs (i-gels), etc.

Tracheostomy

There are 3 types of tracheostomy according to anatomic placement of the incision: upper medial and low.

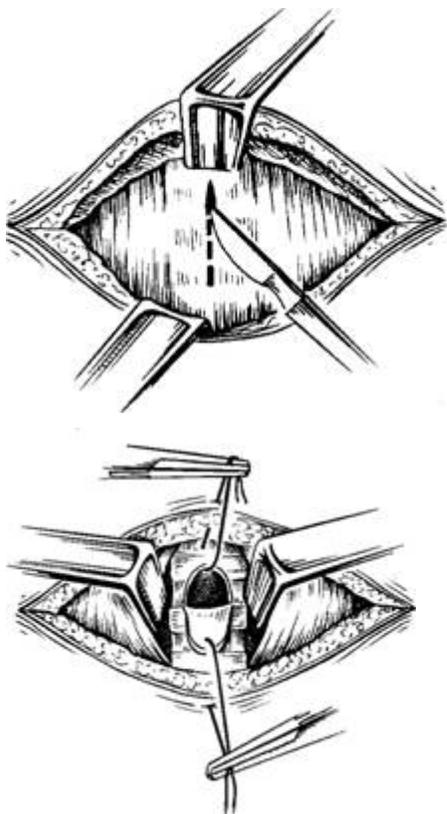

Indications: violations of airways patency in case of tumors, laryngeal stenosis; prolonged artificial ventilation of ITU patients.

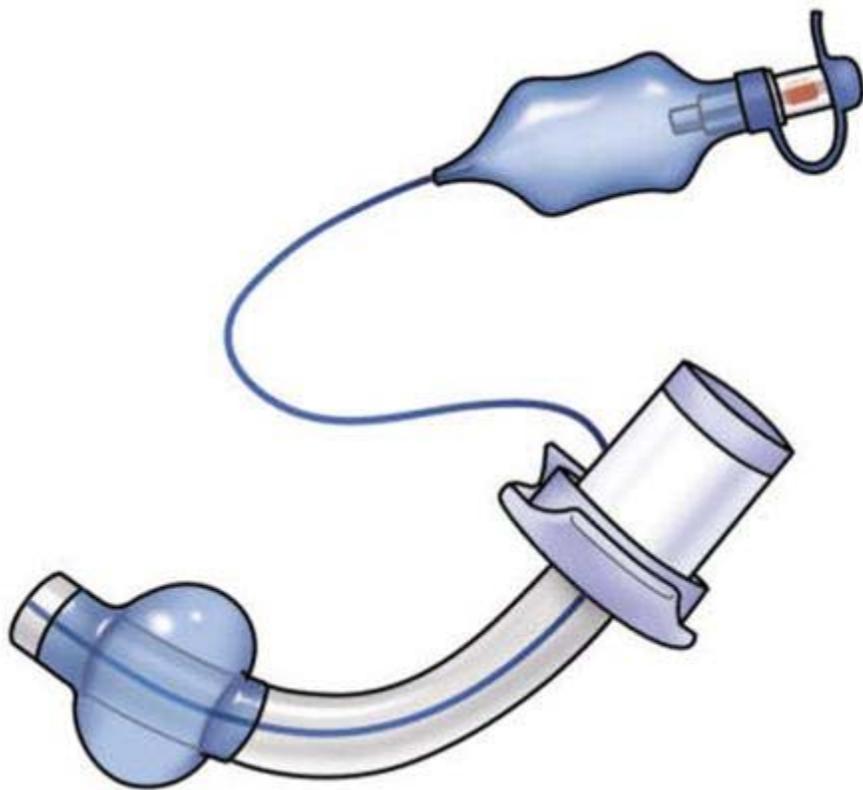

Required equipment: tracheostomy tubes of different sizes, scalpel, clamps, tissue retraction blades, stitch material and dressing, antiseptics, electric suction, respiratory apparatus, anaesthetics.

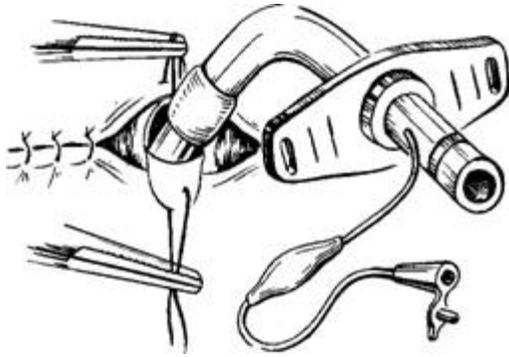

Procedure: perfect conditions for tracheostomy are those in operating room, however it can be done in ITU with specific antiseptic and aseptic measures.

After antiseptic preparation of the operative field immobilize the trachea with fingers of your left hand and cut the skin strictly along the midline of the neck right under the thyroid cartilage (the length of the incision should be 4-5 cm). After skin, hypodermic tissue and aponeurosis are cut start blunt separating of the cricoid cartilage and pull it upwards with a surgical hook. Cut the fascia, which covers the thyroid isthmus, along the lower edge of the cartilage and with a blunt hook pull the isthmus down. Make horizontal incision between the second and third or third and fourth tracheal rings, then cut one or two

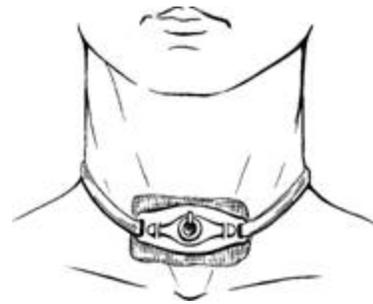

distal tracheal rings and insert the tube (use dilatator if necessary). Don't make opening too large, not more than 1/3 of trachea diameter. After tube is fixated put an aseptic bandage around the wound.

Pic.3.3

Pic.3.4

3.5 Control tests

1. Normally partial pressure of oxygen in alveoli is:

- A. equal to atmospheric pressure
- B. $80 \pm$ mm of Mercury
- C. 140 ± 5 mm of Mercury
- D. 100-110 mm of Mercury
- E. during inspiration is equal to arterial partial oxygen pressure, during expiration – equal to partial oxygen venous pressure

2. Arterial blood is saturated with oxygen for:

- A. 100%
- B. 96-97%
- C. 90-95%
- D. 85-95%
- E. percentage depends on the character of breathing

3. Partial pressure of carbon dioxide in arterial blood is:

- A. depends on partial oxygen pressure
- B. depends on intensity of tissue breathing
- C. normally is 36-44 mm of Mercury
- D. increases in case of hyperventilation

- E. depends on haemoglobin dissociation curve
4. Which pathology does not need artificial respiration?
- A. Kussmaul breathing
 - B. Biot's breathing
 - C. Cheyne-Stokse breathing
 - D. lowering of pO_{2a} to 60 mm of Mercury
 - E. respiratory rate over 40 per minute
5. What should be done for hypercapnia treatment?
- A. sodium bicarbonate solution given
 - B. artificial ventilation started
 - C. cytochrome C given
 - D. oxygenation started
 - E. blood of the same group transfused
6. What is a method of laryngospasm treatment?
- A. muscle relaxants and artificial ventilation
 - B. respiratory stimulants (cordiamin, lobelin)
 - C. sodium bicarbonate
 - D. diuretics
 - E. tracheostomy
7. What should be done to minimize the damage of prolonged (over one week) artificial ventilation?
- A. intubation
 - B. tracheostomy
 - C. conicotomy
 - D. respiratory analeptics should be given
 - E. therapeutic lavage
8. What should be done in order to prevent laryngospasm?
- A. peripheral M-cholinolitics should be given
 - B. oral cavity should be cleaned
 - C. spasmolytics should be given

- D. artificial ventilation should be started
 - E. jaw should be thrust forward
9. What should be done in case of foreign body in the airways?
- A. tracheostomy
 - B. change of body position – upper part should be lowered
 - C. mouth-to-mouth ventilation
 - D. Heimlich manoeuvre
 - E. patient should be punched between blade bones

Task 1.

Patience, the patient of 56 years, was transported by ambulance to the hospital reception with breathlessness and difficult breathing. He is restless, excited: his skin is cyanotic and dry. Respiration rate is 26, respiratory movements are deep, additional muscles participate respiration. Blood pressure is 180/110 mm of Mercury, heart rate – 106 per minute. Gasometry results are: pO_2A 67 mm of Mercury, pCO_2a – 49 mm of Mercury. Name the disorder and principles of its treatment.

Task 2.

Calculate normal spirometry indexes of Andrew, medical student of 22 years (height 170 cm, weight 70 kg): respiratory rate, tidal volume, minute ventilation, dead space volume, alveolar ventilation.

Task 3.

Patience, the patient, during cleaning of his nasal cavity suddenly felt, that inspiration became difficult. His skin gets cyanotic, blood pressure increases. Name the type of complication and describe the urgent help, which is necessary in this situation.

Task 4.

Andrew, the medical student, during a casual meeting in a café was laughing and at the same time chewing his sandwich. Suddenly he became quiet, grabbed his neck and stopped breathing. His face turns blue.

what should be done immediately

What should be done if Bonnie, student of medicine, has convulsions. He is unconscious, his pulse is weak. Describe CPR.

What will be your decision if You find Clyde, student of medicine, 3 minutes after cardiac arrest?

Task 5.

Patience, the patient, was transported to the hospital in a severe condition: unconscious, skin cyanotic, respiratory rate 64 per minute, heart rate 124 per minute, blood pressure 90/60 mm of Mercury, body temperature – normal. Choose the type of help and algorithm of your actions.

Task 6.

Patience, the patient, suffers from bronchial asthma. After regular ambulance visit he doesn't feel better, although medicines were given intravenously. His condition is critical: central nervous system depressed, skin is wet and cyanotic, expiration is prolonged greatly, sibilant rales are combined with “silent lung” parts. Blood pressure is 110/70 mm of Mercury. Heart rate is 116 per minute. Describe your immediate actions and algorithm of intensive care.

Student should repeat next questions

Violations of homeostasis and their correction.

9.1 The importance of the water to the organism.

Life on earth was born in the water environment. Water is a universal solvent for all the biochemical processes of the organism. Only in case of stable quantitative and qualitative composition of both intracellular and extra cellular fluids homeostasis is remained.

The body of an adult human contains 60% of water. Intracellular water makes 40% of the body weight, the water of intercellular space makes 15% of body weight and 5% of body weight are made by the water in the vessels. It is considered that due to unlimited diffusion of water between vessels and extra vascular space the volume of extracellular fluid is 20% of body weight (15%+5%).

Physiologically insignificant amounts of water are distributed beyond the tissues in the body cavities: gastrointestinal tract, cerebral ventricles, joint capsules (nearly 1% of the body weight). However during different pathologic conditions this “third space” can cumulate large amounts of fluid: for example in case of ascites caused by chronic cardiac insufficiency or cirrhosis abdominal cavity contains up to 10 liters of fluid. Peritonitis and intestinal obstructions remove the fluid part of blood from the vessels into the intestinal cavity.

Severe dehydration is extremely dangerous for the patient. Water gets to the body with food and drinks, being absorbed by the mucous membranes of gastro-intestinal tract in total amount of 2-3 liters per day. Additionally in different metabolic transformations of lipids, carbohydrates and proteins nearly 300 of endogenous water are created. Water is evacuated

from the body with urine (1,5-2 liters), stool (300 ml), perspiration and breathing (those two reasons are combined as “perspiration loss” and make from 300 to 1000 ml per day).

Water balance is regulated through complicated, but reliable mechanisms. Control over water and electrolytes excretion is realized by osmotic receptors of posterior hypothalamus, volume receptors of the aerial walls, bar receptors of carotid sinus, juxtaglomerular apparatus of the kidneys and adrenal cortical cells.

When there is a water deficiency or electrolytes excess (sodium, chlorine) thirst appears and this makes us drink water. At the same time posterior pituitary produces antidiuretic hormone, which decreases urine output. Adrenals reveal into the blood flow aldosterone, which stimulates reabsorption of sodium ions in the tubules and thus also decreases diuresis (due to osmosis laws water will move to the more concentrated solution). This way organism can keep precious water.

On the contrary, in case of water excess endocrine activity of glands is inhibited and water is actively removed from the body through the kidneys.

9.2 Importance of osmolarity for homoeostasis.

Water sections of the organism (intracellular and extracellular) are divided with semipermeable membrane – cell wall. Water easily penetrates through it according to the laws of osmosis. Osmosis is a movement of water through a partially permeable membrane from the solution with lower concentration to a solution with higher concentration.

Osmotic concentration (osmolarity) is the concentration of active parts in one liter of solution (water). It is defined as a number of miliosmoles per liter (mOsm/l). Normally osmotic concentration of plasma, intracellular and extracellular fluids is equal and varies between 285mOsm/l. This value is one of the most important constants of the organism, because if it changes in one sector the whole fluid of the body will be redistributed (water will move to the environment with higher concentration). Over hydration of one sector will bring dehydration of another. For example, when there is a tissue damage concentration of active osmotic parts increases and water diffuses to this compartment, causing oedema. On the contrary plasma osmolarity decreases, when there is a loss of electrolytes and osmotic concentration of the cellular fluid stays on the previous level. This brings cellular oedema, because water moves through the intracellular space to the cells due to their higher osmotic concentration.

Cerebral oedema appears when the plasma osmolarity is lower than 270 mOsm/l. Activity of central nervous system is violated and hypoosmolar coma occurs. Hyperosmolar coma appears when the plasma osmolarity is over 320 mOsm/l: water leaves the cells and fills the vascular bed and this leads to cellular dehydration. The sensitive to cellular dehydration are the cells of the brain.

Plasma osmolarity is measured with osmometer. The principle of measurement is based on difference in freezing temperature between distilled water and plasma. The higher is the osmolarity (quantity of molecules) the lower is freezing temperature.

Plasma osmotic concentration can be calculated according to the formula:

$$\text{Osmotic concentration} = 1,86 * \text{Na} + \text{glucose} + \text{urea} + 10,$$

Plasma osmolarity (osmotic concentration) – mOsm/l

Na- sodium concentration of plasma, mmol/l

Glucose- glucose concentration of the plasma, mmol/l

Urea- urea concentration of the plasma, mmol/l

According to this formula sodium concentration is the main factor influencing plasma osmolarity. Normally sodium concentration is 136-144 mmol/l. Water and electrolytes balance can be violated with external fluid and electrolytes loss, their excessive inflow or wrong distribution.

9.3 Fluid imbalance and principles of its intensive treatment.

Water imbalance is divided into dehydration and overhydration.

Dehydration is caused by:

- excessive perspiration in conditions of high temperature;
- rapid breathing (dyspnea, tachypnea) or artificial ventilation without humidification of the air;
- vomiting, diarrhoea, fistulas;
- blood loss, burns;
- diuretics overdose;
- excessive urine output;
- inadequate enteral and parenteral nutrition or infusion therapy (comatose patients, postoperative care);
- pathological water distribution (“third space” in case of inflammation or injury).

Dehydration signs: weight loss, decrease of skin turgor and eyeballs tone, dry skin and mucous membranes; low central venous pressure, cardiac output and blood pressure (collapse is possible); decreased urine output and peripheral veins tone; capillary refill over 2 seconds (microcirculation disorders) and low skin temperature; intracellular dehydration is characterized with thirst and consciousness disorders. Laboratory tests show blood concentration: hematocrit, hemoglobin concentration, protein level and red blood cells concentration increase.

Overhydration appears in case of:

- excessive water consumption, inadequate infusion therapy;
- acute and chronic renal failure, hepatic and cardiac insufficiency;
- disorders of fluid balance regulation;
- low protein edema.

Clinical findings in case of overhydration are: weight gain, peripheral oedema, transudation of the plasma into the body cavities (pleural, abdominal), high blood pressure and central venous pressure. In case of intracellular overhydration appear additional symptoms: nausea, vomiting, signs of cerebral edema (spoor, coma). Laboratory tests prove hemodilution.

According to the osmotic concentration of plasma dehydration and overhydration are divided into hypotonic, isotonic and hypertonic.

Isotonic dehydration is caused by equal loss of electrolytes and fluid from the extracellular space (without cellular disorders). Blood tests show hemoconcentration; sodium level and osmotic concentration are normal.

To treat this type of water imbalance use normal saline solution, Ringer solution, glucose-saline solutions, etc.. The volumes of infusions can be calculated according to the formula:

$$V_{H_2O} = 0,2 * BW * (H_{tp} - 0,4) / 0,4 ,$$

V_{H_2O} – volume of infusion, l

H_{tp} – patient's hematocrit, l/l,

BW – body weight, $0,2 * BW$ – volume of extracellular fluid,

0,4- normal hematocrit, l/l,

Hypertonic dehydration is caused by mostly water loss: first it appears in the vascular bed, than in the cells. Laboratory tests show hemoconcentration: elevated levels of proteins, red blood cells, hematocrit. Plasma sodium is over 155 mmol/l and osmotic concentration increases over 310 mOsm/l.

Intensive treatment: if there is no vomiting allow patients to drink. Intravenously give 0,45% saline solution and 2,5 % glucose solution, mixed with insulin. The volume of infusions is calculated according to the formula:

$$V_{H_2O} = 0,6 * BW (Na_p - 140) / 140,$$

V_{H_2O} – water deficiency, l

Na_p – plasma sodium, mmol/l

BW – body weight, 0,6* BW volume of general body fluid

140 – physiological plasma sodium concentration

Hypotonic dehydration is characterized with clinical features of extracellular dehydration. Laboratory tests show decrease of sodium and chlorine ions. Those changes cause intracellular movement of the water (intracellular overhydration). Hemoglobin, hematocrit and protein levels are increased. Sodium is lower than 136 mmol/l, osmolarity is lower than 280 mOsm/l.

To treat this type of water imbalance use normal or hypertonic saline and sodium bicarbonate solution (depends on blood pH). Do not use glucose solutions!

The deficiency of electrolytes is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

Na_d – sodium deficiency, mmol

Na_p – plasma sodium, mmol/l

BW – body weight, 0,2 BW – volume of extracellular fluid

Isotonic overhydration is caused by excess of the water in the vascular bed and extracellular space; however intracellular homeostasis is not violated. Hemoglobin is less than 120 g/l, protein level is less than 60 g/l, plasma sodium is 136-144 mmol/l, osmotic concentration is 285-310 mOsm/l.

Treat the reason of imbalance: cardiac failure, liver insufficiency, etc. Prescribe cardiac glycosides, limit salt and water consumption. Give osmotic diuretics (mannitol solution 1,5 g/kg), saluretics (furosemide solution 2 mg/kg), aldosterone antagonists (triamterene – 200 mg), steroids (prednisolone solution 1-2 mg/kg) albumin solution if necessary (0,2-0,3 g/kg).

Hypertonic overhydration is a state of extracellular electrolytes and water excess combined with intracellular dehydration. Blood tests show decrease of hemoglobin, hematocrit, protein level, however sodium concentration is increased over 144 mmol/l, osmotic concentration is over 310 mOsm/l.

To treat this condition use solutions without electrolytes: glucose with insulin, albumin solutions and prescribe saluretics (furosemide solution), aldosterone antagonists (spironolactone). If it is necessary perform dialysis and peritoneal dialysis. Do not use crystalloids!

Hypotonic overhydration is a state of extracellular and intracellular water excess. Blood tests show decrease of haemoglobin, hematocrit, proteins, sodium and osmotic concentration. Intensive therapy of this condition includes osmotic diuretics (200-400 ml of 20% mannitol solution), hypertonic solutions (50 ml of 10% saline intravenously), steroids. When it is required use ultrafiltration to remove water excess.

9.4 Electrolytes disorders and their treatment

Potassium is a main intracellular cation. Its normal plasma concentration is 3,8-5,1 mmol/l. Daily required amount of potassium is 1 mmol/kg of body weight.

Potassium level less than 3,8 mmol/l is known as kaliopenia. Potassium deficiency is calculated according to the formula:

$$K_d = (4,5 - K_p) * 0,6 \text{ BW}$$

K- potassium deficiency, mmol;

K_p – potassium level of the patient mmol/l;

$0,6 * \text{BW}$ – total body water, l.

To treat this state use 7,5% solution of potassium chloride (1ml of this solution contains 1 mmol of potassium). Give it intravenously slowly with glucose and insulin (20-25 ml/hour). You can also prescribe magnesium preparations. Standard solution for kaliopenia treatment is:

10% glucose solution 400 ml

7,5% potassium chloride solution 20 ml

25% magnesium sulphate solution 3 ml

insulin 12 units

Give it intravenously slowly, during one hour. Forced bolus infusion of potassium solutions (10-15 ml) can bring cardiac arrest.

Potassium level over 5,2 mmol/l is a state called hyperkalemia. To treat this condition use calcium gluconate or calcium chloride solutions (10 ml of 10% solution intravenously), glucose and insulin solution, saluretics, steroids, sodium bicarbonate solution. Hyperkalemia over 7 mmol/l is an absolute indication for dialysis.

Sodium is the main extracellular cation. Its normal plasma concentration is 135-155 mmol/l. Daily required amount of potassium is 2 mmol/kg of body weight.

Sodium concentration which is lower than 135 mmol/l is known as hyponatraemia. This condition is caused by sodium deficiency or water excess. Sodium deficiency is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

Na- sodium deficiency, mmol;

Na_p – sodium concentration of the patient mmol/l;

0,2*BW – extracellular fluid volume, l.

To treat it use normal saline (1000 ml contains 154 Na mmol) or 5,8% solution of sodium chloride – your choice will depend on osmotic concentration.

Sodium concentration over 155 mmol/l is a state called hypernatremia. This condition usually appears in case of hypertonic dehydration or hypertonic overhydration. Treatment was described in the text above.

Chlorine is the main extracellular anion. Its normal plasma concentration is 98-107 mmol/l. Daily requirement of chlorine is 215 mmol.

Hypochloremia is a condition of decreased plasma chlorine concentration (less than 98 mmol/l).

Chlorine deficiency is calculated according to the formula:

$$Cl_d = (100 - Cl_p) * 0,2 BW,$$

Cl_d- chlorine deficiency, mmol

Cl_p – plasma chlorine concentration of the patient, mmol/l

0,2*BW – extracellular fluid volume, l.

To treat hyponatremia use normal saline (1000 ml contains 154 mmol of chlorine) or 5,8% sodium chloride solution (1 ml contains 1 mmol of chlorine). The choice of solution depends on the osmotic concentration of the plasma.

Hyperchloremia is a condition of increased chlorine concentration (over 107 mmol/l). Intensive therapy of this state includes treatment of the disease, which caused it (decompensated heart failure, hyperchloremic diabetes insipidus, glomerulonephritis). You can also use glucose, albumin solutions and dialysis.

Magnesium is mostly an intracellular cation. Its plasma concentration is 0,8-1,5 mmol/l. Daily requirement of magnesium is 0,3 mmol/kg.

Hypomagnesemia is a state of decreased magnesium concentration: less than 0,8 mmol/l. Magnesium deficiency is calculated according to the formula:

$$Mg_d = (1,0 - Mg_p) * 0,6BW,$$

Mg_d - magnesium deficiency, mmol

Mg_p - plasma magnesium concentration of the patient, mmol/l

0,6*BW - extracellular fluid volume, l.

Use 25% magnesium sulphate solution to treat this state (1 ml of it contains 0,5 mmol of magnesium).

Hypermagnesemia is a state of increased magnesium concentration (more than 1,5 mmol/l). This condition appears usually in case of hyperkalemia and you should treat it as you treat hyperkalemia.

Calcium is one of the extracellular cations. Its normal concentration is 2,35-2,75 mmol/l. Daily requirement of calcium is 0,5 mmol/kg.

Calcium concentration less than 2,35 mmol/l is called hypocalcemia. Calcium deficiency is calculated according to the formula:

$$Ca_d = (2,5 - Ca_p) * 0,2 BW,$$

Ca_d - calcium deficiency, mmol

Ca_p - plasma calcium concentration of the patient, mmol/l

0,2*BW - extracellular fluid volume, l.

To treat this state use 10% calcium chloride (1 ml of the solution contains 1,1 mmol of calcium), ergocalciferol; in case of convulsions prescribe sedative medicines.

Hypercalcemia is a condition with increased calcium concentration (over 2,75 mmol/l). Treat the disease, which caused it: primary hyperparathyroidism, malignant bone tumors, etc. Additionally use infusion therapy (solutions of glucose with insulin), steroids, dialysis and hemosorption.

9.5 Acid-base imbalance and its treatment.

There are 2 main types of acid-base imbalance: acidosis and alkalosis.

pH is a decimal logarithm of the reciprocal of the hydrogen ion activity. It shows acid-base state of the blood.

Normal pH of arterial blood is 7,36-7,44. Acid based imbalance is divided according to the pH level into:

pH 7,35-7,21 – subcompensated acidosis

pH < 7,2 – decompensated acidosis

pH 7,45-7,55 – subcompensated alkalosis

pH > 7,56 – decompensated alkalosis

Respiratory part of the acid-base imbalance is characterized with pCO₂. Normally pCO₂ of arterial blood is 36-44 mm Hg. Hypercapnia (pCO₂ increased over 45 mm Hg) is a sign of respiratory acidosis. Hypocapnia (pCO₂ less than 35 mm Hg) is a symptom of respiratory alkalosis.

Basis excess index is also a characteristic of metabolic processes. Normally H⁺ ions produced during metabolic reactions are neutralized with buffer system. BE of arterial blood is 0±1,5. Positive value of BE (with +) is a sign of base excess or plasma acid deficiency (metabolic alkalosis). Negative value of BE (with -) is a symptom of bases deficiency, which is caused by acid neutralization in case of metabolic acidosis.

Respiratory acidosis (hypercapnia) is a condition caused by insufficient elimination of CO₂ from the body during hypoventilation. Laboratory tests show:

pH < 7,35,

pCO_{2a} > 46 mm Hg

BE - normal values

However when the respiratory acidosis progresses renal compensation fails to maintain normal values and BE gradually increases. In order to improve this condition you should treat

acute and chronic respiratory violations. When pCO₂ is over 60 mm Hg begin artificial lung ventilation (through the mask or tube; when the necessity of ventilation lasts longer than 3 days – perform tracheostomy).

Respiratory alkalosis (hypocapnia) is usually an effect of hyperventilation, caused by excessive stimulation of respiratory centre (injuries, metabolic acidosis, hyperactive metabolism, etc.) or wrong parameters of mechanical ventilation. Gasometry shows:

pH > 7,45,

pCO_{2a} < 33 mm Hg

BE < +1,5 mmol/l.

However prolong alkalosis brings decrease of BE due to compensatory retain of H⁺ ions. To improve this imbalance treat its reason: normalize ventilation parameters; if patients breathing has rate over 40 per minute – sedate the patient, perform the intubation and begin artificial ventilation with normal parameters.

Metabolic acidosis is characterized with absolute and relative increase of H⁺ ions concentration due to acid accumulation (metabolic disorders, block of acid elimination, excessive acid consumption in case of poisonings, etc.). Laboratory tests show:

pH < 7,35,

pCO_{2a} < 35 mm Hg

BE (-3) mmol/l.

Treat the main reason of acid-base disorder: diabetic ketoacidosis, renal insufficiency, poisoning, hyponatremia or hyperchloremia, etc. Normalize pH with 4% sodium bicarbonate solution. Its dose is calculated according to the formula:

$$V = 0,3 * BE * BW$$

V- volume of sodium bicarbonate solution, ml

BE – bases excess with “-”, mmol/l

BW – body weight, kg

Metabolic alkalosis is a condition of absolute and relative decrease of H⁺ ions concentration. Blood tests show:

pH > 7,45,

pCO_{2a} normal or insignificantly increased (compensatory reaction)

BE 3,0 mmol/l.

To treat this condition use “acid” solutions, which contain chlorides (saline, potassium chloride). In case of kaliopenia give potassium solutions.

Respiratory and metabolic imbalances can mix in case of severe decompensated diseases due to failure of compensatory mechanisms. Correct interpretation of these violations is possible only in case of regular and iterative gasometry blood tests.

Control tasks.

Task 1.

Calculate the total body water volume and its extracellular and intracellular volumes of the Patience, the patient of 48 years and body weight 88 kg.

Task 2.

Patience, the patient of 23 with body weight 70 kg has sodium level 152 mmol/l and hematocrit 0,49 l/l. Name the type of water balance disorder.

Task 3.

Patience, the patient of 54 with body weight 76 kg has sodium level 128 mmol/l. Calculate the volume of saline and 7,5% sodium chloride solution necessary for the treatment of this condition.

Task 4.

Patience, the patient of 60 with body weight 60 kg has sodium level 140 mmol/l and hematocrit 0,55 l/l. Name the type of disorder and prescribe infusion therapy.

Task 5.

Patience, the patient of 42 with body weight 80 kg has potassium level 2,6 mmol/l. Calculate the volume of 4% potassium chloride solution necessary for treatment of this condition.

Task 6.

Patience, the patient of 33 with body weight 67 kg and diagnosis “gastric ulcer, complicated with pylorostenosis” has potassium concentration 3 mmol/l, chlorine concentration 88 mmol/l. pH 7,49, pCO_{2a} 42 mm Hg, BE + 10 mmol/l. Name the type of disorder.

Task 7.

Patience, the patient of 50 with body weight 75 kg, was transported to the admission unit of the hospital with: unconsciousness, cyanotic skin, low blood pressure, shallow

breathing. Blood tests show: pH 7,18, pCO_{2a} 78 mm Hg, pO_{2A} – 57 mm Hg, BE -4,2 mmol/l. Name the type of acid-base disorder and prescribe treatment.

Task 8.

Patience, the patient with body weight 62 kg and renal insufficiency has: potassium concentration 5,2 mmol/l, sodium concentration 130 mmol/l, calcium concentration 1,5 mmol/l, pH 7,22, pCO_{2a} 34 mm Hg, BE -9,2 mmol/l. Name the type of disorder.

Life is provided through a variety of mechanisms, however all of them depend on proper circulation. Circulation itself consists of 2 parts: work of heart (pump of the body) and vessels, through which blood is pumped to the most remote organs and tissues. During every systolic contraction heart pump 70-80 ml of blood (so called stroke volume). Thus in case of heart rate 70 beats per minute heart pumps nearly 5 liters of blood, what makes more than 7 tones per day.

From the left ventricle blood gets to the arterial system of the systemic circuit. Arteries contain 15% of the whole circulating blood volume; they carry blood from the heart to their distal departments – arterioles (vessels of resistance). Arterioles themselves are defining blood distribution: in condition of constriction (spasm) they make blood supply of the capillaries impossible (ischemia appears). On the contrary, in condition of dilatation they provide maximal oxygenation. When arterioles are blocked due to the spasm blood is flowing through the arterio-venous anastomosis directly to the venous system.

Distribution of blood in the vascular bed (% of CBV).

- a. heart cavity 3%
- b. arteries 15%
- c. capillaries 12%
- d. venous system 70%

Among the natural vasoconstrictors (agents, which cause constriction of the blood vessel) are epinephrine, norepinephrine, serotonin, angiotensin II. Stress enhances the secretion of catecholamines, their blood concentration increases and arterioles constrict. Spasm of the arterioles is the basis of blood flow centralization: peripheral flow is disregarded in order to provide brain with the oxygenated blood as long as possible. To the group of vasodilators (agents, which provide dilatation of the vessels) belong “acid” metabolites (lactate, pyruvate,

adenylic acid, inosinic acid), bradykinin, acetylcholine, different medicines (neuroleptics, α -adrenergic antagonists, peripheral vasodilators, ganglionic blocking agents, etc.), some exogenous poisons. All of them cause blood flow decentralization: opening of arterioles and distribution of the blood from central vessels to the capillary bed.

Capillaries are the interweaving network of the smallest body vessels with the general length of 90-100 thousands of kilometers. However simultaneously work only 20-25% of them. They provide metabolic exchange bringing oxygen and nutrients to the tissues and take back wastes of metabolism. Periodically, every 30-40 seconds one of them get closed and others open (vasomotion effect). Capillaries contain 12% of the whole circulating blood volume, but different pathological conditions can increase this amount even 3 and more times.

“Used” blood from the capillaries flows to the venous system. Veins are the blood reservoir, which contains 70% of the total circulating blood volume. Unlike arteries they are capable of volume control and thus they influence the amount of blood, which returns to the heart.

The most important haemodynamic index of venous system is central venous pressure. CVP represents the pressure which blood causes to the walls of cava veins and right atrium. This parameter is an integral index of circulating blood volume, systemic vascular resistance and pump function of the heart. It can be measure with a special device called “phlebotonometer” (pic. 4.9) or with a usual infusion set and a ruler. Normally CVP measured from the sternum point is 0-14 cm H₂O and from midaxillary line is 8-15 cm H₂O.

Central venous pressure decreases (sometimes even to negative) in case of:

- blood loss
- excessive water loss (dehydration)
- distributive shock (decrease of peripheral resistance due to venous and arterial dilatation)

In those conditions decreases volume of blood returning to the heart and thus suffers cardiac output. In case of negative CVP cardiac arrest is highly probable.

Central venous pressure increases in case of:

- heart failure (insufficiency of left or right ventricle)
- hypervolemia (excessive blood infusion, improper infusion therapy)
- obstructions to blood flow (pulmonary embolism, cardiac tamponade, etc.)

When CVP over 15-16 cm H₂O is combined with left ventricle insufficiency the risk of pulmonary edema is very high.

Blood pressure is an integral index of arterial part of systemic haemodynamics. Talking about blood pressure we may refer to systolic, diastolic, pulse and mean arterial pressure. Systolic (P_{syst}) and diastolic (P_{diast}) pressures are measured with the manometer (method with the usage of phonendoscope was invented by M. Korotkoff). Pulse pressure (PP) is a difference between systolic and diastolic blood pressure.

Mean arterial pressure (MAP) is calculated according to the formula:

$$\text{MAP} = P_{\text{dias}} + 1/3 \text{ PP} \quad \text{mm Hg}$$

MAP defines the level of pressure necessary for the metabolic exchange in the tissues. Its measurement allows the evaluation of tissue perfusion level.

Blood pressure depends on different factors, but the most important are cardiac output and vascular resistance (mostly arterioles). This dependence is direct, thus you can increase blood pressure using:

- infusion of vasoconstrictors - solutions of epinephrine, phenylephrine (mesaton), etc. (they will increase the vascular resistance);
- infusion of hydroxyethyl starch solutions or saline (they will increase circulating blood volume)
- infusion of cardiac glycosides or other medicine which stimulate myocardium

General volume of blood in the body of a healthy adult is nearly 7% from the body weight: 70 ml per kilogram for male and 65 ml per kilogram of body weight for female. Of course circulating blood volume is lower, because part of blood is out of metabolic processes as a reserve. CBV can be measured with the infusion of coloring substance to the blood flow (Evans blue, polyglucin) and later evaluation of its dissolution degree.

Therefore measurement of CVP, BP, cardiac output and circulating blood volume allow to evaluate condition of circulation system of the patients and to provide adequate correction.

4.2 Acute heart failure; shock and collapse.

Acute cardiovascular failure is a state of cardiac and vascular inability to provide adequate supply of tissue metabolic needs with oxygenated blood and nutrients. This, earlier or later, causes cellular death.

The reasons of the failure vary greatly: mechanic injuries, blood loss, burns,

dehydration, exogenous and endogenous intoxications, immediate hypersensitivity reaction, ischemic heart disease, neural and humoral regulation disorders of vascular tone.

Acute cardiac failure is a disorder of heart pumping action. It develops due to primary heart problems or secondary, under the influence of extracardiac factors such as infection or intoxication. There are two types of heart failure: left-sided and right-sided.

Left-sided heart failure is an inability of left ventricle to pump blood from the pulmonary circuit to the systemic circuit. The most common reasons of it are myocardial infarction, mitral insufficiency, left AV valve stenosis, aortic valve stenosis, aortal insufficiency, hypertonic disease, coronary sclerosis, acute pneumonia.

Coronary circulation is possible only during the diastole and in those conditions every violation of coronary passability decreases cardiac output. This way during the systole part of the blood is not injected into aorta, but stays in the left ventricle. Diastolic pressure in the left ventricle increases and blood is literally forced to stagnate in the left atrium. At the same time right ventricle functions normally and continues to pump usual amounts of blood to the pulmonary circuit. Thus hydrostatic pressure in the vessels of pulmonary circulation increases, fluid part of the blood moves first to the lung tissue and then, through alveolar-capillary membrane, to the alveolar lumen.

Clinically pulmonary edema begins with dyspnea (during physical activity or rest). Later attacks of dyspnea are connected with persistent cough with white or pink blood-tinged phlegm. During the attack patient tries to sit as in this position breathing is easier. This condition is called “heart asthma”. When hydrostatic pressure is over 150-200 mm Hg, fluid part of blood moves to the alveolar lumen causing development of pulmonary edema.

Pulmonary edema is divided into interstitial and alveolar edema.

Interstitial edema is a condition during which serous part of stagnated in the pulmonary circuit blood infiltrates the lung tissue, including peribronchial and perivascular spaces.

During alveolar edema not only the plasma, but also blood components (red and white blood cells, platelets) get out from the vessels. During the respiratory act blood mixes with the air creating large amount of “foam”, which violates gas exchange. This way, in addition to circulatory hypoxia, hypoxic hypoxia appears.

Condition of the patient gets worse quickly. Sitting position is optimal, but not as helping as previously. Respiratory rate is nearly 30-35 breathes per minute, but attacks of breathlessness are constant. Skin is pale with acrocyanosis. Hypoxia of central nervous system usually causes psychomotor agitation. Respiratory acts are noisy; during cough pink blood-tinged phlegm is released. Auscultation allows you to hear different wet rales, sometimes it's even possible to hear them standing aside the patient without phonendoscope.

Pulmonary edema can be also divided according to the blood pressure level: the one with elevated pressure is caused by a hypertonic disease, aorta valve insufficiency or disorders of cerebral perfusion; another one is caused by total myocardial infarction, acute inflammation of myocardial muscle, terminal valve defects, severe pneumonia and is characterized with normal or low blood pressure.

Immediate aid

- make sure patient is sitting with his legs down (orthopnea)
- provide oxygenation through nasal catheter (before placing oil it with glycerin, insert it to the depth of 10-12 cm – distance from the wing of the nose to auricle) or face mask. Do not use Vaseline, because it can burn in atmosphere with high concentration of oxygen.

However if catheter is not deep enough patient will suffer from an unpleasant “burning” feeling, because oxygen flow will dry mucosa layer of the nasal cavity; also in this situation concentration of oxygen will be lower than expected.

- put venous tourniquets on the limbs in order to reduce amount of blood returning to heart: venous bed of limbs can reserve up to 1,7 liters of blood;
- constantly control heart and kidney activity (ECG, SaO₂ , and blood pressure are checked automatically through the monitor; to control diuresis you should insert Foley catheter;
- catheterize central vein, because amount of infusions should be based on central venous pressure;
- use medical “defoamers” if they are available (ethyl alcohol or antiphomsylan solution) combined with oxygen inhalation

Scheme of oxygenation set connected to “defoamer” container

- a. oxygen source (cylinder with oxygen)
 - b. tube with numerous holes sunk into container with defoamer
 - c. tube for humidified oxygen (its opening should be over the level of fluid);
 - d. patient
- medical treatment: 1% morphine solution (decreases intravascular pressure of pulmonary circuit, inhibits respiration center in medulla oblongata preventive dyspnea progress, sedates patient);
 - solutions of diuretics are used to decrease the circulating blood volume (6-12 ml of 1% furosemid solution, solution of ethacrynic acid), however be careful with

them in case of low blood pressure; diuretic effect will last up to 3 hours after i/v infusion, the expected diuresis is 2-3 liters

- if blood pressure allows you can try to use nitroglycerin to reduce intravascular pressure of pulmonary circuit (1 or 2 tablets with 10 minutes interval)
- cardiac glycosides for improvement of heart action (0,025% digoxin solution, 0,05% strophanthin solution, 0,06% corglicon solution);
- in case of high pressure (over 150 mm Hg) use ganglionic blocking agents (1 ml of 5% pentamin solution diluted in 150 ml of saline, give i/v slowly; diluted with saline 250 mg of trimethaphan solution), because they reduce pressure in pulmonary circuit and lower the amount of blood getting to right half of the heart, however be careful with the dosage and monitor blood pressure level carefully;
- never use osmotic diuretics in case of pulmonary edema – they will increase blood volume and thus heart load!!!
- when everything listed above failed and patient is worsening with every second you should intubate him and start artificial ventilation with positive end expiratory pressure (begin with 4-6 cm H₂O)

Right-sided heart failure is an inability of right ventricular to pump blood from systemic circuit to the pulmonary circuit due to its weakness or an obstruction to the blood flow.

It occurs in case of pulmonary embolism, right ventricular infarction, excessive infusion therapy (especially including citrated blood) for patients with heart insufficiency, lung diseases (bronchial asthma, emphysema, pneumosclerosis) which cause increase of right ventricular load.

Patients have acrocyanosis, tachycardia, dyspnea, pronounced neck veins, ankle swelling, enlarged liver, ascytis. Central venous pressure is highly increased (up to 20-25 cm H₂O), however pulmonary edema does not appear.

Intensive treatment is mostly pathogenetic:

- limit the infusions (give only life-necessary solutions, check the water balance of the patient and reduce drinking water if necessary);
- in case of citrated blood transfusions use 5-10 ml of 10% calcium gluconate solution per every 500 ml of blood to prevent hypocalcaemia;
- in case of bronchial spasm use bronchial spasmolytics;

- to remove excessive fluid from the body use diuretics (furosemide solution for example);
- metabolic acidosis is corrected with 4% solution of sodium bicarbonate (i/v slowly with acid-base state control);
- in case of pulmonary embolism anticoagulants are used – fraxiparine 0,6 mg subcutaneously; heparin solution – 5000 IU every 4 hours; fibrinolytic drugs (streptokinase, fibrinolysin, urokinase, etc.)

Shock is a pathological state which can be described as a tissue hypoxia caused by hypoperfusion. Pathogenetic basis of shock depends on its reason (trauma, toxins, thermal injury) and at the same time on reactivity of the organism (level of defense mechanisms mobilization).

Stimulation of sympathetic nervous system - production of catecholamines and other vasoactive substances by hypothalamus and adrenal glands are the universal response of the body to the stress. Those mediators interact with the receptors of peripheral vessels causing their constriction and at the same time they dilatate the vascular bed of life-important organs. This is so called “centralization of the flow”: rational decrease of blood flow in less important tissues (skin, organs of abdominal cavity, kidneys) in case of aggressive external influence for protecting life itself (brain, heart, lungs).

However influence of shock agents (pain, hypovolemia, destroyed cells, toxic metabolites), extended microcirculation violations (vascular spasm, microthrombosis and sludge) and caused by them tissue ischemia lead to hypoxic affection and cellular death of the internal organs. Further it can bring multiple organ dysfunction syndrome.

Collapse is a vascular failure. It occurs when body is not able to provide blood flow according to the new level of its needs (either because reaction is not fast enough or because sympathetic activation fails). Vascular bed volume and circulating blood volume are disproportional: too much blood gets to the microcirculation vascular reserve and the amount, which returns to the heart is not enough for the systemic needs (so called “decentralization” of the blood flow). Cardiac output and blood pressure decrease, that causes hypoperfusion of the central nervous system and thus unconsciousness and life-threatening complications.

Collapse definition is a bit nominal, because if such reaction extends in time the state of shock develops. Shock itself can equally run as a vascular failure or as a sudden clinical death.

Pathogenetic classification of shock (according to P. Marino, 1998):

- hypovolemic
- cardiogenic
- distributive
- mixed (two and more factors).

Clinical classification of shock:

- traumatic shock;
- haemorrhagic shock;
- dehydration shock;
- burn shock;
- septic shock;
- anaphylactic shock;
- cardiogenic shock;
- exotoxic shock.

4 Shock caused by dehydration

It is a type of hypovolemic shock, which occurs during excessive body fluid loss (not blood, because hemorrhagic shock is another shock type).

Its reasons vary greatly:

- gastrointestinal diseases (profuse vomiting, diarrhea, loss of intestinal fluid through fistula);
- polyuria (uncontrolled diuretic treatment, diabetes mellitus and insipidus, diuretic phase of acute renal failure);
- fluid loss through skin and wound surface (burns, high fever);
- inadequate infusion treatment of postoperative or comatose patients;
- hyperventilation (rapid breathing, Kussmaul breathing, inadequate artificial ventilation parameters in case of apparatus without air humidification).

However not only the complete fluid loss can be the reason of shock, but also its pathological distribution into the extracellular space (intestinal cavity in case of intestinal paralysis, abdominal cavity in case of ascites, pleural cavity in case of pleurisy). This way will can also act prolonged heavy tissue inflammations (peritonitis) or massive injuries

(crush-syndrome).

In cases described above electrolytes are also lost (cations of sodium, potassium, calcium, magnesium; anions of chlorine, hydrocarbonate). It causes complex osmolar, acid-base and electrolytic disorders.

Stage of dehydration shock is evaluated according to the actual fluid loss:

less than 5% of body weight – mild dehydration

5-10% of body weight – moderate dehydration

over 10% of body weight – severe dehydration

Water deficiency brings lowering of cardiac output, blood pressure and central venous pressure (through decrease of blood volume returning to the heart, which leads to compensatory adrenergic vasoconstriction).

Dehydration causes body weight loss, skin and mucosa dryness, decrease of subcutaneous turgor and eyeballs tone, hypothermia, tachycardia, oliguria, thirst. While dehydration progresses compensatory mechanisms weaken and central nervous system suffers: patients become sluggish, confused; hallucinations, cramps and unconsciousness are also possible. Laboratory tests show blood concentration.

One of the most important things in treatment of dehydrated patients is daily balance of fluid: check it carefully through measuring of daily received and lost fluids (food, infusions, stool and urine output). In case of fever or tachypnea make necessary corrections. Balance should be calculated every 12-24 hours (special paper forms make this easier).

Daily fluid balance is calculated by adding all the received fluids (both enteral and parenteral ways) and deducting urine output, stool, perspiration and breathing water loss.

You should remember, that perspiration depends on body temperature: in case of normal temperature (36,6°C) patient loses 0,5 ml/kg of water during every hour; 1 degree of temperature elevation adds 0,25 ml/kg to normal value of 0,5 ml/kg.

According to the fluid balance infusion therapy is divided into positive (for dehydrated patients), negative (for overhydrated patients) and “zero” (for patients without balance disorders).

Water deficiency is calculated according to the formula:

$$W_{\text{def}} = (Ht_p - Ht_n) * 0,2 \text{ BW} / Ht_n,$$

W_{def} – water deficiency, l;

Ht_p – hematocrit of the patient, l/l;

Ht_n - normal hematocrit, l/l;

BW – body weight, kg.

Use crystalloids to treat water deficiency: saline solution, Ringer's solution, Ringer-lactate solution, electrolytic solutions, 5%, 10, 20% glucose solution. To control potassium concentration (during dehydration this cation is widely lost) prescribe polarizing GIK mixture (pic.9.4), but don't you ever infuse concentrated potassium solutions quickly – it can cause cardiac arrest (not more than 400 of GIK solution ml per hour).

The essential components of the human cardiovascular system are the [heart](#), [blood](#), and [blood vessels](#). It includes: the [pulmonary circulation](#), a "loop" through the [lungs](#) where blood is oxygenated; and the [systemic circulation](#), a "loop" through the rest of the body to provide [oxygenated](#) blood. An average adult contains five to six quarts (roughly 4.7 to 5.7 liters) of blood, accounting for approximately 7% of their total body weight.

While it is convenient to describe the flow of the blood through the right side of the heart and then through the left side, it is important to realize that both atria contract at the same time and that both ventricles contract at the same time. The heart works as two pumps, one on the right and one on the left that works simultaneously. The right pump pumps the blood to the lungs or the pulmonary circulation at the same time that the left pump pumps blood to the rest of the body or the systemic circulation. Venous blood from systemic circulation (deoxygenated) enters the right atrium through the superior and inferior vena cava. The right atrium contracts and forces the blood through the tricuspid valve (right atrioventricular valve) and into the right ventricles. The right ventricles contract and force the blood through the pulmonary semilunar valve into the pulmonary trunk and out the pulmonary artery. This takes the blood to the lungs where the blood releases carbon dioxide and receives a new supply of oxygen. The new blood is carried in the pulmonary veins that take it to the left atrium. The left atrium then contracts and forces blood through the left atrioventricular, bicuspid, or mitral, valve into the left ventricle. The left ventricle contracts forcing blood through the aortic semilunar valve into the ascending aorta. It then branches to arteries carrying oxygen rich blood to all parts of the body.

Blood Flow Through Capillaries

From the arterioles, the blood then enters one or more capillaries. The walls of capillaries are so thin and fragile that blood cells can only pass in single file. Inside the capillaries, exchange of oxygen and carbon dioxide takes place. Red blood cells inside the capillary releases their oxygen which passes through the wall and into the surrounding tissue. The tissue then releases waste, such as carbon dioxide, which then passes through the wall and

into the red blood cells.

The Circulatory System

The circulatory system is extremely important in sustaining life. It's proper functioning is responsible for the delivery of oxygen and nutrients to all cells, as well as the removal of carbon dioxide, waste products, maintenance of optimum pH, and the mobility of the elements, proteins and cells, of the immune system. In developed countries, the two leading causes of death, myocardial infarction and stroke are each direct results of an arterial system that has been slowly and progressively compromised by years of deterioration.

Arteries

Arteries are muscular blood vessels that carry blood away from the heart, oxygenated and deoxygenated blood . The pulmonary arteries will carry deoxygenated blood to the lungs and the sytemic arteries will carry oxygenated blood to the rest of the body. Arteries have a thick wall that consists of three layers. The inside layer is called the endothelium, the middle layer is mostly smooth muscle and the outside layer is connective tissue. The artery walls are thick so that when blood enters under pressure the walls can expand.

Arterioles

An arteriole is a small artery that extends and leads to capillaries. Arterioles have thick smooth muscular walls. These smooth muscles are able to contract (causing vessel constriction) and relax (causing vessel dilation). This contracting and relaxing affects blood pressure; the higher number of vessels dilated, the lower blood pressure will be. Arterioles are just visible to the naked eye.

Capillaries

Capillaries are the smallest of a body's vessels; they connect arteries and veins, and most closely interact with tissues. They are very prevalent in the body; total surface area is about 6,300 square meters. Because of this, no cell is very far from a capillary, no more than 50 micrometers away. The walls of capillaries are composed of a single layer of cells, the endothelium, which is the inner lining of all the vessels. This layer is so thin that molecules such as oxygen, water and lipids can pass through them by diffusion and enter the tissues. Waste products such as carbon dioxide and urea can diffuse back into the blood to be carried away for removal from the body.

The "capillary bed" is the network of capillaries present throughout the body. These beds are able to be "opened" and "closed" at any given time, according to need. This process is called autoregulation and capillary beds usually carry no more than 25% of the amount of

blood it could hold at any time. The more metabolically active the cells, the more capillaries it will require to supply nutrients.

Veins

Veins carry blood to the heart. The pulmonary veins will carry oxygenated blood to the heart while the systemic veins will carry deoxygenated to the heart. Most of the blood volume is found in the venous system; about 70% at any given time. The veins outer walls have the same three layers as the arteries, differing only because there is a lack of smooth muscle in the inner layer and less connective tissue on the outer layer. Veins have low blood pressure compared to arteries and need the help of skeletal muscles to bring blood back to the heart. Most veins have one-way valves called venous valves to prevent backflow caused by gravity. They also have a thick collagen outer layer, which helps maintain blood pressure and stop blood pooling. If a person is standing still for long periods or is bedridden, blood can accumulate in veins and can cause varicose veins. The hollow internal cavity in which the blood flows is called the lumen. A muscular layer allows veins to contract, which puts more blood into circulation. Veins are used medically as points of access to the blood stream, permitting the withdrawal of blood specimens (venipuncture) for testing purposes, and enabling the infusion of fluid, electrolytes, nutrition, and medications (intravenous delivery).

Venules

A venule is a small vein that allows deoxygenated blood to return from the capillary beds to the larger blood veins, except in the pulmonary circuit where the blood is oxygenated. Venules have three layers; they have the same makeup as arteries with less smooth muscle, making them thinner.

The double circulatory system of blood flow refers to the separate systems of pulmonary circulation and the systemic circulation in amphibians, birds and mammals (including humans.) In contrast, fishes have a single circulation system. For instance, the adult human heart consists of two separated pumps, the right side with the right atrium and ventricle (which pumps deoxygenated blood into the pulmonary circulation), and the left side with the left atrium and ventricle (which pumps oxygenated blood into the systemic circulation). Blood in one circuit has to go through the heart to enter the other circuit. Blood circulates through the body two to three times every minute. In one day, the blood travels a total of 19,000 km (12,000 miles), or four times the distance across the U.S. from coast to coast.

The Pulmonary Circuit

In the pulmonary circuit, blood is pumped to the lungs from the right ventricle of the heart. It is carried to the lungs via pulmonary arteries. At lungs, oxygen in the alveolae diffuses to the capillaries surrounding the alveolae and carbon dioxide inside the blood diffuses to the

alveolae. As a result, blood is oxygenated which is then carried to the heart's left half -to the left atrium via pulmonary veins. Oxygen rich blood is prepared for the whole organs and tissues of the body. This is important because mitochondria inside the cells should use oxygen to produce energy from the organic compounds.

The Systemic Circuit

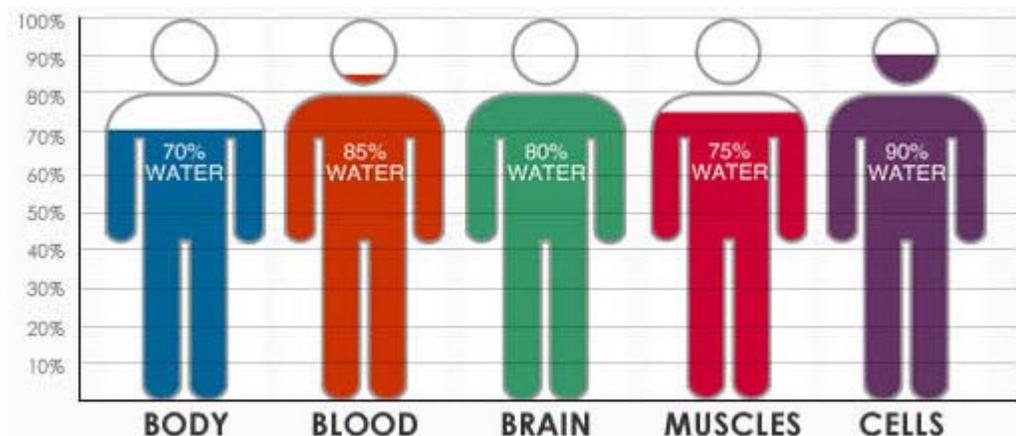

The systemic circuit supplies oxygenated blood to the organ system. Oxygenated blood from the lungs is returned to the left atrium, then the ventricle contracts and pumps blood into the aorta. Systemic arteries split from the aorta and direct blood into the capillaries. Cells consume the oxygen and nutrients and add carbon dioxide, wastes, enzymes and hormones. The veins drain the deoxygenated blood from the capillaries and return the blood to the right atrium.

Pic. 4.1 Distribution of blood in the body:

- a. hear cavity itself 0 3% (% of blood volume)
- b. arteries -15%
- c. capillares -12%
- d. venous system – 70%

Cardiac cycle is the term used to describe the relaxation and contraction that occur, as a heart works to pump blood through the body. Heart rate is a term used to describe the frequency of the cardiac cycle. It is considered one of the four vital signs. Usually it is calculated as the number of contractions (heart beats) of the heart in one minute and expressed as "beats per minute" (bpm). When resting, the adult human heart beats at about 70 bpm (males) and 75 bpm (females), but this rate varies between people. However, the reference range is nominally between 60 bpm (if less termed bradycardia) and 100 bpm (if greater, termed tachycardia). Resting heart rates can be significantly lower in athletes, and significantly higher in the obese. The body can increase the heart rate in response to a wide variety of conditions in order to increase the cardiac output (the amount of blood ejected by the heart per unit time). Exercise, environmental stressors or psychological stress can cause the heart rate to increase above the resting rate. The pulse is the most straightforward way of measuring the heart rate, but it can be deceptive when some strokes do not lead to much cardiac output. In these cases (as happens in some arrhythmias), the heart rate may be considerably higher than the pulse. Every single 'beat' of the heart involves three major stages: atrial systole, ventricular systole and complete cardiac diastole. Throughout the cardiac cycle, the blood pressure increases and decreases. As ventricles contract the pressure rise, causing the AV valves to slam shut.

Water-electrolyte and acid-basic disorders

9.1 The importance of the water to the organism.

Life on earth was born in the water environment. Water is an universal solvent for all the biochemical processes of the organism. Only in case of stable quantitative and qualitative composition of both intracellular and extra cellular fluids homoeostasis is remained.

The body of an adult human contains 60% of water. Intracellular water makes 40% of the body weight, the water of intercellular space makes 15% of body weight and 5% of body weight are made by the water in the vessels. It is considered that due to unlimited diffusion of water between vessels and extra vascular space the volume of extracellular fluid is 20% of body weight (15%+5%).

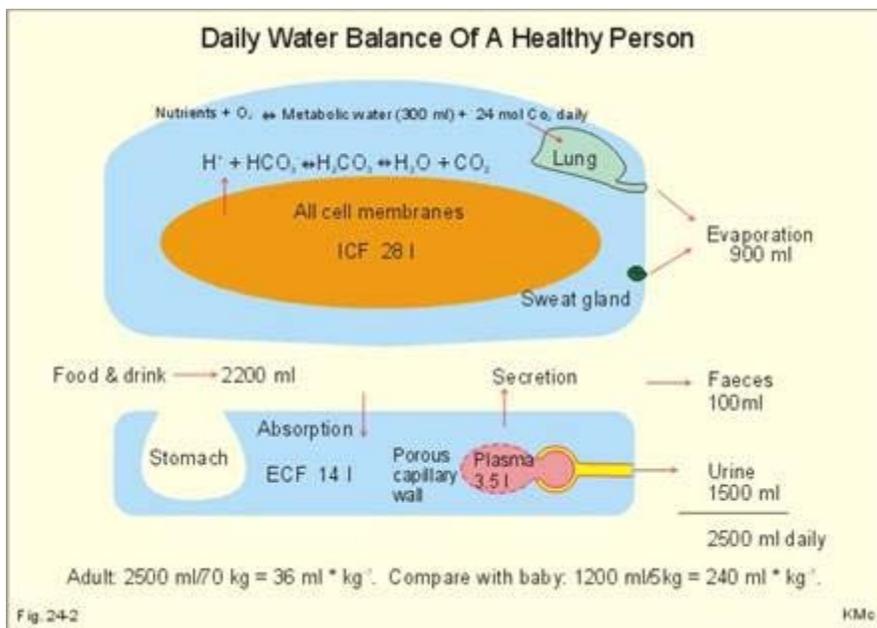

Physiologically insignificant amounts of water are distributed beyond the tissues in the body cavities: gastrointestinal tract, cerebral ventricles, joint capsules (nearly 1% of the body weight). However during different pathologic conditions this “third space” can cumulate large amounts of fluid: for example in case of ascites caused by chronic cardiac insufficiency or cirrhosis abdominal cavity contains up to 10 liters of fluid. Peritonitis and intestinal obstructions remove the fluid part of blood from the vessels into the intestinal cavity.

Severe dehydration is extremely dangerous for the patient. Water gets to the body with food and drinks, being absorbed by the mucous membranes of gastro-intestinal tract in total amount of 2-3 liters per day. Additionally in different metabolic transformations of lipids, carbohydrates and proteins nearly 300 of endogenous water are created. Water is evacuated from the body with urine (1,5-2 liters), stool (300 ml), perspiration and breathing (those two reasons are combined as “perspiration loss” and make from 300 to 1000 ml per day).

Water balance is regulated through complicated, but reliable mechanisms. Control over water and electrolytes excretion is realized by osmotic receptors of posterior hypothalamus, volume receptors of the atrial walls, baroreceptors of carotid sinus, juxtaglomerular apparatus of the kidneys and adrenal cortical cells.

When there is a water deficiency or electrolytes excess (sodium, chlorine) thirst appears and this makes us drink water. At the same time posterior pituitary produces antidiuretic hormone, which decreases urine output. Adrenals release into the blood flow aldosterone, which stimulates reabsorption of sodium ions in the tubules and thus also decreases diuresis (due to osmosis laws water will move to the more concentrated solution). This way organism can keep precious water.

On the contrary, in case of water excess endocrine activity of glands is inhibited and water is actively removed from the body through the kidneys.

9.2 Importance of osmolarity for homeostasis.

Water sections of the organism (intracellular and extracellular) are divided with semipermeable membrane – cell wall. Water easily penetrates through it according to the laws of osmosis. Osmosis is a movement of water through a partially permeable membrane from the solution with lower concentration to a solution with higher concentration.

Osmotic concentration (osmolarity) is the concentration of active parts in one liter of solution (water). It is defined as a number of miliosmoles per liter (mOsm/l). Normally osmotic concentration of plasma, intracellular and extracellular fluids is equal and varies between 285mOsm/l. This value is one of the most important constants of the organism, because if it changes in one sector the whole fluid of the body will be redistributed (water will move to the environment with higher concentration). Over hydration of one sector will bring dehydration of another. For example, when there is a tissue damage concentration of active osmotic parts increases and water diffuses to this compartment, causing oedema. On the contrary plasma osmolarity decreases, when there is a loss of electrolytes and osmotic concentration of the cellular fluid stays on the previous level. This brings cellular oedema, because water moves

through the intracellular space to the cells due to their higher osmotic concentration.

Cerebral oedema appears when the plasma osmolarity is lower than 270 mOsm/l. Activity of central nervous system is violated and hyposmolar coma occurs. Hyperosmolar coma appears when the plasma osmolarity is over 320 mOsm/l: water leaves the cells and fills the vascular bed and this leads to cellular dehydration. The sensitive to cellular dehydration are the cells of the brain.

Plasma osmolarity is measured with osmometer. The principle of measurement is based on difference in freezing temperature between distilled water and plasma. The higher is the osmolarity (quantity of molecules) the lower is freezing temperature.

Plasma osmotic concentration can be calculated according to the formula:

$$\text{Osmotic concentration} = 1,86 * \text{Na} + \text{glucose} + \text{urea} + 10,$$

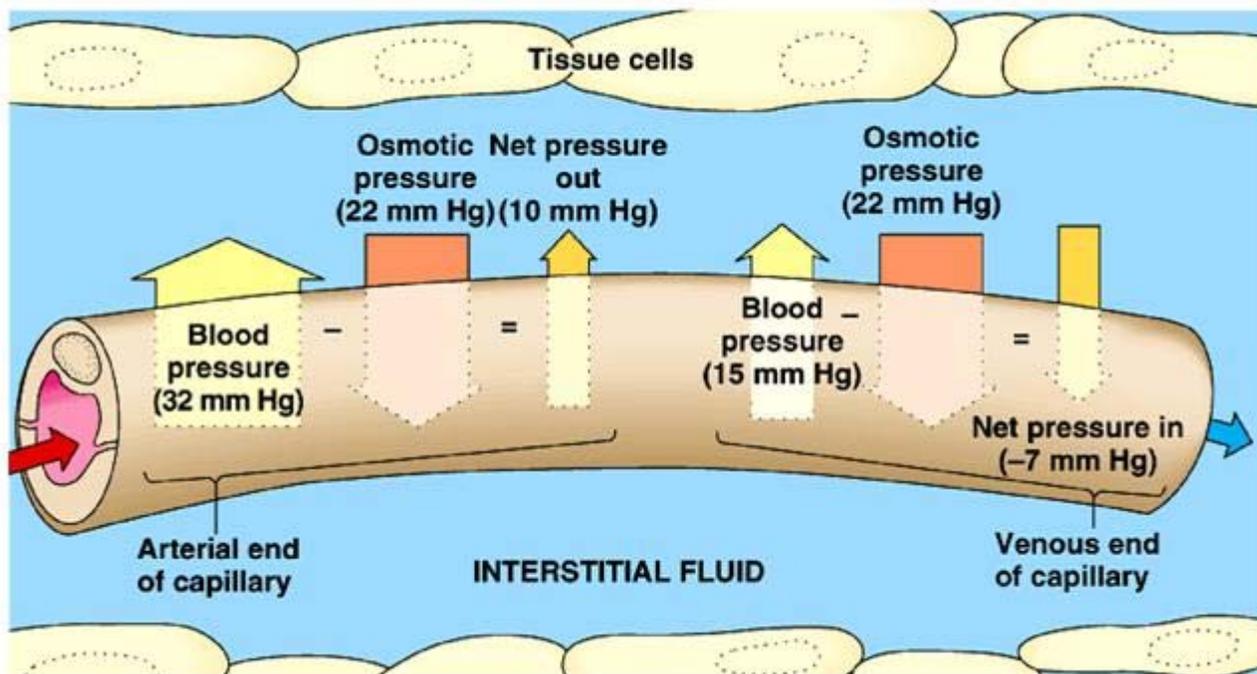

Plasma osmolarity (osmotic concentration) – mOsm/l

Na- sodium concentration of plasma, mmol/l

Glucose- glucose concentration of the plasma, mmol/l

Urea- urea concentration of the plasma, mmol/l

According to this formula sodium concentration is the main factor influencing plasma osmolarity. Normally sodium concentration is 136-144 mmol/l. Water and electrolytes balance can be violated with external fluid and electrolytes loss, their excessive inflow or wrong distribution.

9.3 Fluid imbalance and principles of its intensive treatment.

Water imbalance is divided into dehydration and overhydration.

Dehydration is caused by:

- excessive perspiration in conditions of high temperature;
- rapid breathing (dyspnea, tachypnea) or artificial ventilation without humidification of the air;
- vomiting, diarrhoea, fistulas;
- blood loss, burns;
- diuretics overdose;
- excessive urine output;
- inadequate enteral and parenteral nutrition or infusion therapy (comatose patients, postoperative care);
- pathological water distribution ("third space" in case of inflammation or injury).

Fluid overload ¹⁻³	Dehydration ¹⁻³
Weight gain 	Weight loss 
Swollen ankles and puffy eyes 	Dry mouth 
High blood pressure 	Low blood pressure 
Breathlessness 	Dizziness 

Dehydration signs: weight loss, decrease of skin turgor and eyeballs tone, dry skin and mucous membranes; low central venous pressure, cardiac output and blood pressure (collapse is possible); decreased urine output and peripheral veins tone; capillary refill over 2 seconds (microcirculation disorders) and low skin temperature; intracellular dehydration is characterized with thirst and consciousness disorders. Laboratory tests show blood concentration: hematocrit, hemoglobin concentration, protein level and red blood cells concentration increase.

Overhydration appears in case of:

- excessive water consumption, inadequate infusion therapy;
- acute and chronic renal failure, hepatic and cardiac insufficiency;
- disorders of fluid balance regulation;
- low protein edema.

Clinical findings in case of overhydration are: weight gain, peripheral oedema, transudation of the plasma into the body cavities (pleural, abdominal), high blood pressure and central venous pressure. In case of intracellular overhydration appear additional symptoms: nausea, vomiting, signs of cerebral edema (spoor, coma). Laboratory tests prove hemodilution.

According to the osmotic concentration of plasma dehydration and overhydration are divided into hypotonic, isotonic and hypertonic.

Isotonic dehydration is caused by equal loss of electrolytes and fluid from the extracellular space (without cellular disorders). Blood tests show hemoconcentration; sodium level and osmotic concentration are normal.

To treat this type of water imbalance use normal saline solution, Ringer solution, glucose-saline solutions, etc.. The volumes of infusions can be calculated according to the

formula:

$$V_{H_2O} = 0,2 * BW * (H_{tp} - 0,4) / 0,4 ,$$

V_{H_2O} – volume of infusion, l

H_{tp} – patient's hematocrit, l/l,

BW – body weight, $0,2 * BW$ – volume of extracellular fluid,

0,4- normal hematocrit, l/l,

Hypertonic dehydration is caused by mostly water loss: first it appears in the vascular bed, than in the cells. Laboratory tests show hemoconcentration: elevated levels of proteins, red blood cells, hematocrit. Plasma sodium is over 155 mmol/l and osmotic concentration increases over 310 mOsm/l.

Intensive treatment: if there is no vomiting allow patients to drink. Intravenously give 0,45% saline solution and 2,5 % glucose solution, mixed with insulin. The volume of infusions is calculated according to the formula:

$$V_{H_2O} = 0,6 * BW (Na_p - 140) / 140,$$

V_{H_2O} – water deficiency, l

Na_p – plasma sodium, mmol/l

BW – body weight, $0,6 * BW$ volume of general body fluid

140 – physiological plasma sodium concentration

Hypotonic dehydration is characterized with clinical features of extracellular dehydration. Laboratory tests show decrease of sodium and chlorine ions. Those changes cause intracellular movement of the water (intracellular overhydration). Hemoglobin, hematocrit and protein levels are increased. Sodium is lower than 136 mmol/l, osmolarity is lower than 280 mOsm/l.

To treat this type of water imbalance use normal or hypertonic saline and sodium bicarbonate solution (depends on blood pH). Do not use glucose solutions!

The deficiency of electrolytes is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

Na_d – sodium deficiency, mmol

N_p – plasma sodium, mmol/l

BW – body weight, 0,2 BW – volume of extracellular fluid

Isotonic overhydration is caused by excess of the water in the vascular bed and extracellular space; however intracellular homeostasis is not violated. Hemoglobin is less than 120 g/l, protein level is less than 60 g/l, plasma sodium is 136-144 mmol/l, osmotic concentration is 285-310 mOsm/l.

Treat the reason of imbalance: cardiac failure, liver insufficiency, etc. Prescribe cardiac glycosides, limit salt and water consumption. Give osmotic diuretics (mannitol solution 1,5 g/kg), saluretics (furosemide solution 2 mg/kg), aldosterone antagonists (triamterene – 200 mg), steroids (prednisolone solution 1-2 mg/kg) albumin solution if necessary (0,2-0,3 g/kg).

Hypertonic overhydration is a state of extracellular electrolytes and water excess combined with intracellular dehydration. Blood tests show decrease of hemoglobin, hematocrit, protein level, however sodium concentration is increased over 144 mmol/l, osmotic concentration is over 310 mOsm/l.

To treat this condition use solutions without electrolytes: glucose with insulin, albumin solutions and prescribe saluretics (furosemide solution), aldosterone antagonists (spironolactone). If it is necessary perform dialysis and peritoneal dialysis. Do not use crystalloids!

Hypotonic overhydration is a state of extracellular and intracellular water excess. Blood tests show decrease of haemoglobin, hematocrit, proteins, sodium and osmotic concentration. Intensive therapy of this condition includes osmotic diuretics (200-400 ml of 20% mannitol solution), hypertonic solutions (50 ml of 10% saline intravenously), steroids. When it is required use ultrafiltration to remove water excess.

9.4 Electrolytes disorders and their treatment

Potassium is a main intracellular cation. Its normal plasma concentration is 3,8-5,1 mmol/l. Daily required amount of potassium is 1 mmol/kg of body weight.

Potassium level less than 3,8 mmol/l is known as kaliopenia. Potassium deficiency is calculated according to the formula:

$$K_d = (4,5 - K_p) * 0,6 \text{ BW}$$

K - potassium deficiency, mmol;

K_p – potassium level of the patient mmol/l;

$0,6 * BW$ – total body water, l.

To treat this state use 7,5% solution of potassium chloride (1ml of this solution contains 1 mmol of potassium). Give it intravenously slowly with glucose and insulin (20-25 ml/hour). You can also prescribe magnesium preparations. Standard solution for kaliopenia treatment is:

10% glucose solution 400 ml

7,5% potassium chloride solution 20 ml

25% magnesium sulphate solution 3 ml

insulin 12 units

Give it intravenously slowly, during one hour. Forced bolus infusion of potassium solutions (10-15 ml) can bring cardiac arrest.

Potassium level over 5,2 mmol/l is a state called hyperkalemia. To treat this condition use calcium gluconate or calcium chloride solutions (10 ml of 10% solution intravenously), glucose and insulin solution, saluretics, steroids, sodium bicarbonate solution. Hyperkalemia over 7 mmol/l is an absolute indication for dialysis.

Sodium is the main extracellular cation. Its normal plasma concentration is 135-155 mmol/l. Daily required amount of potassium is 2 mmol/kg of body weight.

Sodium concentration which is lower than 135 mmol/l is known as hyponatraemia. This condition is caused by sodium deficiency or water excess. Sodium deficiency is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

Na - sodium deficiency, mmol;

Na_p – sodium concentration of the patient mmol/l;

$0,2 * BW$ – extracellular fluid volume, l.

To treat it use normal saline (1000 ml contains 154 Na mmol) or 5,8% solution of sodium chloride – your choice will depend on osmotic concentration.

Sodium concentration over 155 mmol/l is a state called hypernatremia. This condition usually appears in case of hypertonic dehydration or hypertonic overhydration. Treatment was described in the text above.

Chlorine is the main extracellular anion. Its normal plasma concentration is 98-107 mmol/l. Daily requirement of chlorine is 215 mmol.

Hypochloremia is a condition of decreased plasma chlorine concentration (less than 98 mmol/l).

Chlorine deficiency is calculated according to the formula:

$$Cl_d = (100 - Cl_p) * 0,2 BW,$$

Cl_d - chlorine deficiency, mmol

Cl_p – plasma chlorine concentration of the patient, mmol/l

$0,2 * BW$ – extracellular fluid volume, l.

To treat hypochloremia use normal saline (1000 ml contains 154 mmol of chlorine) or 5,8% sodium chloride solution (1 ml contains 1 mmol of chlorine). The choice of solution depends on the osmotic concentration of the plasma.

Hyperchloremia is a condition of increased chlorine concentration (over 107 mmol/l). Intensive therapy of this state includes treatment of the disease, which caused it (decompensated heart failure, hyperchloremic diabetes insipidus, glomerulonephritis). You can also use glucose, albumin solutions and dialysis.

Magnesium is mostly an intracellular cation. Its plasma concentration is 0,8-1,5 mmol/l. Daily requirement of magnesium is 0,3 mmol/kg.

Hypomagnesemia is a state of decreased magnesium concentration: less than 0,8 mmol/l. Magnesium deficiency is calculated according to the formula:

$$Mg_d = (1,0 - Mg_p) * 0,6 BW,$$

Mg_d - magnesium deficiency, mmol

Mg_p – plasma magnesium concentration of the patient, mmol/l

$0,6 * BW$ – extracellular fluid volume, l.

Use 25% magnesium sulphate solution to treat this state (1 ml of it contains 0,5 mmol of magnesium).

Hypermagnesemia is a state of increased magnesium concentration (more than 1,5 mmol/l). This condition appears usually in case of hyperkalemia and you should treat it as you treat hyperkalemia.

Calcium is one of the extracellular cations. Its normal concentration is 2,35-2,75 mmol/l. Daily requirement of calcium is 0,5 mmol/kg.

Calcium concentration less than 2,35 mmol/l is called hypocalcemia. Calcium deficiency is calculated according to the formula:

$$Ca_d = (2,5 - Ca_p) * 0,2 BW,$$

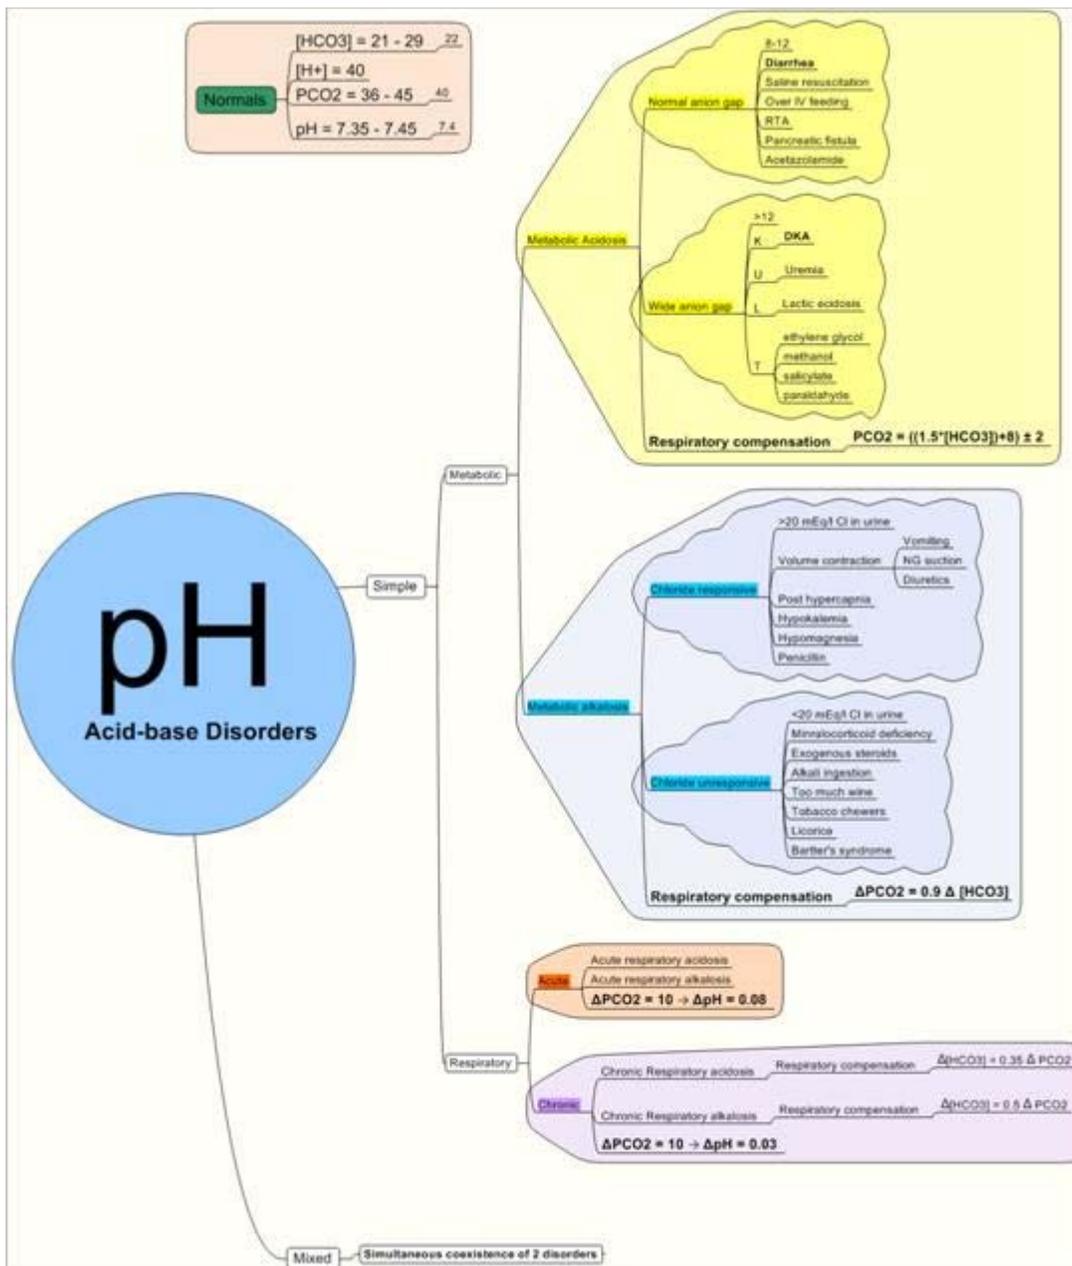

Ca_d – calcium deficiency, mmol

Ca_p – plasma calcium concentration of the patient, mmol/l

$0,2 * BW$ – extracellular fluid volume, l.

To treat this state use 10% calcium chloride (1 ml of the solution contains 1,1 mmol of calcium), ergocalciferol; in case of convulsions prescribe sedative medicines.

Hypercalcemia is a condition with increased calcium concentration (over 2,75 mmol/l). Treat the disease, which caused it: primary hyperparathyroidism, malignant bone tumors, etc. Additionally use infusion therapy (solutions of glucose with insulin), steroids, dialysis and hemosorption.

9.5 Acid-base imbalance and its treatment.

There are 2 main types of acid-base imbalance: acidosis and alkalosis.

pH is a decimal logarithm of the reciprocal of the hydrogen ion activity. It shows acid-base state of the blood.

Normal pH of arterial blood is 7,36-7,44. Acid based imbalance is divided according to the pH level into:

pH 7,35-7,21 – subcompensated acidosis

pH < 7,2 – decompensated acidosis

pH 7,45-7,55 – subcompensated alkalosis

pH > 7,56 – decompensated alkalosis

Respiratory part of the acid-base imbalance is characterized with $p\text{CO}_2$. Normally $p\text{CO}_2$ of arterial blood is 36-44 mm Hg. Hypercapnia ($p\text{CO}_2$ increased over 45 mm Hg) is a sign of respiratory acidosis. Hypocapnia ($p\text{CO}_2$ less than 35 mm Hg) is a symptom of respiratory alkalosis.

Basis excess index is also a characteristic of metabolic processes. Normally H^+ ions produced during metabolic reactions are neutralized with buffer system. BE of arterial blood is $0 \pm 1,5$. Positive value of BE (with +) is a sign of base excess or plasma acid deficiency (metabolic alkalosis). Negative value of BE (with -) is a symptom of bases deficiency, which is caused by acid neutralization in case of metabolic acidosis.

Respiratory acidosis (hypercapnia) is a condition caused by insufficient elimination of CO_2 from the body during hypoventilation. Laboratory tests show:

$\text{pH} < 7,35$,

$p\text{CO}_{2a} > 46$ mm Hg

BE - normal values

However when the respiratory acidosis progresses renal compensation fails to maintain normal values and BE gradually increases. In order to improve this condition you should treat acute and chronic respiratory violations. When $p\text{CO}_2$ is over 60 mm Hg begin artificial lung ventilation (through the mask or tube; when the necessity of ventilation lasts longer than 3 days – perform tracheostomy).

Respiratory alkalosis (hypocapnia) is usually an effect of hyperventilation, caused by excessive stimulation of respiratory centre (injuries, metabolic acidosis, hyperactive metabolism, etc.) or wrong parameters of mechanical ventilation. Gasometry shows:

$\text{pH} > 7,45$,

$p\text{CO}_{2a} < 33$ mm Hg

BE $< +1,5$ mmol/l.

However prolong alkalosis brings decrease of BE due to compensatory retain of H^+ ions. To improve this imbalance treat its reason: normalize ventilation parameters; if patients breathing has rate over 40 per minute – sedate the patient, perform the intubation and begin artificial ventilation with normal parameters.

Metabolic acidosis is characterized with absolute and relative increase of H^+ ions concentration due to acid accumulation (metabolic disorders, block of acid elimination,

excessive acid consumption in case of poisonings, etc.). Laboratory tests show:

pH < 7,35,

pCO_{2a} < 35 mm Hg

BE (-3) mmol/l.

Treat the main reason of acid-base disorder: diabetic ketoacidosis, renal insufficiency, poisoning, hyponatremia or hyperchloremia, etc. Normalize pH with 4% sodium bicarbonate solution. Its dose is calculated according to the formula:

$$V = 0,3 * BE * BW$$

V- volume of sodium bicarbonate solution, ml

BE – bases excess with “-”, mmol/l

BW – body weight, kg

Metabolic alkalosis is a condition of absolute and relative decrease of H⁺ ions concentration. Blood tests show:

pH > 7,45,

pCO_{2a} normal or insignificantly increased (compensatory reaction)

BE 3,0 mmol/l.

To treat this condition use “acid” solutions, which contain chlorides (saline, potassium chloride). In case of kaliopenia give potassium solutions.

Respiratory and metabolic imbalances can mix in case of severe decompensated diseases due to failure of compensatory mechanisms. Correct interpretation of these violations is possible only in case of regular and iterative gasometry blood tests.

Control tasks.

Task 1.

Calculate the total body water volume and its extracellular and intracellular volumes of the Patient, the patient of 48 years and body weight 88 kg.

Task 2.

Patient, the patient of 23 with body weight 70 kg has sodium level 152 mmol/l and hematocrit 0,49 l/l. Name the type of water balance disorder.

Task 3.

Patient, the patient of 54 with body weight 76 kg has sodium level 128 mmol/l.

Calculate the volume of saline and 7,5% sodium chloride solution necessary for the treatment of this condition.

Task 4.

Patience, the patient of 60 with body weight 60 kg has sodium level 140 mmol/l and hematocrit 0,55 l/l. Name the type of disorder and prescribe infusion therapy.

Task 5.

Patience, the patient of 42 with body weight 80 kg has potassium level 2,6 mmol/l. Calculate the volume of 4% potassium chloride solution necessary for treatment of this condition.

Task 6.

Patience, the patient of 33 with body weight 67 kg and diagnosis “gastric ulcer, complicated with pylorostenosis” has potassium concentration 3 mmol/l, chlorine concentration 88 mmol/l. pH 7,49, pCO_{2a} 42 mm Hg, BE + 10 mmol/l. Name the type of disorder.

Task 7.

Patience, the patient of 50 with body weight 75 kg, was transported to the admission unit of the hospital with: unconsciousness, cyanotic skin, low blood pressure, shallow breathing. Blood tests show: pH 7,18, pCO_{2a} 78 mm Hg, pO_{2A} – 57 mm Hg, BE -4,2 mmol/l. Name the type of acid-base disorder and prescribe treatment.

Task 8.

Patience, the patient with body weight 62 kg and renal insufficiency has: potassium concentration 5,2 mmol/l, sodium concentration 130 mmol/l, calcium concentration 1,5 mmol/l, pH 7,22, pCO_{2a} 34 mm Hg, BE -9,2 mmol/l. Name the type of disorder.

Violations of homoeostasis and their correction.

9.1 The importance of the water to the organism.

Life on earth was born in the water environment. Water is a universal solvent for all the biochemical processes of the organism. Only in case of stable quantitative and qualitative composition of both intracellular and extra cellular fluids homoeostasis is remained.

The body of an adult human contains 60% of water. Intracellular water makes 40% of the body weight, the water of intercellular space makes 15% of body weight and 5% of body weight are made by the water in the vessels. It is considered that due to unlimited diffusion of water between vessels and extra vascular space the volume of extracellular fluid is 20% of body

weight (15%+5%).

Physiologically insignificant amounts of water are distributed beyond the tissues in the body cavities: gastrointestinal tract, cerebral ventricles, joint capsules (nearly 1% of the body weight). However during different pathologic conditions this “third space” can cumulate large amounts of fluid: for example in case of ascites caused by chronic cardiac insufficiency or cirrhosis abdominal cavity contains up to 10 liters of fluid. Peritonitis and intestinal obstructions remove the fluid part of blood from the vessels into the intestinal cavity.

Severe dehydration is extremely dangerous for the patient. Water gets to the body with food and drinks, being absorbed by the mucous membranes of gastro-intestinal tract in total amount of 2-3 liters per day. Additionally in different metabolic transformations of lipids, carbohydrates and proteins nearly 300 of endogenous water are created. Water is evacuated from the body with urine (1,5-2 liters), stool (300 ml), perspiration and breathing (those two reasons are combined as “perspiration loss” and make from 300 to 1000 ml per day).

Water balance is regulated through complicated, but reliable mechanisms. Control over water and electrolytes excretion is realized by osmotic receptors of posterior hypothalamus, volume receptors of the atrial walls, baroreceptors of carotid sinus, juxtaglomerular apparatus of the kidneys and adrenal cortical cells.

When there is a water deficiency or electrolytes excess (sodium, chlorine) thirst appears and this makes us drink water. At the same time posterior pituitary produces antidiuretic hormone, which decreases urine output. Adrenals reveal into the blood flow aldosterone, which stimulates reabsorption of sodium ions in the tubules and thus also decreases diuresis (due to osmosis laws water will move to the more concentrated solution). This way organism can keep precious water.

On the contrary, in case of water excess endocrine activity of glands is inhibited and water is actively removed from the body through the kidneys.

9.2 Importance of osmolarity for homeostasis.

Water sections of the organism (intracellular and extracellular) are divided with semipermeable membrane – cell wall. Water easily penetrates through it according to the laws of osmosis. Osmosis is a movement of water through a partially permeable membrane from the solution with lower concentration to a solution with higher concentration.

Osmotic concentration (osmolarity) is the concentration of active parts in one liter of solution (water). It is defined as a number of miliosmoles per liter (mOsm/l). Normally osmotic concentration of plasma, intracellular and extracellular fluids is equal and varies between 285mOsm/l. This value is one of the most important constants of the organism, because if it

changes in one sector the whole fluid of the body will be redistributed (water will move to the environment with higher concentration). Over hydration of one sector will bring dehydration of another. For example, when there is a tissue damage concentration of active osmotic parts increases and water diffuses to this compartment, causing oedema. On the contrary plasma osmolarity decreases, when there is a loss of electrolytes and osmotic concentration of the cellular fluid stays on the previous level. This brings cellular oedema, because water moves through the intracellular space to the cells due to their higher osmotic concentration.

Cerebral oedema appears when the plasma osmolarity is lower than 270 mOsm/l. Activity of central nervous system is violated and hyposmolar coma occurs. Hyperosmolar coma appears when the plasma osmolarity is over 320 mOsm/l: water leaves the cells and fills the vascular bed and this leads to cellular dehydration. The sensitive to cellular dehydration are the cells of the brain.

Plasma osmolarity is measured with osmometer. The principle of measurement is based on difference in freezing temperature between distilled water and plasma. The higher is the osmolarity (quantity of molecules) the lower is freezing temperature.

Plasma osmotic concentration can be calculated according to the formula:

$$\text{Osmotic concentration} = 1,86 * \text{Na} + \text{glucose} + \text{urea} + 10,$$

Plasma osmolarity (osmotic concentration) – mOsm/l

Na- sodium concentration of plasma, mmol/l

Glucose- glucose concentration of the plasma, mmol/l

Urea- urea concentration of the plasma, mmol/l

According to this formula sodium concentration is the main factor influencing plasma osmolarity. Normally sodium concentration is 136-144 mmol/l. Water and electrolytes balance can be violated with external fluid and electrolytes loss, their excessive inflow or wrong distribution.

9.3 Fluid imbalance and principles of its intensive treatment.

Water imbalance is divided into dehydration and overhydration.

Dehydration is caused by:

- excessive perspiration in conditions of high temperature;

- rapid breathing (dyspnea, tachypnea) or artificial ventilation without humidification of the air;
- vomiting, diarrhoea, fistulas;
- blood loss, burns;
- diuretics overdose;
- excessive urine output;
- inadequate enteral and parenteral nutrition or infusion therapy (comatose patients, postoperative care);
- pathological water distribution (“third space” in case of inflammation or injury).

Dehydration signs: weight loss, decrease of skin turgor and eyeballs tone, dry skin and mucous membranes; low central venous pressure, cardiac output and blood pressure (collapse is possible); decreased urine output and peripheral veins tone; capillary refill over 2 seconds (microcirculation disorders) and low skin temperature; intracellular dehydration is characterized with thirst and consciousness disorders. Laboratory tests show blood concentration: hematocrit, hemoglobin concentration, protein level and red blood cells concentration increase.

Overhydration appears in case of:

- excessive water consumption, inadequate infusion therapy;
- acute and chronic renal failure, hepatic and cardiac insufficiency;
- disorders of fluid balance regulation;
- low protein edema.

Clinical findings in case of overhydration are: weight gain, peripheral oedema, transudation of the plasma into the body cavities (pleural, abdominal), high blood pressure and central venous pressure. In case of intracellular overhydration appear additional symptoms: nausea, vomiting, signs of cerebral edema (spoor, coma). Laboratory tests prove hemodilution.

According to the osmotic concentration of plasma dehydration and overhydration are divided into hypotonic, isotonic and hypertonic.

Isotonic dehydration is caused by equal loss of electrolytes and fluid from the extracellular space (without cellular disorders). Blood tests show hemoconcentration; sodium level and osmotic concentration are normal.

To treat this type of water imbalance use normal saline solution, Ringer solution,

glucose-saline solutions, etc.. The volumes of infusions can be calculated according to the formula:

$$V_{H_2O} = 0,2 * BW * (H_{tp} - 0,4) / 0,4 ,$$

V_{H_2O} – volume of infusion, l

H_{tp} – patient's hematocrit, l/l,

BW – body weight, $0,2 * BW$ – volume of extracellular fluid,

0,4- normal hematocrit, l/l,

Hypertonic dehydration is caused by mostly water loss: first it appears in the vascular bed, than in the cells. Laboratory tests show hemoconcentration: elevated levels of proteins, red blood cells, hematocrit. Plasma sodium is over 155 mmol/l and osmotic concentration increases over 310 mOsm/l.

Intensive treatment: if there is no vomiting allow patients to drink. Intravenously give 0,45% saline solution and 2,5 % glucose solution, mixed with insulin. The volume of infusions is calculated according to the formula:

$$V_{H_2O} = 0,6 * BW (Na_p - 140) / 140,$$

V_{H_2O} – water deficiency, l

Na_p – plasma sodium, mmol/l

BW – body weight, $0,6 * BW$ volume of general body fluid

140 – physiological plasma sodium concentration

Hypotonic dehydration is characterized with clinical features of extracellular dehydration. Laboratory tests show decrease of sodium and chlorine ions. Those changes cause intracellular movement of the water (intracellular overhydration). Hemoglobin, hematocrit and protein levels are increased. Sodium is lower than 136 mmol/l, osmolarity is lower than 280 mOsm/l.

To treat this type of water imbalance use normal or hypertonic saline and sodium bicarbonate solution (depends on blood pH). Do not use glucose solutions!

The deficiency of electrolytes is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

N_{d} – sodium deficiency, mmol

N_{p} – plasma sodium, mmol/l

BW – body weight, 0,2 BW – volume of extracellular fluid

Isotonic overhydration is caused by excess of the water in the vascular bed and extracellular space; however intracellular homeostasis is not violated. Hemoglobin is less than 120 g/l, protein level is less than 60 g/l, plasma sodium is 136-144 mmol/l, osmotic concentration is 285-310 mOsm/l.

Treat the reason of imbalance: cardiac failure, liver insufficiency, etc. Prescribe cardiac glycosides, limit salt and water consumption. Give osmotic diuretics (mannitol solution 1,5 g/kg), saluretics (furosemide solution 2 mg/kg), aldosterone antagonists (triamterene – 200 mg), steroids (prednisolone solution 1-2 mg/kg) albumin solution if necessary (0,2-0,3 g/kg).

Hypertonic overhydration is a state of extracellular electrolytes and water excess combined with intracellular dehydration. Blood tests show decrease of hemoglobin, hematocrit, protein level, however sodium concentration is increased over 144 mmol/l, osmotic concentration is over 310 mOsm/l.

To treat this condition use solutions without electrolytes: glucose with insulin, albumin solutions and prescribe saluretics (furosemide solution), aldosterone antagonists (spironolactone). If it is necessary perform dialysis and peritoneal dialysis. Do not use crystalloids!

Hypotonic overhydration is a state of extracellular and intracellular water excess. Blood tests show decrease of haemoglobin, hematocrit, proteins, sodium and osmotic concentration. Intensive therapy of this condition includes osmotic diuretics (200-400 ml of 20% mannitol solution), hypertonic solutions (50 ml of 10% saline intravenously), steroids. When it is required use ultrafiltration to remove water excess.

9.4 Electrolytes disorders and their treatment

Potassium is a main intracellular cation. Its normal plasma concentration is 3,8-5,1 mmol/l. Daily required amount of potassium is 1 mmol/kg of body weight.

Potassium level less than 3,8 mmol/l is known as kaliopenia. Potassium deficiency is calculated according to the formula:

$$K_d = (4,5 - K_p) * 0,6 \text{ BW}$$

K- potassium deficiency, mmol;

K_p – potassium level of the patient mmol/l;

$0,6 * BW$ – total body water, l.

To treat this state use 7,5% solution of potassium chloride (1ml of this solution contains 1 mmol of potassium). Give it intravenously slowly with glucose and insulin (20-25 ml/hour). You can also prescribe magnesium preparations. Standard solution for kaliopenia treatment is:

10% glucose solution 400 ml

7,5% potassium chloride solution 20 ml

25% magnesium sulphate solution 3 ml

insulin 12 units

Give it intravenously slowly, during one hour. Forced bolus infusion of potassium solutions (10-15 ml) can bring cardiac arrest.

Potassium level over 5,2 mmol/l is a state called hyperkalemia. To treat this condition use calcium gluconate or calcium chloride solutions (10 ml of 10% solution intravenously), glucose and insulin solution, saluretics, steroids, sodium bicarbonate solution. Hyperkalemia over 7 mmol/l is an absolute indication for dialysis.

Sodium is the main extracellular cation. Its normal plasma concentration is 135-155 mmol/l. Daily required amount of potassium is 2 mmol/kg of body weight.

Sodium concentration which is lower than 135 mmol/l is known as hyponatraemia. This condition is caused by sodium deficiency or water excess. Sodium deficiency is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

Na - sodium deficiency, mmol;

Na_p – sodium concentration of the patient mmol/l;

$0,2 * BW$ – extracellular fluid volume, l.

To treat it use normal saline (1000 ml contains 154 Na mmol) or 5,8% solution of sodium chloride – your choice will depend on osmotic concentration.

Sodium concentration over 155 mmol/l is a state called hypernatremia. This condition usually appears in case of hypertonic dehydration or hypertonic overhydration. Treatment was described in the text above.

Chlorine is the main extracellular anion. Its normal plasma concentration is 98-107 mmol/l. Daily requirement of chlorine is 215 mmol.

Hypochloremia is a condition of decreased plasma chlorine concentration (less than 98 mmol/l).

Chlorine deficiency is calculated according to the formula:

$$Cl_d = (100 - Cl_p) * 0,2 BW,$$

Cl_d - chlorine deficiency, mmol

Cl_p – plasma chlorine concentration of the patient, mmol/l

$0,2 * BW$ – extracellular fluid volume, l.

To treat hypochloremia use normal saline (1000 ml contains 154 mmol of chlorine) or 5,8% sodium chloride solution (1 ml contains 1 mmol of chlorine). The choice of solution depends on the osmotic concentration of the plasma.

Hyperchloremia is a condition of increased chlorine concentration (over 107 mmol/l). Intensive therapy of this state includes treatment of the disease, which caused it (decompensated heart failure, hyperchloremic diabetes insipidus, glomerulonephritis). You can also use glucose, albumin solutions and dialysis.

Magnesium is mostly an intracellular cation. Its plasma concentration is 0,8-1,5 mmol/l. Daily requirement of magnesium is 0,3 mmol/kg.

Hypomagnesemia is a state of decreased magnesium concentration: less than 0,8 mmol/l. Magnesium deficiency is calculated according to the formula:

$$Mg_d = (1,0 - Mg_p) * 0,6 BW,$$

Mg_d - magnesium deficiency, mmol

Mg_p – plasma magnesium concentration of the patient, mmol/l

$0,6 * BW$ – extracellular fluid volume, l.

Use 25% magnesium sulphate solution to treat this state (1 ml of it contains 0,5 mmol of magnesium).

Hypermagnesemia is a state of increased magnesium concentration (more than 1,5 mmol/l). This condition appears usually in case of hyperkalemia and you should treat it as you treat hyperkalemia.

Calcium is one of the extracellular cations. Its normal concentration is 2,35-2,75

mmol/l. Daily requirement of calcium is 0,5 mmol/kg.

Calcium concentration less than 2,35 mmol/l is called hypocalcemia. Calcium deficiency is calculated according to the formula:

$$Ca_d = (2,5 - Ca_p) * 0,2 BW,$$

Ca_d – calcium deficiency, mmol

Ca_p – plasma calcium concentration of the patient, mmol/l

$0,2 * BW$ – extracellular fluid volume, l.

To treat this state use 10% calcium chloride (1 ml of the solution contains 1,1 mmol of calcium), ergocalciferol; in case of convulsions prescribe sedative medicines.

Hypercalcemia is a condition with increased calcium concentration (over 2,75 mmol/l). Treat the disease, which caused it: primary hyperparathyroidism, malignant bone tumors, etc. Additionally use infusion therapy (solutions of glucose with insulin), steroids, dialysis and hemosorption.

9.5 Acid-base imbalance and its treatment.

There are 2 main types of acid-base imbalance: acidosis and alkalosis.

pH is a decimal logarithm of the reciprocal of the hydrogen ion activity. It shows acid-base state of the blood.

Normal pH of arterial blood is 7,36-7,44. Acid based imbalance is divided according to the pH level into:

pH 7,35-7,21 – subcompensated acidosis

pH < 7,2 – decompensated acidosis

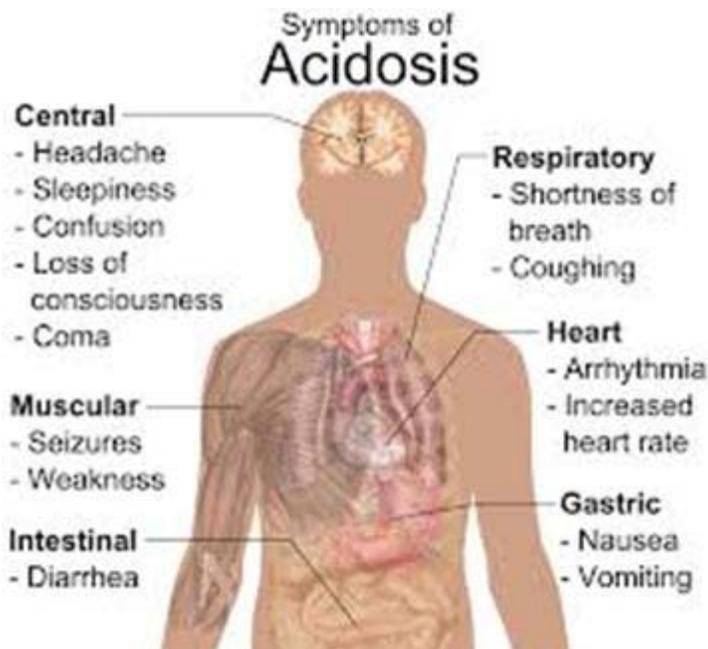

pH 7,45-7,55 – subcompensated alkalosis

pH > 7,56 – decompensated alkalosis

Respiratory part of the acid-base imbalance is characterized with pCO_2 . Normally pCO_2 of arterial blood is 36-44 mm Hg. Hypercapnia (pCO_2 increased over 45 mm Hg) is a sign of respiratory acidosis. Hypocapnia (pCO_2 less than 35 mm Hg) is a symptom of respiratory alkalosis.

Basis excess index is also a characteristic of metabolic processes. Normally H^+ ions produced during metabolic reactions are neutralized with buffer system. BE of arterial blood is $0 \pm 1,5$. Positive value of BE (with +) is a sign of base excess or plasma acid deficiency

(metabolic alkalosis). Negative value of BE (with -) is a symptom of bases deficiency, which is caused by acid neutralization in case of metabolic acidosis.

Respiratory acidosis (hypercapnia) is a condition caused by insufficient elimination of CO₂ from the body during hypoventilation. Laboratory tests show:

pH < 7,35,

pCO_{2a} > 46 mm Hg

BE - normal values

However when the respiratory acidosis progresses renal compensation fails to maintain normal values and BE gradually increases. In order to improve this condition you should treat acute and chronic respiratory violations. When pCO₂ is over 60 mm Hg begin artificial lung ventilation (through the mask or tube; when the necessity of ventilation lasts longer than 3 days – perform tracheostomy).

Respiratory alkalosis (hypocapnia) is usually an effect of hyperventilation, caused by excessive stimulation of respiratory centre (injuries, metabolic acidosis, hyperactive metabolism, etc.) or wrong parameters of mechanical ventilation. Gasometry shows:

pH > 7,45,

pCO_{2a} < 33 mm Hg

BE < +1,5 mmol/l.

However prolong alkalosis brings decrease of BE due to compensatory retain of H⁺ ions. To improve this imbalance treat its reason: normalize ventilation parameters; if patients

breathing has rate over 40 per minute – sedate the patient, perform the intubation and begin artificial ventilation with normal parameters.

Metabolic acidosis is characterized with absolute and relative increase of H^+ ions concentration due to acid accumulation (metabolic disorders, block of acid elimination, excessive acid consumption in case of poisonings, etc.). Laboratory tests show:

$$pH < 7,35,$$

$$pCO_{2a} < 35 \text{ mm Hg}$$

$$BE (-3) \text{ mmol/l.}$$

Treat the main reason of acid-base disorder: diabetic ketoacidosis, renal insufficiency, poisoning, hyponatremia or hyperchloremia, etc. Normalize pH with 4% sodium bicarbonate solution. Its dose is calculated according to the formula:

$$V = 0,3 * BE * BW$$

V- volume of sodium bicarbonate solution, ml

BE – bases excess with “-”, mmol/l

BW – body weight, kg

Metabolic alkalosis is a condition of absolute and relative decrease of H^+ ions concentration. Blood tests show:

$$pH > 7,45,$$

pCO_{2a} normal or insignificantly increased (compensatory reaction)

$$BE 3,0 \text{ mmol/l.}$$

To treat this condition use “acid” solutions, which contain chlorides (saline, potassium chloride). In case of kaliopenia give potassium solutions.

Respiratory and metabolic imbalances can mix in case of severe decompensated diseases due to failure of compensatory mechanisms. Correct interpretation of these violations is possible only in case of regular and iterative gasometry blood tests.

Control tasks.

Task 1.

Calculate the total body water volume and its extracellular and intracellular volumes of the Patient, the patient of 48 years and body weight 88 kg.

Task 2.

Patience, the patient of 23 with body weight 70 kg has sodium level 152 mmol/l and hematocrit 0,49 l/l. Name the type of water balance disorder.

Task 3.

Patience, the patient of 54 with body weight 76 kg has sodium level 128 mmol/l. Calculate the volume of saline and 7,5% sodium chloride solution necessary for the treatment of this condition.

Task 4.

Patience, the patient of 60 with body weight 60 kg has sodium level 140 mmol/l and hematocrit 0,55 l/l. Name the type of disorder and prescribe infusion therapy.

Task 5.

Patience, the patient of 42 with body weight 80 kg has potassium level 2,6 mmol/l. Calculate the volume of 4% potassium chloride solution necessary for treatment of this condition.

Task 6.

Patience, the patient of 33 with body weight 67 kg and diagnosis “gastric ulcer, complicated with pylorostenosis” has potassium concentration 3 mmol/l, chlorine concentration 88 mmol/l. pH 7,49, pCO_{2a} 42 mm Hg, BE + 10 mmol/l. Name the type of disorder.

Task 7.

Patience, the patient of 50 with body weight 75 kg, was transported to the admission unit of the hospital with: unconsciousness, cyanotic skin, low blood pressure, shallow breathing. Blood tests show: pH 7,18, pCO_{2a} 78 mm Hg, pO_{2A} – 57 mm Hg, BE -4,2 mmol/l. Name the type of acid-base disorder and prescribe treatment.

Task 8.

Patience, the patient with body weight 62 kg and renal insufficiency has: potassium concentration 5,2 mmol/l, sodium concentration 130 mmol/l, calcium concentration 1,5 mmol/l, pH 7,22, pCO_{2a} 34 mm Hg, BE -9,2 mmol/l. Name the type of disorder.

Student should repeat next questions

Violations of homeostasis and their correction.

9.1 The importance of the water to the organism.

Life on earth was born in the water environment. Water is a universal solvent for all the

biochemical processes of the organism. Only in case of stable quantitative and qualitative composition of both intracellular and extra cellular fluids homoeostasis is remained.

The body of an adult human contains 60% of water. Intracellular water makes 40% of the body weight, the water of intercellular space makes 15% of body weight and 5% of body weight are made by the water in the vessels. It is considered that due to unlimited diffusion of water between vessels and extra vascular space the volume of extracellular fluid is 20% of body weight (15%+5%).

Physiologically insignificant amounts of water are distributed beyond the tissues in the body cavities: gastrointestinal tract, cerebral ventricles, joint capsules (nearly 1% of the body weight). However during different pathologic conditions this “third space” can cumulate large amounts of fluid: for example in case of ascites caused by chronic cardiac insufficiency or cirrhosis abdominal cavity contains up to 10 liters of fluid. Peritonitis and intestinal obstructions remove the fluid part of blood from the vessels into the intestinal cavity.

Severe dehydration is extremely dangerous for the patient. Water gets to the body with food and drinks, being absorbed by the mucous membranes of gastro-intestinal tract in total amount of 2-3 liters per day. Additionally in different metabolic transformations of lipids, carbohydrates and proteins nearly 300 of endogenous water are created. Water is evacuated from the body with urine (1,5-2 liters), stool (300 ml), perspiration and breathing (those two reasons are combined as “perspiration loss” and make from 300 to 1000 ml per day).

Water balance is regulated through complicated, but reliable mechanisms. Control over water and electrolytes excretion is realized by osmotic receptors of posterior hypothalamus, volume receptors of the aerial walls, bar receptors of carotid sinus, juxtaglomerular apparatus of the kidneys and adrenal cortical cells.

When there is a water deficiency or electrolytes excess (sodium, chlorine) thirst appears and this makes us drink water. At the same time posterior pituitary produces antidiuretic hormone, which decreases urine output. Adrenals reveal into the blood flow aldosterone, which stimulates reabsorption of sodium ions in the tubules and thus also decreases diuresis (due to osmosis laws water will move to the more concentrated solution). This way organism can keep precious water.

On the contrary, in case of water excess endocrine activity of glands is inhibited and water is actively removed from the body through the kidneys.

9.2 Importance of osmolarity for homoeostasis.

Water sections of the organism (intracellular and extracellular) are divided with semipermeable membrane – cell wall. Water easily penetrates through it according to the laws

of osmosis. Osmosis is a movement of water through a partially permeable membrane from the solution with lower concentration to a solution with higher concentration.

Osmotic concentration (osmolarity) is the concentration of active parts in one liter of solution (water). It is defined as a number of miliosmoles per liter (mOsm/l). Normally osmotic concentration of plasma, intracellular and extracellular fluids is equal and varies between 285mOsm/l. This value is one of the most important constants of the organism, because if it changes in one sector the whole fluid of the body will be redistributed (water will move to the environment with higher concentration). Over hydration of one sector will bring dehydration of another. For example, when there is a tissue damage concentration of active osmotic parts increases and water diffuses to this compartment, causing oedema. On the contrary plasma osmolarity decreases, when there is a loss of electrolytes and osmotic concentration of the cellular fluid stays on the previous level. This brings cellular oedema, because water moves through the intracellular space to the cells due to their higher osmotic concentration.

Cerebral oedema appears when the plasma osmolarity is lower than 270 mOsm/l. Activity of central nervous system is violated and hypoosmolar coma occurs. Hyperosmolar coma appears when the plasma osmolarity is over 320 mOsm/l: water leaves the cells and fills the vascular bed and this leads to cellular dehydration. The sensitive to cellular dehydration are the cells of the brain.

Plasma osmolarity is measured with osmometer. The principle of measurement is based on difference in freezing temperature between distilled water and plasma. The higher is the osmolarity (quantity of molecules) the lower is freezing temperature.

Plasma osmotic concentration can be calculated according to the formula:

$$\text{Osmotic concentration} = 1,86 * \text{Na} + \text{glucose} + \text{urea} + 10,$$

Plasma osmolarity (osmotic concentration) – mOsm/l

Na- sodium concentration of plasma, mmol/l

Glucose- glucose concentration of the plasma, mmol/l

Urea- urea concentration of the plasma, mmol/l

According to this formula sodium concentration is the main factor influencing plasma osmolarity. Normally sodium concentration is 136-144 mmol/l. Water and electrolytes balance can be violated with external fluid and electrolytes loss, their excessive inflow or wrong distribution.

9.3 Fluid imbalance and principles of its intensive treatment.

Water imbalance is divided into dehydration and overhydration.

Dehydration is caused by:

- excessive perspiration in conditions of high temperature;
- rapid breathing (dyspnea, tachypnea) or artificial ventilation without humidification of the air;
- vomiting, diarrhoea, fistulas;
- blood loss, burns;
- diuretics overdose;
- excessive urine output;
- inadequate enteral and parenteral nutrition or infusion therapy (comatose patients, postoperative care);
- pathological water distribution (“third space” in case of inflammation or injury).

Dehydration signs: weight loss, decrease of skin turgor and eyeballs tone, dry skin and mucous membranes; low central venous pressure, cardiac output and blood pressure (collapse is possible); decreased urine output and peripheral veins tone; capillary refill over 2 seconds (microcirculation disorders) and low skin temperature; intracellular dehydration is characterized with thirst and consciousness disorders. Laboratory tests show blood concentration: hematocrit, hemoglobin concentration, protein level and red blood cells concentration increase.

Overhydration appears in case of:

- excessive water consumption, inadequate infusion therapy;
- acute and chronic renal failure, hepatic and cardiac insufficiency;
- disorders of fluid balance regulation;
- low protein edema.

Clinical findings in case of overhydration are: weight gain, peripheral oedema, transudation of the plasma into the body cavities (pleural, abdominal), high blood pressure and central venous pressure. In case of intracellular overhydration appear additional symptoms: nausea, vomiting, signs of cerebral edema (spoor, coma). Laboratory tests prove hemodilution.

According to the osmotic concentration of plasma dehydration and overhydration are divided into hypotonic, isotonic and hypertonic.

Isotonic dehydration is caused by equal loss of electrolytes and fluid from the extracellular space (without cellular disorders). Blood tests show hemoconcentration; sodium level and osmotic concentration are normal.

To treat this type of water imbalance use normal saline solution, Ringer solution, glucose-saline solutions, etc.. The volumes of infusions can be calculated according to the formula:

$$V_{H_2O} = 0,2 * BW * (H_{tp} - 0,4) / 0,4 ,$$

V_{H_2O} – volume of infusion, l

H_{tp} – patient's hematocrit, l/l,

BW – body weight, $0,2 * BW$ – volume of extracellular fluid,

0,4- normal hematocrit, l/l,

Hypertonic dehydration is caused by mostly water loss: first it appears in the vascular bed, than in the cells. Laboratory tests show hemoconcentration: elevated levels of proteins, red blood cells, hematocrit. Plasma sodium is over 155 mmol/l and osmotic concentration increases over 310 mOsm/l.

Intensive treatment: if there is no vomiting allow patients to drink. Intravenously give 0,45% saline solution and 2,5 % glucose solution, mixed with insulin. The volume of infusions is calculated according to the formula:

$$V_{H_2O} = 0,6 * BW (Na_p - 140) / 140,$$

VH₂O – water deficiency, l

Na_p – plasma sodium, mmol/l

BW – body weight, 0,6*BW volume of general body fluid

140 – physiological plasma sodium concentration

Hypotonic dehydration is characterized with clinical features of extracellular dehydration. Laboratory tests show decrease of sodium and chlorine ions. Those changes cause intracellular movement of the water (intracellular overhydration). Hemoglobin, hematocrit and protein levels are increased. Sodium is lower than 136 mmol/l, osmolarity is lower than 280 mOsm/l.

To treat this type of water imbalance use normal or hypertonic saline and sodium bicarbonate solution (depends on blood pH). Do not use glucose solutions!

The deficiency of electrolytes is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

Na_d – sodium deficiency, mmol

Na_p – plasma sodium, mmol/l

BW – body weight, 0,2 BW – volume of extracellular fluid

Isotonic overhydration is caused by excess of the water in the vascular bed and extracellular space; however intracellular homeostasis is not violated. Hemoglobin is less than 120 g/l, protein level is less than 60 g/l, plasma sodium is 136-144 mmol/l, osmotic concentration is 285-310 mOsm/l.

Treat the reason of imbalance: cardiac failure, liver insufficiency, etc. Prescribe cardiac glycosides, limit salt and water consumption. Give osmotic diuretics (mannitol solution 1,5 g/kg), saluretics (furosemide solution 2 mg/kg), aldosterone antagonists (triamterene – 200 mg), steroids (prednisolone solution 1-2 mg/kg) albumin solution if necessary (0,2-0,3 g/kg).

Hypertonic overhydration is a state of extracellular electrolytes and water excess combined with intracellular dehydration. Blood tests show decrease of hemoglobin, hematocrit, protein level, however sodium concentration is increased over 144 mmol/l, osmotic concentration is over 310 mOsm/l.

To treat this condition use solutions without electrolytes: glucose with insulin, albumin solutions and prescribe saluretics (furosemide solution), aldosterone antagonists (spironolactone). If it is necessary perform dialysis and peritoneal dialysis. Do not use crystalloids!

Hypotonic overhydration is a state of extracellular and intracellular water excess. Blood tests show decrease of haemoglobin, hematocrit, proteins, sodium and osmotic concentration. Intensive therapy of this condition includes osmotic diuretics (200-400 ml of 20% mannitol solution), hypertonic solutions (50 ml of 10% saline intravenously), steroids. When it is required use ultrafiltration to remove water excess.

Normal range	Causes of elevation	Causes of decline
Sodium (Na): 135 – 145 mEq/L	Hypernatremia: Excessive loss of water through GI system, lungs, or skin; fluid restriction, certain diuretics, hypertonic IV solutions, tube feeding; hypothalamic lesions, hyperaldosteronism, corticosteroid use, Cushing's syndrome, diabetes insipidus	Hyponatremia: Congestive heart failure, cirrhosis, nephrosis, excess fluid intake, syndrome of inappropriate antidiuretic hormone secretion (dilutional hyponatremia); sodium depletion, loss of body fluids without replacement, diuretic therapy, laxatives, nasogastric suctioning, hypoaldosteronism, cerebral salt-wasting disease
Potassium (K): 3.5 – 5.0 mEq/L	Hyperkalemia: Aldosterone deficiency, sodium depletion, acidosis, trauma, hemolysis of red blood cells, potassium-sparing diuretics	Hypokalemia: Lack of dietary intake of potassium, vomiting, nasogastric suctioning, potassium-depleting diuretics, aldosteronism, salt-wasting kidney disease, major GI surgery, diuretic therapy with inadequate potassium replacement
Calcium (Ca): 8.5 – 10.5 mg/dL	Hypercalcemia: Excessive vitamin D, immobility, hyperparathyroidism, potassium-sparing diuretics, ACE inhibitors, malignancy of bone or blood	Hypocalcemia: Hypoparathyroidism, malabsorption, insufficient or inactivated vitamin D or inadequate intake of calcium, hypoalbuminemia, diuretic therapy, diarrhea, acute pancreatitis, bone cancer, gastric surgery
Magnesium (Mg): 1.5 – 2.5 mg/dL	Hypermagnesemia: Excessive use of magnesium-containing antacids and laxatives, untreated diabetic ketoacidosis, excessive magnesium infusions	Hypomagnesemia: Malabsorption related to GI disease, excessive loss of GI fluids, acute alcoholism/cirrhosis, diuretic therapy, hyper- or hypothyroidism, pancreatitis, preeclampsia, nasogastric suctioning, fistula drainage

9.4 Electrolytes disorders and their treatment

Potassium is a main intracellular cation. Its normal plasma concentration is 3,8-5,1 mmol/l. Daily required amount of potassium is 1 mmol/kg of body weight.

Potassium level less than 3,8 mmol/l is known as kaliopenia. Potassium deficiency is calculated according to the formula:

$$K_d = (4,5 - K_p) * 0,6 \text{ BW}$$

K- potassium deficiency, mmol;

K_p – potassium level of the patient mmol/l;

0,6*BW – total body water, l.

To treat this state use 7,5% solution of potassium chloride (1ml of this solution contains 1 mmol of potassium). Give it intravenously slowly with glucose and insulin (20-25 ml/hour). You can also prescribe magnesium preparations. Standard solution for kaliopenia treatment is:

10% glucose solution 400 ml

7,5% potassium chloride solution 20 ml

25% magnesium sulphate solution 3 ml

insulin 12 units

Give it intravenously slowly, during one hour. Forced bolus infusion of potassium solutions (10-15 ml) can bring cardiac arrest.

Potassium level over 5,2 mmol/l is a state called hyperkalemia. To treat this condition use calcium gluconate or calcium chloride solutions (10 ml of 10% solution intravenously), glucose and insulin solution, saluretics, steroids, sodium bicarbonate solution. Hyperkalemia over 7 mmol/l is an absolute indication for dialysis.

Sodium is the main extracellular cation. Its normal plasma concentration is 135-155 mmol/l. Daily required amount of potassium is 2 mmol/kg of body weight.

Sodium concentration which is lower than 135 mmol/l is known as hyponatraemia. This condition is caused by sodium deficiency or water excess. Sodium deficiency is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

Na- sodium deficiency, mmol;

Na_p – sodium concentration of the patient mmol/l;

0,2*BW – extracellular fluid volume, l.

To treat it use normal saline (1000 ml contains 154 Na mmol) or 5,8% solution of sodium chloride – your choice will depend on osmotic concentration.

Sodium concentration over 155 mmol/l is a state called hypernatremia. This condition usually appears in case of hypertonic dehydration or hypertonic overhydration. Treatment was described in the text above.

Chlorine is the main extracellular anion. Its normal plasma concentration is 98-107 mmol/l. Daily requirement of chlorine is 215 mmol.

Hypochloremia is a condition of decreased plasma chlorine concentration (less than 98 mmol/l).

Chlorine deficiency is calculated according to the formula:

$$Cl_d = (100 - Cl_p) * 0,2 \text{ BW},$$

Cl_d - chlorine deficiency, mmol

Cl_p – plasma chlorine concentration of the patient, mmol/l

$0,2 * BW$ – extracellular fluid volume, l.

To treat hypochloremia use normal saline (1000 ml contains 154 mmol of chlorine) or 5,8% sodium chloride solution (1 ml contains 1 mmol of chlorine). The choice of solution depends on the osmotic concentration of the plasma.

Hyperchloremia is a condition of increased chlorine concentration (over 107 mmol/l). Intensive therapy of this state includes treatment of the disease, which caused it (decompensated heart failure, hyperchloremic diabetes insipidus, glomerulonephritis). You can also use glucose, albumin solutions and dialysis.

Magnesium is mostly an intracellular cation. Its plasma concentration is 0,8-1,5 mmol/l. Daily requirement of magnesium is 0,3 mmol/kg.

Hypomagnesemia is a state of decreased magnesium concentration: less than 0,8 mmol/l. Magnesium deficiency is calculated according to the formula:

$$Mg_d = (1,0 - Mg_p) * 0,6 \text{ BW},$$

Mg_d - magnesium deficiency, mmol

Mg_p – plasma magnesium concentration of the patient, mmol/l

$0,6 * BW$ – extracellular fluid volume, l.

Use 25% magnesium sulphate solution to treat this state (1 ml of it contains 0,5 mmol of magnesium).

Hypermagnesemia is a state of increased magnesium concentration (more than 1,5 mmol/l). This condition appears usually in case of hyperkalemia and you should treat it as you treat hyperkalemia.

Calcium is one of the extracellular cations. Its normal concentration is 2,35-2,75 mmol/l. Daily requirement of calcium is 0,5 mmol/kg.

Calcium concentration less than 2,35 mmol/l is called hypocalcemia. Calcium deficiency is calculated according to the formula:

$$Ca_d = (2,5 - Ca_p) * 0,2 \text{ BW},$$

Ca_d – calcium deficiency, mmol

Cl_p – plasma calcium concentration of the patient, mmol/l

$0,2 \cdot BW$ – extracellular fluid volume, l.

To treat this state use 10% calcium chloride (1 ml of the solution contains 1,1 mmol of calcium), ergocalciferol; in case of convulsions prescribe sedative medicines.

Hypercalcemia is a condition with increased calcium concentration (over 2,75 mmol/l). Treat the disease, which caused it: primary hyperparathyroidism, malignant bone tumors, etc. Additionally use infusion therapy (solutions of glucose with insulin), steroids, dialysis and hemosorbition.

9.5 Acid-base imbalance and its treatment.

There are 2 main types of acid-base imbalance: acidosis and alkalosis.

pH is a decimal logarithm of the reciprocal of the hydrogen ion activity. It shows acid-base state of the blood.

Normal pH of arterial blood is 7,36-7,44. Acid based imbalance is divided according to the pH level into:

pH 7,35-7,21 – subcompensated acidosis

pH < 7,2 – decompensated acidosis

pH 7,45-7,55 – subcompansated alkalosis

pH > 7,56 – decompensated alkalosis

Respiratory part of the acid-base imbalance is characterized with pCO_2 . Normally pCO_2 of arterial blood is 36-44 mm Hg. Hypercapnia (pCO_2 increased over 45 mm Hg) is a sign of respiratory acidosis. Hypocapnia (pCO_2 less than 35 mm Hg) is a symptom of respiratory alkalosis.

Basis excess index is also a characteristic of metabolic processes. Normally H^+ ions produced during metabolic reactions are neutralized with buffer system. BE of arterial blood is $0 \pm 1,5$. Positive value of BE (with +) is a sign of base excess or plasma acid deficiency (metabolic alkalosis). Negative value of BE (with -) is a symptom of bases deficiency, which is caused by acid neutralization in case of metabolic acidosis.

Respiratory acidosis (hypercapnia) is a condition caused by insufficient elimination of CO_2 from the body during hypoventilation. Laboratory tests show:

pH < 7,35,

pCO_{2a} > 46 mm Hg

BE - normal values

However when the respiratory acidosis progresses renal compensation fails to maintain normal values and BE gradually increases. In order to improve this condition you should treat acute and chronic respiratory violations. When pCO₂ is over 60 mm Hg begin artificial lung ventilation (through the mask or tube; when the necessity of ventilation lasts longer than 3 days – perform tracheostomy).

Respiratory alkalosis (hypocapnia) is usually an effect of hyperventilation, caused by excessive stimulation of respiratory centre (injuries, metabolic acidosis, hyperactive metabolism, etc.) or wrong parameters of mechanical ventilation. Gasometry shows:

pH > 7,45,

pCO_{2a} < 33 mm Hg

BE < +1,5 mmol/l.

However prolong alkalosis brings decrease of BE due to compensatory retain of H⁺ ions. To improve this imbalance treat its reason: normalize ventilation parameters; if patients breathing has rate over 40 per minute – sedate the patient, perform the intubation and begin artificial ventilation with normal parameters.

Metabolic acidosis is characterized with absolute and relative increase of H⁺ ions concentration due to acid accumulation (metabolic disorders, block of acid elimination, excessive acid consumption in case of poisonings, etc.). Laboratory tests show:

pH < 7,35,

pCO_{2a} < 35 mm Hg

BE (-3) mmol/l.

Treat the main reason of acid-base disorder: diabetic ketoacidosis, renal insufficiency, poisoning, hyponatremia or hyperchloremia, etc. Normalize pH with 4% sodium bicarbonate solution. Its dose is calculated according to the formula:

$$V = 0,3 * BE * BW$$

V- volume of sodium bicarbonate solution, ml

BE – bases excess with “-”, mmol/l

BW – body weight, kg

Metabolic alkalosis is a condition of absolute and relative decrease of H^+ ions concentration. Blood tests show:

pH > 7,45,

pCO_{2a} normal or insignificantly increased (compensatory reaction)

BE 3,0 mmol/l.

To treat this condition use “acid” solutions, which contain chlorides (saline, potassium chloride). In case of kaliopenia give potassium solutions.

Respiratory and metabolic imbalances can mix in case of severe decompensated diseases due to failure of compensatory mechanisms. Correct interpretation of these violations is possible only in case of regular and iterative gasometry blood tests.

Control tasks.

Task 1.

Calculate the total body water volume and its extracellular and intracellular volumes of the Patient, the patient of 48 years and body weight 88 kg.

Task 2.

Patient, the patient of 23 with body weight 70 kg has sodium level 152 mmol/l and hematocrit 0,49 l/l. Name the type of water balance disorder.

Task 3.

Patient, the patient of 54 with body weight 76 kg has sodium level 128 mmol/l. Calculate the volume of saline and 7,5% sodium chloride solution necessary for the treatment of this condition.

Task 4.

Patient, the patient of 60 with body weight 60 kg has sodium level 140 mmol/l and hematocrit 0,55 l/l. Name the type of disorder and prescribe infusion therapy.

Task 5.

Patient, the patient of 42 with body weight 80 kg has potassium level 2,6 mmol/l. Calculate the volume of 4% potassium chloride solution necessary for treatment of this condition.

Task 6.

Patient, the patient of 33 with body weight 67 kg and diagnosis “gastric ulcer, complicated with pylorostenosis” has potassium concentration 3 mmol/l, chlorine

vessel) are epinephrine, norepinephrine, serotonin, angiotensin II. Stress enhances the secretion of catecholamines, their blood concentration increases and arterioles constrict. Spasm of the arterioles is the basis of blood flow centralization: peripheral flow is disregarded in order to provide brain with the oxygenated blood as long as possible. To the group of vasodilators (agents, which provide dilatation of the vessels) belong “acid” metabolites (lactate, pyruvate, adenylic acid, inosinic acid), bradykinin, acetylcholine, different medicines (neuroleptics, α -adrenergic antagonists, peripheral vasodilators, ganglionic blocking agents, etc.), some exogenous poisons. All of them cause blood flow decentralization: opening of arterioles and distribution of the blood from central vessels to the capillary bed.

Capillaries are the interweaving network of the smallest body vessels with the general length of 90-100 thousands of kilometers. However simultaneously work only 20-25% of them. They provide metabolic exchange bringing oxygen and nutrients to the tissues and take back wastes of metabolism. Periodically, every 30-40 seconds one of them get closed and others open (vasomotion effect). Capillaries contain 12% of the whole circulating blood volume, but different pathological conditions can increase this amount even 3 and more times.

“Used” blood from the capillaries flows to the venous system. Veins are the blood reservoir, which contains 70% of the total circulating blood volume. Unlike arteries they are capable of volume control and thus they influence the amount of blood, which returns to the heart.

The most important haemodynamic index of venous system is central venous pressure. CVP represents the pressure which blood causes to the walls of cava veins and right atrium. This parameter is an integral index of circulating blood volume, systemic vascular resistance and pump function of the heart. It can be measure with a special device called “phlebotonometer” (pic. 4.9) or with a usual infusion set and a ruler. Normally CVP measured from the sternum point is 0-14 cm H₂O and from midaxillary line is 8-15 cm H₂O.

Central venous pressure decreases (sometimes even to negative) in case of:

- blood loss
- excessive water loss (dehydration)
- distributive shock (decrease of peripheral resistance due to venous and arterial dilatation)

In those conditions decreases volume of blood returning to the heart and thus suffers cardiac output. In case of negative CVP cardiac arrest is highly probable.

Central venous pressure increases in case of:

- heart failure (insufficiency of left or right ventricle)
- hypervolemia (excessive blood infusion, improper infusion therapy)

- obstructions to blood flow (pulmonary embolism, cardiac tamponade, etc.)

When CVP over 15-16 cm H₂O is combined with left ventricle insufficiency the risk of pulmonary edema is very high.

Blood pressure is an integral index of arterial part of systemic haemodynamics. Talking about blood pressure we may refer to systolic, diastolic, pulse and mean arterial pressure. Systolic (P_{syst}) and diastolic (P_{diast}) pressures are measured with the manometer (method with the usage of phonendoscope was invented by M. Korotkoff). Pulse pressure (PP) is a difference between systolic and diastolic blood pressure.

Mean arterial pressure (MAP) is calculated according to the formula:

$$\text{MAP} = P_{\text{dias}} + 1/3 \text{ PP} \quad \text{mm Hg}$$

MAP defines the level of pressure necessary for the metabolic exchange in the tissues. Its measurement allows the evaluation of tissue perfusion level.

Blood pressure depends on different factors, but the most important are cardiac output and vascular resistance (mostly arterioles). This dependence is direct, thus you can increase blood pressure using:

- infusion of vasoconstrictors - solutions of epinephrine, phenylephrine (mesaton), etc. (they will increase the vascular resistance);
- infusion of hydroxyethyl starch solutions or saline (they will increase circulating blood volume)
- infusion of cardiac glycosides or other medicine which stimulate myocardium

General volume of blood in the body of a healthy adult is nearly 7% from the body weight: 70 ml per kilogram for male and 65 ml per kilogram of body weight for female. Of course circulating blood volume is lower, because part of blood is out of metabolic processes as a reserve. CBV can be measured with the infusion of coloring substance to the blood flow (Evans blue, polyglucin) and later evaluation of its dissolution degree.

Therefore measurement of CVP, BP, cardiac output and circulating blood volume allow to evaluate condition of circulation system of the patients and to provide adequate correction.

4.2 Acute heart failure; shock and collapse.

Acute cardiovascular failure is a state of cardiac and vascular inability to provide

adequate supply of tissue metabolic needs with oxygenated blood and nutrients. This, earlier or later, causes cellular death.

The reasons of the failure vary greatly: mechanic injuries, blood loss, burns, dehydration, exogenous and endogenous intoxications, immediate hypersensitivity reaction, ischemic heart disease, neural and humoral regulation disorders of vascular tone.

Acute cardiac failure is a disorder of heart pumping action. It develops due to primary heart problems or secondary, under the influence of extracardiac factors such as infection or intoxication. There are two types of heart failure: left-sided and right-sided.

Left-sided heart failure is an inability of left ventricle to pump blood from the pulmonary circuit to the systemic circuit. The most common reasons of it are myocardial infarction, mitral insufficiency, left AV valve stenosis, aortic valve stenosis, aortal insufficiency, hypertonic disease, coronary sclerosis, acute pneumonia.

Coronary circulation is possible only during the diastole and in those conditions every violation of coronary passability decreases cardiac output. This way during the systole part of the blood is not injected into aorta, but stays in the left ventricle. Diastolic pressure in the left ventricle increases and blood is literally forced to stagnate in the left atrium. At the same time right ventricle functions normally and continues to pump usual amounts of blood to the pulmonary circuit. Thus hydrostatic pressure in the vessels of pulmonary circulation increases, fluid part of the blood moves first to the lung tissue and then, through alveolar-capillary membrane, to the alveolar lumen.

Clinically pulmonary edema begins with dyspnea (during physical activity or rest). Later attacks of dyspnea are connected with persistent cough with white or pink blood-tinged phlegm. During the attack patient tries to sit as in this position breathing is easier. This condition is called "heart asthma". When hydrostatic pressure is over 150-200 mm Hg, fluid part of blood moves to the alveolar lumen causing development of pulmonary edema.

Pulmonary edema is divided into interstitial and alveolar edema.

Interstitial edema is a condition during which serous part of stagnated in the pulmonary circuit blood infiltrates the lung tissue, including peribronchial and perivascular spaces.

During alveolar edema not only the plasma, but also blood components (red and white blood cells, platelets) get out from the vessels. During the respiratory act blood mixes with the air creating large amount of "foam", which violates gas exchange. This way, in addition to circulatory hypoxia, hypoxic hypoxia appears.

Condition of the patient gets worse quickly. Sitting position is optimal, but not as helping as previously. Respiratory rate is nearly 30-35 breathes per minute, but attacks of

breathlessness are constant. Skin is pale with acrocyanosis. Hypoxia of central nervous system usually causes psychomotor agitation. Respiratory acts are noisy; during cough pink blood-tinged phlegm is released. Auscultation allows you to hear different wet rales, sometimes it's even possible to hear them standing aside the patient without phonendoscope.

Pulmonary edema can be also divided according to the blood pressure level: the one with elevated pressure is caused by a hypertonic disease, aorta valve insufficiency or disorders of cerebral perfusion; another one is caused by total myocardial infarction, acute inflammation of myocardial muscle, terminal valve defects, severe pneumonia and is characterized with normal or low blood pressure.

Immediate aid

- make sure patient is sitting with his legs down (orthopnea)
- provide oxygenation through nasal catheter (before placing oil it with glycerin, insert it to the depth of 10-12 cm – distance from the wing of the nose to auricle) or face mask. Do not use Vaseline, because it can burn in atmosphere with high concentration of oxygen.

However if catheter is not deep enough patient will suffer from an unpleasant “burning” feeling, because oxygen flow will dry mucosa layer of the nasal cavity; also in this situation concentration of oxygen will be lower than expected.

- put venous tourniquets on the limbs in order to reduce amount of blood returning to heart: venous bed of limbs can reserve up to 1,7 liters of blood;
- constantly control heart and kidney activity (ECG, SaO₂ , and blood pressure are checked automatically trough the monitor; to control diuresis you should insert Foley catheter;
- catheterize central vein, because amount of infusions should be based on central venous pressure;
- use medical “defoamers” if they are available (ethyl alcohol or antiphomsylan solution) combined with oxygen inhalation

Scheme of oxygenation set connected to “defoamer” container

- a. oxygen source (cylinder with oxygen)
- b. tube with numerous holes sunk into container with defoamer
- c. tube for humidified oxygen (its opening should be over the level of fluid);
- d. patient

- medical treatment: 1% morphine solution (decreases intravascular

pressure of pulmonary circuit, inhibits respiration center in medulla oblongata preventive dyspnea progress, sedates patient);

- solutions of diuretics are used to decrease the circulating blood volume (6-12 ml of 1% furosemid solution, solution of ethacrynic acid), however be careful with them in case of low blood pressure; diuretic effect will last up to 3 hours after i/v infusion, the expected diuresis is 2-3 liters

- if blood pressure allows you can try to use nitroglycerin to reduce intravascular pressure of pulmonary circuit (1 or 2 tablets with 10 minutes interval)

- cardiac glycosides for improvement of heart action (0,025% digoxin solution, 0,05% strophanthin solution, 0,06% corglicon solution);

- in case of high pressure (over 150 mm Hg) use ganglionic blocking agents (1 ml of 5% pentamin solution diluted in 150 ml of saline, give i/v slowly; diluted with saline 250 mg of trimethaphan solution), because they reduce pressure in pulmonary circuit and lower the amount of blood getting to right half of the heart, however be careful with the dosage and monitor blood pressure level carefully;

- never use osmotic diuretics in case of pulmonary edema – they will increase blood volume and thus heart load!!!

- when everything listed above failed and patient is worsening with every second you should intubate him and start artificial ventilation with positive end expiratory pressure (begin with 4-6 cm H₂O)

Right-sided heart failure is an inability of right ventricular to pump blood from systemic circuit to the pulmonary circuit due to its weakness or an obstruction to the blood flow.

It occurs in case of pulmonary embolism, right ventricular infarction, excessive infusion therapy (especially including citrated blood) for patients with heart insufficiency, lung diseases (bronchial asthma, emphysema, pneumosclerosis) which cause increase of right ventricular load.

Patients have acrocyanosis, tachycardia, dyspnea, pronounced neck veins, ankle swelling, enlarged liver, ascytis. Central venous pressure is highly increased (up to 20-25 cm H₂O), however pulmonary edema does not appear.

Intensive treatment is mostly pathogenetic:

- limit the infusions (give only life-necessary solutions, check the water balance of the patient and reduce drinking water if necessary);

- in case of citrated blood transfusions use 5-10 ml of 10% calcium gluconate solution per every 500 ml of blood to prevent hypocalcaemia;
- in case of bronchial spasm use bronchial spasmolytics;
- to remove excessive fluid from the body use diuretics (furosemide solution for example);
- metabolic acidosis is corrected with 4% solution of sodium bicarbonate (i/v slowly with acid-base state control);
- in case of pulmonary embolism anticoagulants are used – fraxiparine 0,6 mg subcutaneously; heparin solution – 5000 IU every 4 hours; fibrinolytic drugs (streptokinase, fibrinolysin, urokinase, etc.)

Shock is a pathological state which can be described as a tissue hypoxia caused by hypoperfusion. Pathogenetic basis of shock depends on its reason (trauma, toxins, thermal injury) and at the same time on reactivity of the organism (level of defense mechanisms mobilization).

Stimulation of sympathetic nervous system - production of catecholamines and other vasoactive substances by hypothalamus and adrenal glands are the universal response of the body to the stress. Those mediators interact with the receptors of peripheral vessels causing their constriction and at the same time they dilate the vascular bed of life-important organs. This is so called “centralization of the flow”: rational decrease of blood flow in less important tissues (skin, organs of abdominal cavity, kidneys) in case of aggressive external influence for protecting life itself (brain, heart, lungs).

However influence of shock agents (pain, hypovolemia, destroyed cells, toxic metabolites), extended microcirculation violations (vascular spasm, microthrombosis and sludge) and caused by them tissue ischemia lead to hypoxic affection and cellular death of the internal organs. Further it can bring multiple organ dysfunction syndrome.

Collapse is a vascular failure. It occurs when body is not able to provide blood flow according to the new level of its needs (either because reaction is not fast enough or because sympathetic activation fails). Vascular bed volume and circulating blood volume are disproportional: too much blood gets to the microcirculation vascular reserve and the amount, which returns to the heart is not enough for the systemic needs (so called “decentralization” of the blood flow). Cardiac output and blood pressure decrease, that causes hypoperfusion of the central nervous system and thus unconsciousness and life-threatening complications.

Collapse definition is a bit nominal, because if such reaction extends in time the

state of shock develops. Shock itself can equally run as a vascular failure or as a sudden clinical death.

Pathogenetic classification of shock (according to P. Marino, 1998):

- hypovolemic
- cardiogenic
- distributive
- mixed (two and more factors).

Clinical classification of shock:

- traumatic shock;
- haemorrhagic shock;
- dehydration shock;
- burn shock;
- septic shock;
- anaphylactic shock;
- cardiogenic shock;
- exotoxic shock.

4 Shock caused by dehydration

It is a type of hypovolemic shock, which occurs during excessive body fluid loss (not blood, because hemorrhagic shock is another shock type).

Its reasons vary greatly:

- gastrointestinal diseases (profuse vomiting, diarrhea, loss of intestinal fluid through fistula);
- polyuria (uncontrolled diuretic treatment, diabetes mellitus and insipidus, diuretic phase of acute renal failure);
- fluid loss through skin and wound surface (burns, high fever);
- inadequate infusion treatment of postoperative or comatose patients;
- hyperventilation (rapid breathing, Kussmaul breathing, inadequate artificial ventilation parameters in case of apparatus without air humidification).

However not only the complete fluid loss can be the reason of shock, but also it's pathological distribution into the extracellular space (intestinal cavity in case of intestinal paralysis, abdominal cavity in case of ascites, pleural cavity in case of pleurisy). This way will can also act prolonged heavy tissue inflammations (peritonitis) or massive injuries (crush-syndrome).

In cases described above electrolytes are also lost (cations of sodium, potassium, calcium, magnesium; anions of chlorine, hydrocarbonate). It causes complex osmolar, acid-base and electrolytic disorders.

Stage of dehydration shock is evaluated according to the actual fluid loss:

less than 5% of body weight – mild dehydration

5-10% of body weight – moderate dehydration

over 10% of body weight – severe dehydration

Water deficiency brings lowering of cardiac output, blood pressure and central venous pressure (through decrease of blood volume returning to the heart, which leads to compensatory adrenergic vasoconstriction).

Dehydration causes body weight loss, skin and mucosa dryness, decrease of subcutaneous turgor and eyeballs tone, hypothermia, tachycardia, oliguria, thirst. While dehydration progresses compensatory mechanisms weaken and central nervous system suffers: patients become sluggish, confused; hallucinations, cramps and unconsciousness are also possible. Laboratory tests show blood concentration.

One of the most important things in treatment of dehydrated patients is daily balance of fluid: check it carefully trough measuring of daily received and lost fluids (food, infusions, stool and urine output). In case of fever or tachypnea make necessary corrections. Balance should be calculated every 12-24 hours (special paper forms make this easier).

Daily fluid balance is calculated by adding all the received fluids (both enteral and parenteral ways) and deducting urine output, stool, perspiration and breathing water loss.

You should remember, that perspiration depends on body temperature: in case of normal temperature (36,6°C) patient loses 0,5 ml/kg of water during every hour; 1 degree of temperature elevation adds 0,25 ml/kg to normal value of 0,5 ml/kg.

According to the fluid balance infusion therapy is divided into positive (for dehydrated patients), negative (for overhydrated patients) and “zero” (for patients without balance disorders).

Water deficiency is calculated according to the formula:

$$W_{\text{def}} = (Ht_p - Ht_n) * 0,2 \text{ BW} / Ht_n,$$

W_{def} – water deficiency, l;

Ht_p – hematocrit of the patient, l/l;

Ht_n - normal hematocrit, l/l;

BW – body weight, kg.

Use crystalloids to treat water deficiency: saline solution, Ringer's solution, Ringer-lactate solution, electrolytic solutions, 5%, 10, 20% glucose solution. To control potassium concentration (during dehydration this cation is widely lost) prescribe polarizing GIK mixture (pic.9.4), but don't you ever infuse concentrated potassium solutions quickly – it can cause cardiac arrest (not more than 400 of GIK solution ml per hour).

INTENSIVE THERAPY IN SURGERY

Surgical Intensive Care Unit (SICU)

Surgical Intensive Care Unit (SICU)

The Surgical Intensive Care Unit (SICU) is a 10-bed adult critical care unit designed to provide comprehensive care for critically ill surgical and trauma patients. SICU patients require highly skilled nursing care, including close observation and the use of extensive monitoring equipment, mechanical ventilation and potential end-of-life care. The level of care in an intensive care unit is greater than that available on intermediate care units. The SICU serves as the admitting unit for most trauma patients at Johns Hopkins Bayview. As a level 2 trauma center, the Medical Center ensures state-of-the-art trauma care to all the citizens of Maryland.

A Multidisciplinary Approach

The multidisciplinary team in the SICU consists of intensivists, physicians, mid-level practitioners and critical care nurses trained in critical care, surgery and trauma care of adult patients. Many of the nurses are certified through The American Association of Critical Care Nurses and are CCRN recipients. Other multidisciplinary services include:

- Respiratory therapy
- Physical and occupational therapy
- Dietary services
- Pharmacy services
- Social work
- Case management
- Ancillary support

Patient Population

The SICU's patient population includes:

- General surgery
- Trauma services
- ENT
- Orthopaedic surgery
- Vascular surgery
- Urology

- Plastic surgery
- Bariatric surgery
- OB/GYN
- Thoracic surgery

A Patient's Guide to Lung Surgery

Recovering in the ICU (Intensive Care Unit)

Waking Up in the ICU

Immediately after your surgery, you will be taken to the intensive care unit (ICU) to recover, where a team of specially trained cardiothoracic nurses will take care of you. Their goal is to help you recover as quickly and safely as possible. Along with your surgeon, members of the cardiothoracic anesthesia and surgical teams who took care of you in the operating room will continue to follow your progress in the ICU.

Because the ICU is a busy place, you can expect bright lights and a great deal of activity during the day. Many of the sounds you will hear are made by monitors and different types of equipment. Your medications, including those for pain control, will be given through intravenous (IV) tubes at very controlled rates using pumps.

To help you breathe, an endotracheal tube (breathing tube) was inserted while you were asleep. This tube is connected to a respirator that assists your breathing. Because you will not be able to talk or swallow while this tube is in place, your nurse will anticipate your needs and ask you questions that require only a yes or no answer. Nod your head to say yes, and shake your head to say no. When you are fully awake and breathing on your own, the breathing tube will be removed, and you will be able to talk.

It's normal to feel cold and to shiver for a short while after you arrive in the ICU. Your nurse will give you blankets to keep you warm. It's also normal to wake up feeling thirsty, because of

the medications you received before or during the surgery, or because you had nothing to eat or drink before your operation. Despite your thirst, you will be limited in what and how much you may drink while in the ICU.

Controlling Pain

Although all patients are concerned about the pain they will experience, pain after surgery is not as severe as most patients anticipate. To control your pain, you will be given medication that is injected, given orally or by suppository. While you are in the ICU, pain medications will be given to you as scheduled. While doses are calculated to keep you as comfortable as possible, if the medications affect your breathing and/or blood pressure, your physician may decrease the amount of pain medication given to you.

Coughing and Deep Breathing

As you recover in the ICU, the nurses will monitor your blood pressure, pulse rate and breathing. The endotracheal tube (breathing tube) will continue to help you breathe. To prevent postoperative pneumonia, the nurses and respiratory therapists will periodically remove any secretions that may have settled in your lungs during surgery. As soon as your breathing tube is removed, you should begin using your incentive spirometer, followed by coughing exercises. You should continue these exercises every hour while you are awake when you are transferred to your hospital room.

Movement and Changes in Position

While lying in bed, moving and changing position will help improve blood flow in your legs and remove secretions in your lungs. You can move your feet, wiggle your toes and point your toes up toward your head and then down toward the foot of the bed. Your nurse will help you change positions by turning you from one side to another.

Discharge from the ICU

Your surgeon, anesthesiologist and pulmonologist will determine the best time for you to be transferred from the ICU to the Cardiothoracic Unit Floor (CT Unit). Most patients are transferred the day after surgery. If you remain in the ICU for more than a day, your surgeon or a member of your surgery team will explain the specific reasons for the delay. The extra time spent in ICU is often for precautionary reasons and does not indicate any problem.

Breathing and Coughing Exercises

Incentive Spirometer

While recover from surgery, it might be uncomfortable or painful to breathe in as deeply as you normally would. But in order for your lungs to function properly, you need to use your incentive spirometer. You will be given one to take home to practice. You do not need to bring it back to the hospital.

The incentive spirometer is a small, handheld device that is used after surgery to help you expand your lungs and cough up any secretions from your lungs. It also helps maintain normal breathing pattern and measures your inspiratory volume, or how well your lungs are being filled with air when breathe in. In addition, the incentive spirometer will help exercise lungs, just as if you were going through your normal daily routine.

PEP Therapy

Positive Expiratory Pressure (PEP) therapy uses a breathing device that helps expand lungs and remove pulmonary secretions, or mucus. Therapist will assist you with this treatment. Breathing through the PEP valve, you will inhale normally, then exhale through the PEP valve, which has some resistance. This resistance will work out your lungs. After two series of ten breaths, follow with 2-3 huff coughs.

Huff Coughing

Coughing is a natural way to force mucus out of lungs. During huff coughing, gently say the word "huff". Therapist will help you with this breathing exercise.

Hepatorenal Syndrome

Introduction

Initial reports by Frerichs (1861) and Flint (1863), who had noted an association between advanced liver disease with ascites and acute oliguric renal failure in the absence of significant histological changes in the kidneys, led Heyd , and later Helwig and Schutz , to introduce the concept of the hepatorenal syndrome (HRS) to explain the increased frequency of acute renal failure after biliary surgery. However, because HRS could not be reproduced in animal models, pathophysiological concepts remained speculative and its clinical entity was not generally accepted. During the 1950s, HRS was more specifically characterised as a functional renal failure in patients with advanced liver disease, electrolyte disturbances and low urinary sodium concentrations. Hecker and Sherlock showed its temporal reversibility by norepinephrine administration. Over the next few decades, haemodynamic and perfusion studies by Epstein and other investigators identified splanchnic and systemic vasodilatation and active renal vasoconstriction as the pathophysiological hallmarks of HRS. Improved models of ascites and circulatory dysfunction contributed to therapeutic advances, including the introduction of large-volume paracentesis, vasopressin analogues, and transjugular intrahepatic stent-shunt (TIPS), which in turn have led to an improved pathophysiological understanding of HRS. Definition HRS is defined as the development of renal failure in patients with severe liver disease (acute or chronic) in the absence of any other identifiable cause of renal pathology. It is diagnosed following the exclusion of other causes of renal failure in patients with liver disease, such as hypovolaemia, drug nephrotoxicity, sepsis or glomerulonephritis. A similar syndrome can also occur in the setting of acute liver failure. In the kidney there is marked renal vasoconstriction, resulting in a low glomerular filtration rate (GFR). In the extrarenal circulation arterial vasodilatation predominates, resulting in reduction of the total systemic vascular resistance and arterial hypotension.

Diagnostic Criteria

The International Ascites Club (1996) group has defined the diagnostic criteria for HRS, and these are listed in Table 1.

Major criteria

Chronic or acute liver disease with advanced hepatic failure and portal hypertension

Low GFR, as indicated by serum creatinine > 1.5 mg/dl or 24-h creatinine clearance < 500 g/d for several days in patients with ascites without peripheral oedema or > 1000 ml in patients with peripheral oedema)

No sustained improvement in renal function (decrease of serum creatinine to 1.5 mg/dl or less or increase in 24 h creatinine clearance to 40 ml/min or more) after withdrawal of diuretics and expansion of plasma volume with 1.5 l of isotonic saline

Proteinuria

Additional criteria

Urine sodium $\lt \gt$ plasma osmolality

Urine red blood cells $\lt \gt$

Epidemiology

HRS occurs in about 4% of patients admitted to hospital with decompensated cirrhosis, the cumulative probability being 18% at 1 year, increasing to 39% at 5 years. Retrospective studies indicate that HRS is present in approximately 17% of patients admitted to hospital with ascites and in more than 50% of cirrhotic patients dying of liver failure. The most frequent cause of renal failure in cirrhosis is spontaneous bacterial peritonitis (SBP). Approximately 30% of patients with SBP develop renal failure. Type 1 HRS is characterised by rapid and progressive renal impairment and is precipitated most commonly by SBP. Type 1 HRS occurs in approximately 25% of patients with SBP, even when rapid resolution of the infection is obtained with antibiotics. Without treatment, the median survival of patients with HRS type 1 is less than 2 weeks, and virtually all patients die within 10 weeks after the onset of renal failure. Type 2 HRS is characterised by a moderate and stable reduction in GFR and commonly occurs in patients with relatively well-preserved hepatic function. The median survival is 3–6 months. Although this is markedly longer than that in type 1 HRS, it is still shorter than that of patients with cirrhosis and ascites who do not have renal failure. People of all races who have chronic liver disease are at risk of HRS, and its frequency is equal in both sexes; most patients with chronic liver disease are in the 4th–8th decade of life.

Prognosis

In a prospective study published by Gines et al., once HRS had developed the median survival was only 1.7 weeks, and it was poorer particularly in patients with apparent precipitating factors. Overall survival at 4 and 10 weeks was 20% and 10%, respectively. Patients with low urinary sodium excretion

Pathophysiology

The hallmark of HRS is renal vasoconstriction, although the pathogenesis is not fully understood. Multiple mechanisms are probably involved and include interplay between disturbances in systemic haemodynamics, activation of vasoconstrictor systems and a reduction in activity of the vasodilator systems. The haemodynamic pattern of patients with HRS is characterised by increased cardiac output, low arterial pressure and reduced systemic vascular resistance. Renal vasoconstriction occurs in the absence of reduced cardiac output and blood volume, which is a point of contrast to most clinical conditions associated with renal hypoperfusion. Although the pattern of increased renal vascular resistance and decreased peripheral resistance is characteristic of HRS, it also occurs in other conditions, such as anaphylaxis and sepsis. Doppler studies of the brachial, middle cerebral and femoral arteries suggest that extrarenal resistance is increased in patients with HRS, while the splanchnic circulation is responsible for arterial vasodilatation and reduced total systemic vascular resistance. The renin-angiotensin-aldosterone system (RAAS) and the sympathetic nervous system (SNS) are the predominant systems responsible for renal vasoconstriction. The activity of both systems is increased in patients with cirrhosis and ascites, and this effect is magnified in HRS. In contrast, an inverse relationship exists between the activity of these two systems and renal plasma flow (RPF) and the glomerular filtration rate (GFR). Endothelin is another renal vasoconstrictor that is present in increased concentration in HRS, although its role in the pathogenesis of this syndrome has yet to be identified. Adenosine is well known for its vasodilator properties, although it acts as a vasoconstrictor in the lungs and kidneys. Elevated levels of adenosine are more common in patients with heightened activity of the RAAS and may work synergistically with angiotensin II to produce renal vasoconstriction in HRS. This

effect has also been described with the powerful renal vasoconstrictor, leukotriene E4. The vasoconstricting effect of these various systems is antagonised by local renal vasodilatory factors, the most important of which are the prostaglandins. Perhaps the strongest evidence supporting their role in renal perfusion is the marked decrease in RPF and the GFR when nonsteroidal medications known to bring about a sharp reduction in PG levels are administered. Nitrous oxide (NO) is another vasodilator that is believed to play an important part in renal perfusion. Preliminary studies, predominantly based on animal experiments, have demonstrated that NO production is increased in the presence of cirrhosis, although NO inhibition does not result in renal vasoconstriction owing to a compensatory increase in PG synthesis. However, when both NO and PG production are inhibited, marked renal vasoconstriction develops. These findings demonstrate that renal vasodilators have a critical role in maintaining renal perfusion, particularly in the presence of overactivity of renal vasoconstrictors. However, we do not yet know for certain whether vasoconstrictor activity becomes the predominant system in HRS and whether a reduction in the activity of the vasodilator system contributes to this. Various theories have been proposed to explain the development of HRS in cirrhosis. The two main ones are the arterial vasodilatation theory and the hepatorenal reflex theory. The first not only describes sodium and water retention in cirrhosis, but may also be the most rational hypothesis for the development of HRS. Splanchnic arteriolar vasodilatation in patients with compensated cirrhosis and portal hypertension may be mediated by several factors, the most important of which is probably NO. In the early phases of portal hypertension and compensated cirrhosis, this underfilling of the arterial bed causes a decrease in the effective arterial blood volume and results in homeostatic reflex activation of the endogenous vasoconstrictor systems. Activation of the RAAS and SNS occurs early with antidiuretic hormone secretion, a later event when a more marked derangement in circulatory function is present. This results in vasoconstriction not only of the renal vessels, but also in the vascular beds of the brain, muscle, spleen and extremities. The splanchnic circulation is resistant to these effects because of the continuous production of local vasodilators, such as NO. In the early phases of portal hypertension, renal perfusion is maintained within normal or near-normal limits as the vasodilatory systems antagonise the renal effects of the vasoconstrictor systems. However, as liver disease progresses in severity, a critical level of vascular underfilling is achieved; renal vasodilatory systems are unable to counteract the maximal activation of the endogenous vasoconstrictors and/or intrarenal vasoconstrictors, which leads to uncontrolled renal vasoconstriction. Support for this hypothesis is provided by studies in which the administration of splanchnic vasoconstrictors in

combination with volume expanders results in improvement in arterial pressure, RPF and GFR. The alternative theory proposes that renal vasoconstriction in HRS is not related to systemic haemodynamics but is due either to a deficiency in the synthesis of a vasodilator factor or to a hepatorenal reflex that leads to renal vasoconstriction. Evidence points to the vasodilatation theory as a more tangible explanation for the development of HRS.

Histopathology of HRS

In previous definitions of HRS, changes in renal histology were reported to be absent or minimal, which reflected a rapid progression to death after development of HRS. Considering that many patients with HRS currently receive aggressive supportive treatment including renal replacement therapy to prolong survival until liver transplantation, it seems obvious that prolonged renal hypoperfusion, renal medullary hypoxia and the high frequency of infectious complications ultimately contribute to histologically detectable renal damage. However, it is increasingly recognised that structural renal damage may already be found even before renal dysfunction becomes manifest. In a series of cirrhotic patients undergoing liver transplantation, 100% of renal biopsies showed glomerular abnormalities. Tubular function is usually well preserved at the time when HRS develops, but tubular abnormalities, including increased B2 microglobulin excretion, have been reported in deeply jaundiced patients with HRS. With progressive circulatory dysfunction, prolonged renal hypoperfusion may eventually result in acute tubular necrosis by increasing the susceptibility to additional insults by radiographic contrast agents, aminoglycosides, haemorrhage, endotoxaemia or any other cause of medullary hypoxia. The presence of acute tubular necrosis could partially explain the slow or absent renal recovery in HRS type 1 even after the initiation of vasopressor support. For instance, a recent case study reports full recovery of renal function in dialysis-dependent HRS after 7 weeks of treatment with ornipressin, dopamine and intravenous albumin.

Prevention

The following measures may decrease the incidence of renal failure or HRS in patients with liver disease.

Prophylaxis Against

Bacterial Infections Bacterial infections occur in approximately 50% of patients with variceal haemorrhage, and antibiotic prophylaxis improves survival by approximately 10%. Patients who have had a previous episode of SBP have a 68% chance of recurrent infection at 1 year,

and this carries a 33% chance of developing renal failure. As bacterial infections are an important cause of renal dysfunction in cirrhotic patients, prophylaxis with antibiotics is recommended in two clinical settings, namely variceal bleeding and a history of previous SBP.

Volume Expansion

To prevent the development of renal failure in patients who develop SBP, it is now recommended that plasma volume expansion should be implemented in these patients by giving 20% albumin (1–1.5 g/kg over 1–3 days) at diagnosis to prevent circulatory dysfunction, renal impairment and mortality. Use of low-salt albumin as fluid replacement in patients undergoing large-volume paracentesis (8 g for each litre of ascitic fluid removed) is known to prevent paracentesis-induced circulatory dysfunction.

Judicious Use of Diuretics

It is important to identify the lowest effective dose of a diuretic for any individual patient, as diuretic-induced renal impairment is seen in approximately 20% of patients with ascites. It develops when the rate of diuresis exceeds the rate of ascites reabsorption, leading to intravascular volume depletion. Diuretic-induced renal impairment is usually moderate and rapidly reversible following diuretic withdrawal.

Avoidance of Nephrotoxic Drugs

Patients with cirrhosis and ascites are predisposed to the development of acute tubular necrosis during the use of aminoglycosides, with renal failure occurring in 33% of such patients as against 3–5% in the general population. Another important cause of renal failure is the use of nonsteroidal antiinflammatory drugs (NSAIDs).

Treatment

The ideal treatment for HRS is liver transplantation; however, because of the long waiting lists in the majority of transplant centres, most patients die before being offered a transplant. There is an urgent need for effective alternative therapies to increase survival chances for patients with HRS until transplantation can be performed. Treatment can be divided into initial management, pharmacological treatment and surgical manoeuvres.

Initial Management Optimise fluid management.

Renal function rarely recovers in the absence of liver recovery. The key goal in the management

of these patients is to exclude reversible or treatable lesions (mainly hypovolaemia) and to support the patient until liver recovery or liver transplantation. The treatment of HRS is directed at reversing the haemodynamic changes induced by reduced renal perfusion pressure, stimulated sympathetic nervous system and increased synthesis of humoral and renal vasoconstrictor factors. In cirrhotic patients renal failure is frequently secondary to hypovolaemia (diuretics or gastrointestinal bleeding), NSAIDs or sepsis. Precipitating factors should be recognised and treated and nephrotoxic drugs, discontinued. All patients should be challenged with up to 1.5 l of fluid, such as albumin solution or normal saline, to assess the renal response, as many patients with subclinical hypovolaemia will respond to this simple measure. This should be done with careful monitoring to avoid fluid overload. In practice, fluid overload is not usually a problem, as patients with severe liver disease function as 'fluid sumps' and their vasculature adapts to accommodate the extra fluid. This has been described by Hadengue et al., who reported increased venous compliance following fluid challenge in advanced cirrhosis. Monitor for sepsis. Evidence of sepsis should be sought in blood, ascitic, cannulae and urine cultures, and nonnephrotoxic broad-spectrum antibiotics should be started regardless of whether such evidence is found, as any delay in effective treatment of undiagnosed infection can increase mortality. In advanced cirrhosis, endotoxins and cytokines play important parts in fostering the hyperdynamic circulation and worsening renal function. Optimise blood pressure. If mean arterial pressure is low

Pharmacological Treatment

All the drugs that have been investigated in HRS have one overriding aim: to increase renal blood flow. This has been achieved either indirectly, by splanchnic vasoconstriction, or directly, using renal vasodilators. One of the principal difficulties has been the lack of agents that act purely on the splanchnic circulation. Drugs that 'spill over' into the systemic circulation may actually exacerbate the intense renal vasoconstriction already present. Currently, there is significant enthusiasm for the use of vasoconstrictor agents in HRS. However, the numbers of patients studied have been small, mortality remains high and there have been no randomised placebo-controlled trials. This deficit clearly needs to be addressed but the possibilities are limited by the relative rarity of patients with 'pure' HRS without such confounding variables as sepsis and gastrointestinal bleeding. Important aspects of the situation mentioned in these reports are the need for a pressor response to the agents used and the recurrence of abnormal renal function after the cessation of vasoconstrictor therapy. HRS is effectively a marker of poor hepatic function, and these agents are probably best utilised as a

bridge to further improvement in liver function following either cessation of alcohol abuse or liver transplantation. Thus, the decision to use vasoconstrictor agents for HRS should be based on whether the patient is a realistic transplant candidate and, if not, whether liver function might improve. Patients who do not satisfy these criteria will be tested unnecessarily, merely prolonging the process of dying when palliative care would be more appropriate.

Dopamine. Nonpressor renal doses of dopamine [2–5 $\mu\text{g kg}^{-1} \text{min}^{-1}$) are frequently prescribed to patients with acute deterioration of renal function. As shown by a recent, large scale, randomised trial, early renal dose dopamine has no role in the prevention of acute renal failure in critically ill patients and does not significantly improve renal function in patients with HRS. At higher doses, dopamine worsens the hyperdynamic circulation by exaggerating splanchnic hyperaemia and increasing portal pressure and may cause tachyarrhythmia. Thus, the use of dopamine monotherapy seems to offer no benefit in HRS. Combination therapy with dopamine and vasopressors has produced inconsistent results in HRS. Because beneficial renal effects have been reported only with vasopressor, and not with dopamine, monotherapy, it seems unlikely that dopamine contributed to renal improvement in these studies.

Misoprostol. Misoprostol, a synthetic prostaglandin E-1 analogue, has been used to reverse renal vasoconstriction in HRS. Low doses of misoprostol are vasodilatory, natriuretic and diuretic, whereas high-dose misoprostol increases renal vascular tone and inhibits sodium and water excretion. None of the five studies investigating misoprostol in HRS seems to indicate substantial benefit. Improvement of renal function occurred in 1 of these studies, but could also be explained by volume expansion.

N-Acetylcysteine. In 1999, the group at the Royal Free Hospital reported their experience with N-acetylcysteine (NAC) for the treatment of HRS. This was based on experimental models of acute cholestasis, in which the administration of NAC resulted in an improvement in renal function. Twelve patients with HRS were treated with intravenous NAC, without any adverse effects, and the survival rates were 67% and 58% at 1 month and 3 months, respectively (this included 2 patients who received liver transplantation after improvement in renal function). The mechanism of action remains unknown, but this interesting study encourages further optimism for medical treatment of a condition that once carried a hopeless diagnosis without liver transplantation. Controlled studies with longer follow-up may help answer these pressing questions.

Renal vasoconstrictor antagonists. Saralasin, an antagonist of angiotensin II receptors, was first used in 1979 in an attempt to reverse renal vasoconstriction. Because this drug inhibited the homeostatic response to hypotension commonly observed in patients with cirrhosis, it led to worsening hypotension and deterioration in renal function. Poor results were also observed with phentolamine, an alpha-

adrenergic antagonist, highlighting the importance of the sympathetic nervous system in maintaining renal haemodynamics in patients with HRS. Antagonists of endothelin A receptor. A recent case series by Soper et al. reported an improvement in GFR in patients with cirrhosis, ascites and HRS who received an endothelin A receptor antagonist. All patients showed a dose-dependent response in the form of improved inulin and para-aminohippurate excretion, RPF and GFR without changes in systemic haemodynamics. These patients were not candidates for liver transplantation and subsequently died. More work is needed to explore this therapeutic approach as a possible bridge to transplantation for patients with HRS. Systemic vasoconstrictors. These medications have shown the most promise for treatment of HRS in recent years. Hecker and Sherlock used norepinephrine in 1956 to treat patients with cirrhosis who had HRS, and they were the first to describe an improvement in arterial pressure and urine output. However, no improvement was observed in the biochemical parameters of renal function, and all patients subsequently died. Octapressin, a synthetic vasopressin analogue, was first used in 1970 to treat HRS type 1. RPF and the GFR improved in all patients, all of whom subsequently died of sepsis, gastrointestinal bleeding or liver failure. Because of these discouraging results, the use of alternative vasopressin analogues, particularly ornipressin, attracted attention. Two important studies by Lenz et al. demonstrated that short term use of ornipressin resulted in an improvement in circulatory function and a significant increase in RPF and the GFR. The combination of ornipressin and albumin was subsequently tried by Guevera in patients with HRS. This idea was based on data suggesting that the combination of plasma volume expansion and vasoconstrictors normalised renal sodium and water handling in patients who had cirrhosis with ascites. In this study, 8 patients were originally treated for 15 days with ornipressin and albumin. Treatment had to be discontinued in 4 patients after fewer than 9 days because of complications of ornipressin use that included ischaemic colitis, tongue ischaemia and glossitis. Although a marked improvement in the serum creatinine was observed during treatment, renal function deteriorated on treatment withdrawal. In the remaining 4 patients the improvement in RPF and the GFR was significant and was associated with a lowering of serum creatinine levels. These patients subsequently died, but no recurrence of HRS was observed. Owing to the high incidence of severe adverse effects with ornipressin, the same investigators used another vasopressin analogue with fewer adverse effects, namely terlipressin. In this study, nine patients were treated with terlipressin + albumin for 5–15 days. This treatment was associated with a marked fall in serum creatinine levels and an improvement in mean arterial pressure. Reversal of HRS was noted in seven of the nine patients, and HRS did not recur when treatment was discontinued. No adverse ischemic effects were reported:

according to this study, terlipressin with albumin is a safe and effective treatment for HRS. Alpha adrenergic agonists. Angeli et al. showed that long-term administration of midodrine (an alpha-adrenergic agonist) and octreotide improved renal function in patients with HRS type 1. All patients also received albumin, and the results obtained with this approach were compared against those observed with dopamine at nonpressor doses. None of the patients treated with dopamine showed any improvement in renal function, but in all the patients treated with midodrine, octreotide and volume expansion renal function did improve. No adverse effects were reported in these patients. Gulberg et al. treated seven patients who had cirrhosis and HRS type 1 with a combination of ornipressin and dopamine for infusion periods as long as 27 days, but only three of the seven patients survived. This treatment can be used as a bridge to liver transplantation. Aquaretic agents. K-Opioid antagonists inhibit antidiuretic hormone secretion by the neurohypophysis and induce water excretion. Administration of niravoline at doses ranging from 0.5 to 2 mg induced a strong aquaretic response and was well tolerated in 18 cirrhotic patients with preserved renal function, but no data are available on the use of niravoline in patients with HRS.

Surgical Manoeuvres

Transjugular intrahepatic portosystemic shunting. It is well documented that portal hypertension plays a central role in the development of refractory ascites and HRS. Earlier studies showed improved renal function after side-to-side portocaval shunting, but at the cost of a high surgical mortality in advanced cirrhosis. The transjugular intrahepatic portosystemic shunt (TIPS) was introduced as a less invasive method of reducing increased portal pressure. Guevarra et al. have investigated hepatic and renal haemodynamic changes after placement of TIPS in patients with HRS. One month after placement of TIPS a marked improvement in renal function was observed, as indicated by a significant reduction in serum creatinine and blood urea nitrogen and increased urine volume, RPF and GFR. These improvements were associated with a reduction in plasma rennin, aldosterone and norepinephrine activity. These changes were statistically significant, albeit less pronounced than observed in a similar group of patients receiving ornipressin and albumin infusions. Renal improvements were more pronounced at 30 days than at 7 days, possibly because of the deleterious effects of contrast media or the resolution of concomitant problems. After TIPS, GFR improved significantly but did not reach normal values, suggesting that TIPS does not correct all mechanisms contributing to HRS. Brensing et al. found a sustained improvement of renal function after TIPS in 31 patients with type 1 or 2 HRS, allowing the discontinuation of haemodialysis in four of seven patients. After

TIPS 3-, 6-, 12- and 18-month survival rates were 81%, 71%, 48% and 35%, respectively, in the total patient cohort, with survival in HRS type 1 patients being significantly worse than in the others. The use of TIPS to prolong survival until liver transplantation seems promising.

Other surgical shunts. Despite the theoretical benefit of improving portal hypertension and thus HRS by means of a portosystemic shunt, only a few scattered case reports have shown any benefit. Currently, particularly with the recent introduction of TIPS, portocaval shunts are not indicated in this setting.

Renal replacement therapy. Many clinicians are reluctant to institute renal replacement therapy in advanced cirrhosis, because the outcome is poor unless liver transplantation is a realistic option. Intermittent haemodialysis can be a problem because patients with HRS are prone to develop circulatory and coagulation problems, and biocompatibility is also a problematic issue. In an early study in the United Kingdom 100% mortality was observed in cirrhotic patients with HRS despite early institution of renal support. However, modern renal replacement therapies such as continuous endogenous haemofiltration (CVVH) are certainly capable of prolonging life in patients with type 1 HRS who have not responded to medical therapies or TIPS. Because the underlying hepatic problem persists, the long-term prognosis is grim and treatment should be confined to patients who are candidates for liver transplantation or have a realistic chance of hepatic recovery. The molecular adsorbent recirculating system (MARS) is a modified dialysis method that uses albumin-containing dialysate in a closed-loop secondary circuit for adsorptive removal of albumin-bound toxins. In a randomised study, short-term survival of eight HRS patients treated with MARS was superior to that of five other HRS patients treated with CVVH. In contrast to previous reports on haemodialysis, treatment was well tolerated. Unfortunately, the study was terminated after enrolment of only 13 patients, which makes evaluation of any influence on mortality difficult. Moreover, the control group seems to have received a smaller dialytic dose: creatinine levels were decreased in the MARS group only. Nonetheless, the favourable effects of this system deserve evaluation in a prospective study of adequate power.

Liver transplantation. Liver transplantation is the ideal treatment for HRS, but is completely dependent on the availability of Donors. Patients with HRS have a higher risk of postoperative morbidity, early mortality and longer hospitalisation than other transplant recipients. Gonwa et al. reported that at least one third of such patients require haemodialysis postoperatively, with a smaller proportion (5%) requiring long-term dialysis. Because renal dysfunction is common in the first few days after transplantation, avoidance nephrotoxic immunosuppressants is generally recommended until renal function is recovered. However, the GFR gradually improves to an average of 40–50 ml/min by the 6th postoperative week. The systemic and neurohumoral

abnormalities associated with HRS also resolve in the 1st postoperative month. Long-term survival rates are excellent, with the survival rate at 3 years approaching approximately 60%. This is only slightly lower than the 70–80% survival rate of transplant recipients without HRS and is markedly better than the survival rate of patients with HRS who do not receive transplants, which is virtually nil at 3 years.

VASCULAR ACCESS

PREPARING FOR VASCULAR CANNULATION

HANDWASHING

Handwashing is mandatory (and often overlooked) before the insertion of vascular devices. Scrubbing with antimicrobial cleansing solutions does not reduce the incidence of catheter-related sepsis, so a simple soap-and-water scrub is sufficient.

UNIVERSAL PRECAUTIONS

In 1985, the Centers for Disease Control introduced a strategy for blood and body fluid precautions known as universal precautions. This strategy is based on the assumption that all patients are potential sources of human immunodeficiency virus (HIV) and other blood-borne pathogens (e.g., hepatitis viruses) until proven otherwise. The following recommendations apply to the insertion of vascular catheters.

Use protective gloves for all vascular cannulations.

Use sterile gloves for all cannulations except those involving the introduction of a short catheter into a peripheral vein.

Caps, gowns, masks, and protective eyewear are not necessary unless splashes of blood are anticipated (e.g., in a trauma victim). These measures do not reduce the incidence of catheter-related sepsis.

Avoid needlestick injuries. Do not recap needles or manually remove needles from syringes.

Place all sharp instruments in puncture-resistant containers immediately after use.

If a needlestick injury is sustained during the procedure, follow the recommendations in Table 4.1.

Needlestick injuries are reported in up to 80% of medical students and interns. Therefore, in patients who are known risks for transmitting HIV or viral hepatitis, vascular cannulation should be performed only by an experienced senior-level resident or fellow.

LATEX ALLERGY

The increased use of rubber gloves (made of latex or vinyl) as protection against HIV infections has resulted in an increased recognition of allergic reactions to latex. These reactions can be manifest as a contact dermatitis (urticarial lesions of the hands and face), or as a conjunctivitis, rhinitis, or asthma. The latter three manifestations are reactions to airborne latex particles, and they do not require direct physical contact with gloves. They often appear when the affected individual enters an area where latex gloves are being used. Therefore, a latex allergy should be suspected in any ICU team member who develops atopic symptoms when in the ICU. When this occurs, a switch to vinyl gloves will eliminate the problem. Latex allergy can be manifest as anaphylaxis, so the transition to vinyl gloves for suspected latex allergy should not be delayed.

CLEANSING THE SKIN

Agents that reduce skin microflora are called antiseptics, whereas agents that reduce the microflora on inanimate objects are called disinfectants. Common antiseptic agents are listed in Table 4.2 (11,12). The most widely used antiseptic agents are alcohol and iodine, both of which have a broad spectrum of antimicrobial activity. Alcohol (commonly used as a 70% solution) may not work well on dirty skin (that is, it does not have a detergent action), so it is often used in combination with another antiseptic agent. The most popular antiseptic solution currently in use is a povidone-iodine preparation (e.g., Betadine), also known as an iodophor, a water-soluble complex of iodine and a carrier molecule. The iodine is released slowly from the carrier molecule, and this reduces the irritating effects of iodine on the skin. This preparation should be left in contact with the skin for at least 2 minutes to allow sufficient time for iodine to be

released from the carrier molecule.

HAIR REMOVAL

Shaving is not recommended for hair removal because it abrades the skin and promotes bacterial colonization. If hair removal is necessary, the hair can be clipped or a depilatory can be applied.

CATHETER INSERTION DEVICES

Vascular cannulation can be performed by advancing the catheter over a needle or guidewire that is in contact with the lumen of a blood vessel.

CATHETER-OVER-NEEDLE

A catheter-over-needle device is shown in Figure 4.1. The catheter fits snugly over the insertion needle, and has a tapered end to minimize damage to the catheter tip and soft tissues during insertion. This device can be held like a pencil (i.e., between the thumb and forefinger) as it is inserted through the skin and directed to the target vessel. When the tip of the needle enters the lumen of a patent blood vessel, blood moves up the needle by capillary action and enters the flashback chamber. When this occurs, the catheter is threaded over the needle and into the lumen of the blood vessel as the needle is withdrawn.

The advantage of a catheter-over-needle device is the ability to cannulate vessels in a simple one-step procedure. The disadvantage is the tendency for the catheter tip to become frayed as it passes through the skin and soft tissues, and to subsequently damage the vascular endothelium and promote phlebitis and thrombosis. To minimize this risk, the catheter-over-needle device is usually reserved for cannulation of superficial vessels.

CATHETER-OVER-GUIDEWIRE

Guidewire-assisted vascular cannulation was introduced in the early 1950s and is often called the Seldinger technique, after its inventor. This technique is illustrated in Figure 4.2. A small-bore needle (usually 20 gauge) is used to probe for the target vessel. When the tip of the

needle enters the vessel, a thin wire with a flexible tip (called a J-tip because of its shape) is passed through the needle and into the vessel lumen. The needle is then removed, leaving the wire in place to serve as a guide for cannulation of the vessel. When cannulating deep vessels, a rigid dilator catheter is first threaded over the guidewire and removed; this creates a tract that facilitates insertion of the vascular catheter.

The guidewire technique has the presumed advantage of minimizing damage to soft tissues and blood vessels by using a small-bore probe needle. However, the use of a rigid dilator catheter (as explained above) seems to nullify this advantage. Nevertheless, the guidewire technique is currently the preferred method for central venous and arterial cannulation.

THE CATHETERS

Vascular catheters are composed of plastic polymers impregnated with barium or tungsten salts to enhance radiopacity. Catheters intended for short-term cannulation (days) are usually made of polyurethane; catheters used for long-term venous access (weeks to months) are composed of a more flexible and less thrombogenic derivative of silicone. The silicone catheters (e.g., Hickman and Broviac catheters) are too flexible for routine percutaneous insertion, and are not appropriate for use in the ICU.

HEPARIN BONDING

Some vascular catheters are impregnated or coated with heparin to reduce thrombogenicity. However, this measure has not proven effective in reducing the incidence of catheter-associated thrombosis. Because heparin-coated catheters can be a source of heparin-induced thrombocytopenia, catheters used in the ICU should not be impregnated or coated with heparin.

CATHETER SIZE

The size of vascular catheters is commonly expressed in terms of the outside diameter, and the units of measurement are shown in Table 4.3. The French size is a metric derivative equivalent to the outside diameter in millimeters multiplied by 3; that is, French size = outside diameter (in mm) \times 3. The gauge system was developed for wires and needles, and has been adopted for catheters. There is no simple mathematical relationship between gauge size and other units of

measurement, and a table of reference values such as Table 4.3 is needed to make the appropriate conversions. Gauge sizes usually range from 14 (largest diameter) to 27 (smallest diameter).

The steady or laminar flow through a rigid tube is influenced most by the radius of the tube (see the Hagen-Poiseuille equation in the section on peripheral blood flow in Chapter 1). The influence of tube diameter on flow rate is demonstrated in Table 4.3 for gravity flow of one unit of packed red blood cells diluted with 250 mL normal saline flowing through catheters of equal length. Note that a little more than a doubling of tube diameter (from 0.7 mm to 1.65 mm) is associated with almost a quadrupling of flow rate (from 24.7 to 96.3 mL/minute). Thus, catheter size (diameter) is an important consideration if rapid flow rates are desired.

MULTILUMEN CATHETERS

Multilumen catheters were introduced for clinical use in the early 1980s, and are now used routinely for central venous cannulation. The design of a triple-lumen catheter is shown in Figure 4.3. These catheters have an outside diameter of 2.3 mm (6.9 French) and may have three channels of equal diameter (usually 18 gauge) or may have one larger channel (16 gauge) and two smaller channels of equal diameter (18 gauge). The distal opening of each channel is separated from the other by at least 1 cm to help minimize mixing of infusate solutions.

Multilumen catheters have proven to be valuable aids because they minimize the number of venipunctures needed for monitoring and infusion therapy, yet they do not increase the risk of thrombosis or infection when compared with single-lumen catheters.

INTRODUCER CATHETERS

Another valuable addition to the family of vascular catheters is the introducer catheter, shown in Figure 4.3. These large-bore catheters (8 to 9 French) can be used as conduits for insertion and removal of smaller vascular catheters (including multilumen catheters and pulmonary artery catheters) through a single venipuncture. The side-arm infusion port on the catheter provides an additional infusion line, and allows a continuous flush to prevent thrombus formation around smaller catheters that sit in the lumen of the introducer catheter. This side-arm infusion port also allows the introducer catheter to be used as a stand-alone infusion device (a rubber

membrane on the hub of the catheter provides an effective seal when fluids are infusing through the side-arm port of the catheter). The large diameter of introducer catheters makes them particularly valuable as infusion devices when rapid infusion rates are necessary (e.g., in the resuscitation of massive hemorrhage).

ACCESS ROUTES

The following is a brief description of common vascular access routes in the arm (antecubital veins and radial artery), the thoracic inlet (subclavian and jugular veins), and the groin (femoral artery and vein).

ANTECUBITAL VEINS

The veins in the antecubital fossa provide rapid and safe vascular access for acute resuscitative therapy. Although long catheters can be inserted into the antecubital veins and advanced into the superior vena cava, such peripherally inserted central venous catheters (PICC devices) are more appropriate for home infusion therapy than for treating critically ill patients. Short catheters (5 to 7 cm) are preferred for acute resuscitation via the antecubital veins because they are more easily inserted and allow more rapid infusion rates than the longer PICC catheters.

Anatomy

The surface anatomy of the antecubital veins is shown in Figure 4.4. The basilic vein runs along the medial aspect of the antecubital fossa, and the cephalic vein is situated on the opposite side. The basilic vein is preferred for cannulation because it runs a straighter and less variable course up the arm than the cephalic vein.

Insertion Technique

The patient need not be supine, but the arm should be straight and abducted. The antecubital veins can be distended by tourniquet or by inflating a blood pressure cuff to just above the diastolic pressure (this allows arterial inflow while impeding venous outflow). Once the veins are visible or palpable, a catheter-over-needle device is used to insert a short 16- or 18-gauge catheter into the basilic or cephalic vein.

Blind Insertion

If the antecubital veins are neither visible nor palpable, palpate the brachial artery pulse at a point 1 inch above the antecubital crease. The basilic vein (or brachial vein) should lie just medial to the palpated pulse at this point, and can be entered by inserting the catheter-over-needle device through the skin at a 35° to 45° angle and advancing the needle until blood return is noted. This approach has a reported success rate of 80%. Injury to the median nerve (which is also medial to the artery, but deep to the veins) can occur with excessive movement of the probe needle.

Comment

Cannulation of the antecubital veins is recommended (18,19).

For rapid venous access (e.g., cardiopulmonary resuscitation)

For thrombolytic therapy in acute myocardial infarction

For trauma victims who require thoracotomy

Remember that the shorter the catheter, the more rapid the flow rate through the catheter (see Chapter 1). Thus, insertion of short catheters into the antecubital veins permits more rapid volume resuscitation than insertion of the longer central venous catheters.

RADIAL ARTERY

The radial artery is a favored site for arterial cannulation because the vessel is superficial and accessible and the insertion site is easy to keep clean. The major disadvantage of the radial artery is its small size, which limits the success rate of cannulation and promotes vascular occlusion.

Anatomy

The surface anatomy of the radial and ulnar arteries is shown in Figure 4.4. The radial artery is usually palpable at a point just medial to the styloid process of the radius. The ulnar artery is on the opposite (medial) side of the wrist, just lateral to the pisiform bone. Although the radial artery is preferred, the ulnar artery is the larger of the two arteries and should be easier to cannulate.

The Allen Test

The Allen test evaluates the capacity of the ulnar artery to supply blood to the digits when the radial artery is occluded. The test is performed by first occluding the radial and ulnar arteries with the thumb and index finger. The patient is then instructed to raise the wrist above the head and to make a fist repeatedly until the fingers turn white. The ulnar artery is then released, and the time required for return of the normal color to the fingers is recorded. A normal response time is 7 seconds or less, and a delay of 14 seconds or greater is evidence of insufficient flow in the ulnar artery.

Although a positive Allen test (i.e., 14 seconds or longer for return of color to the digits) is often stated as a contraindication to radial artery cannulation, in numerous instances the Allen test has indicated inadequate flow in the ulnar artery, yet subsequent radial artery cannulation has been uneventful (2,21). Thus, a positive Allen test is not a contraindication to radial artery cannulation. Another limitation is the need for patient cooperation to perform the test. Therefore, this test is not worth the time it takes.

Insertion Technique

The wrist should be hyperextended to bring the artery closer to the surface. A short 20-gauge catheter is appropriate, and can be inserted by a catheter-over-needle device or by the guidewire technique. When using a catheter-over-needle device, the following through-and-through technique is recommended: When the needle tip first punctures the artery (and blood appears in the flashback chamber), the tip of the catheter is just outside the vessel. To position the catheter tip in the lumen of the vessel, the needle is passed completely through the artery and then withdrawn until blood returns again through the needle. At this point, the catheter tip should be in the lumen of the artery, and the catheter can be advanced while the needle is retracted. If two attempts at cannulation are unsuccessful, switch to an alternative site (to

reduce trauma to the vessel).

Comment

Arterial occlusion occurs in as many as 25% of radial artery cannulations, but digital ischemia is rare (2,22). Despite being well tolerated in most patients, cannulation of the radial artery (or any artery) should be reserved for monitoring blood pressure, and is not to be used as a convenience measure for monitoring blood gases or other blood components.

THE SUBCLAVIAN VEIN

More than 3 million central venous cannulations are performed yearly in the United States , and a majority of these procedures are performed via the subclavian vein. The subclavian vein is well suited for cannulation because it is a large vessel (about 20 mm in diameter) and is prevented from collapsing by its surrounding structures. The immediate risks of subclavian vein cannulation include pneumothorax (1% to 2%) and hemothorax (less than 1%). The incidence of bleeding is no different in the presence or absence of a coagulopathy ; that is, the presence of a coagulation disorder is not a contraindication to subclavian vein cannulation.

Anatomy

The subclavian vein is a continuation of the axillary vein as it passes over the first rib, and the apical pleura lies about 5 mm deep to the vein at its point of origin. As shown in Figure 4.5, the subclavian vein runs most of its course along the underside of the clavicle. The vein runs along the outer surface of the anterior scalene muscle, which separates the vein from its companion artery on the underbelly of the muscle. At the thoracic inlet, the subclavian vein meets the internal jugular vein to form the brachiocephalic vein. The convergence of the right and left brachiocephalic veins forms the superior vena cava.

Anatomic Distances

The lengths of the vascular segments involved in subclavian (and internal jugular) vein cannulation are shown in Table 4.4. The average distance from venipuncture site to the right atrium is 14.5 cm and 18.5 cm for right-sided and left-sided cannulations, respectively. These

distances are far shorter than catheter lengths recommended for right-sided (20 cm) and left-sided (30 cm) central venous cannulations, and are more consistent with a recent report showing that the average distance to the right atrium is 16.5 cm in central venous cannulation from either side in adults. Therefore, to avoid placing catheter tips in the right atrium (which can lead to cardiac perforation and fatal cardiac tamponade), all central venous catheters should be no longer than 15 or 16 cm in length.

INSERTION TECHNIQUE

The patient is placed supine, with arms at the sides and head faced away from the insertion site. A towel roll can be placed between the shoulder blades, but this is uncomfortable and unnecessary. Identify the clavicular insertion of the sternocleidomastoid muscle. The subclavian vein lies just underneath the clavicle where the muscle inserts onto the clavicle. The vein can be entered from either side of the clavicle.

Infraclavicular Approach (Insertion Site 1 in Figure 4.5). Identify the lateral margin of the sternocleidomastoid muscle as it inserts on the clavicle. The catheter is inserted in line with this margin, but below the clavicle. Insert the probing needle (18 or 20 gauge) with the bevel pointing upward (toward the ceiling) and advance the needle along the underside of the clavicle and toward the suprasternal notch. The path of the needle should be parallel to the patient's back. When the vein is entered, turn the bevel of the needle to 3 o'clock so the guidewire threads in the direction of the superior vena cava.

Supraclavicular Approach (Insertion Site 2 in Figure 4.5). Identify the angle formed by the lateral margin of the sternocleidomastoid muscle and the clavicle. The probe needle is inserted so that it bisects this angle. Keep the bevel of the needle facing upward and direct the needle under the clavicle in the direction of the opposite nipple. The vein should be entered at a distance of 1 to 2 cm from the skin surface (the subclavian vein is more superficial in the supraclavicular approach). When the vein is entered, turn the bevel of the needle to 9 o'clock so the guidewire threads in the direction of the superior vena cava.

Comment

Patient comfort and ease of insertion are the most compelling reasons to select the subclavian

vein for central venous access. Selection of the infraclavicular versus supraclavicular approach is largely a matter of personal preference. Some recommend avoiding the subclavian vein in ventilator-dependent patients because of the risk of pneumothorax. However, the risk of pneumothorax is too small to justify abandoning the subclavian vein in patients with respiratory failure.

THE INTERNAL JUGULAR VEIN

Cannulation of the internal jugular vein reduces (but does not eliminate) the risk of pneumothorax, but introduces new risks (e.g., carotid artery puncture and thoracic duct injury).

Anatomy

The internal jugular vein is located under the sternocleidomastoid muscle in the neck and, as shown in Figure 4.5, the vein follows an oblique course as it runs down the neck. When the head is turned to the opposite side, the vein forms a straight line from the pinna of the ear to the sternoclavicular joint. Near the base of the neck, the internal jugular vein becomes the most lateral structure in the carotid sheath (which contains the carotid artery sandwiched between the vein laterally and the vagus nerve medially).

Insertion Technique

The right side is preferred because the vessels run a straighter course to the right atrium. The patient is placed in a supine or Trendelenburg position, with the head turned to the opposite side. The internal jugular vein can be entered from an anterior or posterior approach.

The Anterior Approach (Insertion Site 4 in Figure 4.5). The anterior approach is through a triangular region created by two heads of the sternocleidomastoid muscle. The carotid artery is palpated in the triangle and retracted medially. The probe needle is inserted at the apex of the triangle with the bevel facing up, and the needle is advanced toward the ipsilateral nipple, at a 45° angle with the skin surface. If the vein is not encountered by a depth of 5 cm, the needle is withdrawn 4 cm and advanced again in a more lateral direction. When a vessel is entered, look for pulsations. If the blood is red and pulsating, you have entered the carotid artery. In this situation, remove the needle and tamponade the area for 5 to 10 minutes. When the carotid

artery has been punctured, no further attempts should be made on either side because puncture of both arteries can have serious consequences.

The Posterior Approach (Insertion Site 3 in Figure 4.5). The insertion site for this approach is 1 centimeter superior to the point where the external jugular vein crosses over the lateral edge of the sternocleidomastoid muscle. The probe needle is inserted with the bevel positioned at 3 o'clock. The needle is advanced along the underbelly of the muscle in a direction pointing to the suprasternal notch. The internal jugular vein should be encountered 5 to 6 cm from the skin surface with this approach.

Carotid Artery Puncture. If the carotid artery has been punctured with a probing needle, the needle should be removed and pressure should be applied to the site for at least 5 minutes (10 minutes is recommended for patients with a coagulopathy). No further attempts should be made to cannulate the internal jugular vein on either side, to avoid puncture of both carotid arteries. If the carotid artery has been inadvertently cannulated, the catheter should not be removed, as this could provoke serious hemorrhage. In this situation, a vascular surgeon should be consulted immediately.

Comment

As with the subclavian vein, cannulation of the internal jugular vein is safe and effective when performed by skilled operators. However, several disadvantages of internal jugular cannulation deserve mention. (a) Accidental puncture of the carotid artery is reported in 2 to 10% of attempted cannulations. (b) Awake patients often complain of the limited neck mobility when the internal jugular vein is cannulated. (c) In agitated patients, inappropriate neck flexion can result in thrombotic occlusion of the catheter and vein. (d) In patients with tracheostomies, the insertion site can be exposed to infected secretions that drain from the tracheal stoma.

THE EXTERNAL JUGULAR VEIN

Cannulation of the external jugular vein has two advantages: (a) There is no risk of pneumothorax, and (b) hemorrhage is easily controlled. The major drawback is difficulty advancing the catheter.

Anatomy

The external jugular vein runs along a line extending from the angle of the jaw to a point midway along the clavicle. The vein runs obliquely across the surface of the sternocleidomastoid muscle and joins the subclavian vein at an acute angle. This acute angle is the major impediment to advancing catheters that have been inserted into the external jugular vein.

Insertion Technique

The patient is placed in the supine or Trendelenburg position, with the head turned away from the insertion site. If necessary, the vein can be occluded just above the clavicle (with the forefinger of the nondominant hand) to engorge the entry site. As many as 15% of patients so not have an identifiable external jugular vein, even under optimal conditions of vein engorgement.

The external jugular vein has little support from surrounding structures, so the vein should be anchored between the thumb and forefinger when the needle is inserted. The bevel of the needle should be pointing upward when it enters the vein. The recommended insertion point is midway between the angle of the jaw and the clavicle (see Fig. 4.5). Use a 16-gauge single-lumen catheter that is 10 to 15 cm in length. If the catheter does not advance easily, do not force it, as this may result in vascular perforation at the junction between the external jugular and subclavian veins.

Comment

This approach is best reserved for temporary access in patients with a severe coagulopathy, particularly when the operator is inexperienced and does not feel comfortable cannulating the subclavian or internal jugular veins. Contrary to popular belief, cannulation of the external jugular is not always easier to accomplish than central venous cannulation because of the difficulty in advancing catheters past the acute angle at the junction of the subclavian vein.

THE FEMORAL VEIN

The femoral vein is the easiest of the large veins to cannulate and also does not carry a risk of [pneumothorax](#). The disadvantages associated with this route are venous thrombosis (10%), femoral artery puncture (5%), and limited ability to flex the hip (which can be bothersome for awake patients). Contrary to popular belief, the infection rate with femoral vein catheters is no different from that of subclavian or internal jugular vein catheters.

Anatomy

The anatomy of the femoral sheath is shown in Figure 4.6. The femoral vein is the most medial structure in the femoral sheath and is situated just medial to the femoral artery. At the inguinal ligament, the femoral vessels are just a few centimeters below the skin surface.

Insertion Technique

Palpate the femoral artery just below the inguinal crease and insert the needle (bevel up) 1 to 2 cm medial to the palpated pulse. Advance the needle at a 45° angle to the skin surface, entering the vein at a depth of 2 to 4 cm. Once in the vessel, if the catheter or guidewire will not pass beyond the tip of the needle, tilt the needle so that it is more parallel to the skin surface (this may move the needle tip away from the far side of the vessel wall and into more direct contact with the lumen of the vessel). Femoral vein catheters should be at least 15 cm long.

Blind Insertion

If the femoral artery pulse is not palpable, draw an imaginary line from the anterior superior iliac crest to the pubic tubercle, and divide the line into three equal segments. The femoral artery lies at the junction between the middle and most medial segment, and the femoral vein is 1 to 2 cm medial to this point. This method of locating the femoral vein has a reported success rate of over 90%.

Comment

Femoral vein cannulation is usually reserved for patients who are paralyzed or comatose and immobile. This approach is not recommended for cardiopulmonary resuscitation (because of the delayed transit times for bolus drug injections) or in patients with bleeding disorders.

THE FEMORAL ARTERY

Cannulation of the femoral artery is usually reserved for situations where radial artery cannulation is unsuccessful or contraindicated. Despite its reserve status, the femoral artery is larger than the radial artery, and is easier to cannulate. The complications of femoral artery cannulation are the same as for radial artery cannulation (thrombosis, bleeding, and infection). The incidence of infection is the same with radial and femoral artery catheters, and the incidence of thrombosis is lower with femoral artery cannulation. Thrombosis of the femoral artery, like that in the radial artery, only rarely results in troublesome ischemia in the distal extremity.

Localization and cannulation of the femoral artery proceeds as described in the section on femoral vein cannulation. The Seldinger technique is preferred for catheter insertion, and catheters should be 18 gauge in diameter and 15 to 20 cm long.

Comment

Femoral artery cannulation is a viable alternative and may be preferable to radial artery cannulation in patients who are paralyzed or otherwise immobile, unless they have a significant coagulopathy (in which case the radial artery is preferred). The incidence of thrombotic complications is lower in femoral artery cannulations, and the pressure in the femoral artery more closely approximates the pressure in the aorta than does the pressure in the radial artery (see Chapter 8).

IMMEDIATE CONCERNS

VENOUS AIR EMBOLISM

Inadvertent air entry is one of the most feared complications of central venous cannulation. The importance of maintaining a closed system during insertion is highlighted by the following statement:

A pressure gradient of 4 mm Hg along a 14-gauge catheter can entrain air at a rate of 90

mL/second and can produce a fatal air embolus in 1 second.

Preventive Measures

Prevention is the hallmark of reducing the morbidity and mortality of venous air embolism. The most effective method of preventing air entry is to keep the venous pressure more positive than atmospheric pressure. This is facilitated by placing the patient in the Trendelenburg position with the head 15° below the horizontal plane. Remember that the Trendelenburg position does not prevent venous air entry because patients still generate negative intrathoracic pressures while in the Trendelenburg position. When changing connections in a central venous line, a temporary positive pressure can be created by having the patient hum audibly. This not only produces a positive intrathoracic pressure, but allows clinicians to hear when the intrathoracic pressure is positive. In ventilator-dependent patients, the nurse or respiratory therapist should initiate a mechanical lung inflation when changing connections.

Clinical Presentation

The usual presentation is acute onset of dyspnea that occurs during the procedure. Hypotension and cardiac arrest can develop rapidly. Air can pass across a patent foramen ovale and obstruct the cerebral circulation, producing an acute ischemic stroke. A characteristic "mill wheel" murmur can be heard over the right heart, but this murmur may be fleeting.

Therapeutic Maneuvers

If a venous air embolism is suspected, immediately place the patient with the left side down, and attempt to aspirate air directly from the venous line. In dire circumstances, a needle should be inserted through the chest wall and into the right ventricle to aspirate the air. Unfortunately, the mortality in severe cases of venous air embolism remains high despite these maneuvers.

PNEUMOTHORAX

Pneumothorax is a concern primarily with subclavian vein cannulation but can also complicate jugular vein cannulation (2,30). This is one reason that postinsertion chest films are recommended after all central venous cannulations (or attempts). If possible, postinsertion

films should be obtained in the upright position and during expiration. Expiratory films facilitate the detection of small pneumothoraxes because expiration decreases the volume of air in the lungs, but not the volume of air in the pleural space. Thus, during expiration, the volume of air in [the pleural space](#) is a larger fraction of the total volume of the hemithorax, thereby magnifying the radiographic appearance of the pneumothorax.

Upright films are not always possible in ICU patients. When supine films are necessary, remember that pleural air does not often collect at the apex of the lung when the patient is in the supine position (32,33). In this situation, pleural air tends to collect in the subpulmonic recess and along the anteromedial border of the mediastinum (see Chapter 28).

Delayed Pneumothorax

Pneumothoraxes may not be radiographically evident until 24 to 48 hours after central venous cannulation (31,33). Therefore, the absence of a pneumothorax on an immediate postinsertion chest film does not absolutely exclude the possibility of a catheter-induced pneumothorax. This is an important consideration in patients who develop dyspnea or other signs of pneumothorax in the first few days after central venous cannulation. In the absence of signs and symptoms, there is little justification for serial chest films following central venous catheter placement.

CATHETER TIP POSITION

The properly placed central venous catheter should run parallel to the superior vena cava, and the tip of the catheter should be positioned above the junction of the superior vena cava and right atrium. The following conditions warrant corrective measures.

Tip Against the Wall of the Vena Cava

Catheters inserted from the left side must make an acute turn downward when they reach the superior vena cava. If they fail to make this turn, the catheters can end up in a position like the one shown in Figure 4.7. The tip of the catheter is up against the lateral wall of the vena cava, and in this position, the catheter tip can stab the vessel wall and perforate the vena cava. Therefore, catheters that abut the wall of the vena cava should be repositioned as soon as

possible. (The problem of vascular perforation is discussed in more detail in Chapter 5.)

Tip in the Right Atrium

The Food and Drug Administration has issued a strong warning about the risk of cardiac perforation from catheter tips that are advanced into the heart. However, cardiac perforation is a rare complication of central venous cannulation, even though over half of central venous catheters may be misplaced in the right atrium. Nevertheless, tamponade is often fatal, so cardiac placement of catheters should be avoided. A few measures help to minimize the risk of cardiac perforation. The most effective measure is to use shorter catheters, as recommended earlier. The tip of indwelling catheters should be above the third right costal cartilage (this is the level where the vena cava meets the right atrium). If the anterior portion of the third rib cannot be visualized, keep the catheter tip at or above the tracheal carina.

Cardiopulmonary resuscitation

Cardiopulmonary resuscitation (CPR) is an emergency first aid procedure for a victim of cardiac arrest. It is part of the chain of survival, which includes early access (to emergency medical services), early CPR, early defibrillation, and early advanced care. It is also performed as part of the choking protocol if all else has failed. It can be performed by trained laypersons or by health care or emergency response professionals. It is normally begun on an unbreathing unconscious person and continued until the underlying cause can be identified and a pulse is restored. CPR consists of chest compressions and rescue breaths (i.e. artificial blood circulation and lung ventilation) and is intended to maintain a flow of oxygenated blood to the brain and the heart, thereby extending the brief window of opportunity for a successful resuscitation without permanent brain damage.

Many countries have official guidelines on how CPR should be provided, and these naturally override the general description of CPR in this article.

In 2005, new CPR guidelines were published with input from International Resuscitation Councils, and was agreed at the 2005 International Consensus Conference on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science. The primary goal was to simplify CPR for lay rescuers and healthcare providers alike to maximise the potential

for early resuscitation. The important changes for 2005 are as follow.

A universal compression-ventilation ratio (30:2) is recommended for all single rescuers of infant (less than one year old), child (1 year old to puberty), and adult (puberty and above) victims (excluding newborns). The only difference between the age groups is that with adults the rescuer uses two hands for the chest compressions, while with children it is only one, and with infants only two fingers (pointer and middle fingers). It is worth noting that paediatric guidelines for healthcare professionals differ from the 30:2 compression-ventilation ratio stated here.

Lay rescuers do not need to assess for pulse or signs of circulation for an unresponsive adult victim.

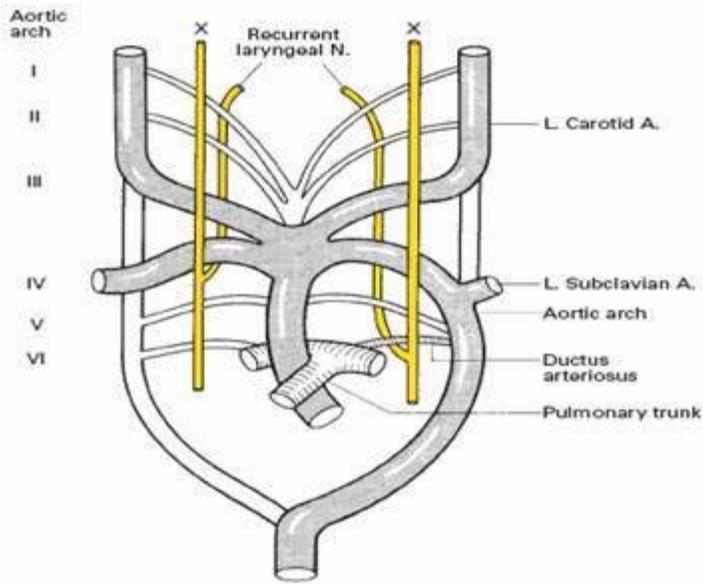

Lay rescuers do not need to provide rescue breathing without chest compressions for an adult victim.

As research has shown that lay personnel cannot accurately detect a pulse in about 40% of cases and cannot accurately discern the absence of pulse in about 10%, the pulse check step has been removed from the CPR procedure completely for lay persons and de-emphasized for healthcare professionals.

Cardiac arrest and the place of CPR

The medical term for the condition in which a person's heart has stopped is cardiac arrest (also referred to as cardiorespiratory arrest). CPR appropriate for cardiac arrest. If the patient still has a pulse, but is not breathing, this is called respiratory arrest and rescue breathing is more appropriate.

The Heart

However, since people often can't tell the difference (can't accurately feel a pulse to determine whether the heart is still beating), CPR is often recommended for both.

The most common cause of cardiac arrest outside of a hospital is ventricular fibrillation (VF), a potentially fatal arrhythmia that is usually (but not always) caused by a heart attack. Other causes of cardiac arrest include drowning, drug overdose, poisoning, electrocution.

Sudden cardiac arrest is a leading cause of death, approximately 250,000 per annum outside a hospital setting in the USA. CPR can double or triple the victim's chances of survival when commenced immediately. According to American Heart Association, only two thirds of victims of a witnessed cardiac arrest are administered CPR. Rapid access to defibrillation is also vital.

Blood circulation and lung ventilation are absolute requirements in transporting oxygen to the tissues. The brain may sustain damage after four minutes and irreversible damage after about seven minutes. The heart also rapidly loses the ability to maintain a normal rhythm. Low body temperatures as seen in drownings prolong the time the brain survives. Following cardiac arrest, effective CPR enables enough oxygen to reach the brain to delay brain death, and allows the heart to remain responsive to defibrillation attempts.

CPR is taught to the general public because they are the only ones present in the crucial few

minutes before emergency personnel are available. Simple training is the goal of the 2005 guidelines to maximise the prospect that CPR will be performed successfully.

Effectiveness

CPR is almost never effective if started more than 15 minutes after collapse because permanent brain damage has probably already occurred, especially if the person has stopped breathing, since the brain can only survive for 4-6 minutes without oxygen.[citation needed] A notable exception is cardiac arrest occurring in conjunction with exposure to very cold temperatures. Hypothermia seems to protect the victim by slowing down metabolic and physiologic processes, greatly decreasing the tissues' need for oxygen.[citation needed] There are cases where CPR, defibrillation, and advanced warming techniques have revived victims after substantial periods of hypothermia.

Used alone, few patients will make a complete recovery, and those that do survive often develop serious complications. Estimates vary, but many organizations[citation needed] stress that CPR does not "bring anyone back," it simply preserves the body for defibrillation and advanced life support. However, in the case of "non-shockable" rhythms such as Pulseless Electrical Activity (PEA), defibrillation is not indicated, and the importance of CPR rises. On average, only 5%-10% of people who receive CPR survive. The purpose of CPR is not to "start" the heart, but rather to circulate oxygenated blood, and keep the brain alive until advanced care (especially defibrillation) can be initiated. As many of these patients may have a pulse that is unpalpable by the layperson rescuer, the current consensus is to perform CPR on a patient that is not breathing. A pulse check is not required in basic CPR since it is so often missed when present, or even felt when absent, even by health care professionals

Studies have shown the importance of immediate CPR followed by defibrillation within 3–5 minutes of sudden VF cardiac arrest improve survival. In cities such as Seattle where CPR training is widespread and defibrillation by EMS personnel follows quickly, the survival rate is about 30 percent. In cities such as New York City, without those advantages, the survival rate is only 1-2 percent.

CPR is often severely misportrayed in movies and television as being highly effective in resuscitating a person who is not breathing and has no circulation. A 1996 study published in the New England Journal of Medicine showed that CPR success rates in television shows was

75%.

It is considered by a number of international bodies that in order for CPR to be effective, the guidelines must be simple and easy to remember.[citation needed]

CPR training

CPR is a practical skill and needs professional instruction followed up by regular practice on a resuscitation mannequin to gain and maintain full competency. Training is available through many commercial, volunteer and government organizations worldwide.

CPR training is not confined to the medical professionals. To be effective, CPR must be applied almost immediately after a patient's heart has stopped. Early CPR on the scene of an incident is essential to the prevention of brain damage during a cardiac arrest. Blood flow and air supply to the brain and other major organs is maintained until a defibrillator and professional medical help arrives. Almost anyone is able to perform CPR with training, and health organizations advocate the development of CPR skills throughout the general public.

It is best to obtain training in CPR before a medical emergency occurs. One needs hands-on training by experts to perform CPR safely, and guidelines change, so that training should be repeated every one or two years. Training in first aid is often available through community organizations such as the Red Cross and St. John Ambulance. In many countries in the Commonwealth of Nations, St. John Ambulance and the Medic First Aid Organization provide CPR training. In Scotland, St. Andrew's Ambulance Association provides first aid training. In the United States, the American Red Cross, American Heart Association and American CPR Training also offer CPR training. In addition, many employees at public areas or community centres are trained in CPR. Lifeguards are also trained in CPR and other first aid protocols.

In most CPR Classes a simple shortform is used for people to remember everything they need to do. The most common one used worldwide is DRABCD which stands for Danger, Response, Airway, Breathing, Compressions and Defibrillation.

History

CPR has been known in theory, if not practice, for many hundreds or even thousands of years; some claim it is described in the Bible, discerning a superficial similarity to CPR in a passage from the Books of Kings (II 4:34), wherein the Hebrew prophet Elisha warms a dead boy's body and "places his mouth over his". In the 19th century, doctor H. R. Silvester described a method (The Silvester Method) of artificial respiration in which the patient is laid on their back, and their arms are raised above their head to aid inhalation and then pressed against their chest to aid exhalation. The procedure is repeated sixteen times per minute. This type of artificial respiration is occasionally seen in movies made in the early part of the 20th century.

A second technique, described in the first edition of the Boy Scout Handbook in the United States in 1911, described a form of artificial respiration where the person was laid on their front, with their head to the side, and a process of lifting their arms and pressing on their back was utilized, essentially the Silvester Method with the patient flipped over. This form is seen well into the 1950s (it is used in an episode of Lassie during the Jeff Miller era), and was often used, sometimes for comedic effect, in theatrical cartoons of the time. This method would continue to be shown, for historical purposes, side-by-side with modern CPR in the Boy Scout Handbook until its ninth edition in 1979.

However it wasn't until the middle of the 20th century that the wider medical community started to recognise and promote it as a key part of resuscitation following cardiac arrest. Peter Safar wrote the book ABC of resuscitation in 1957. In the U.S., it was first promoted as a technique for the public to learn in the 1970s. Early marketing efforts oversold the effectiveness of CPR in rescuing heart attack and other victims, and this misperception continues even today, as the success rate for CPR is only 1/20.

Self-CPR

A form of "self-CPR" termed "Cough CPR" may help a person maintain blood flow to the brain during a heart attack while waiting for medical help to arrive and has been used in a hospital emergency room in cases where "standard CPR" was contraindicated. While this technique is not in widespread use, one researcher has recommended that it be taught broadly to the public. However, the American Heart Association (AHA), does not endorse "Cough CPR", which it terms a misnomer as it is not a recognized form of resuscitation. The AHA does recognize a limited legitimate use of the coughing technique:

This coughing technique to maintain blood flow during brief arrhythmias has been useful in the hospital, particularly during cardiac catheterization. In such cases the patient's ECG is monitored continuously, and a physician is present.

"Cough CPR" was the subject of a hoax chain e-mail entitled "How to Survive a Heart Attack When Alone" which wrongly cited "ViaHealth Rochester General Hospital" as the source of the technique. Rochester General Hospital has denied any connection with the technique.

The ABC Of Resuscitation

1. To check an unconscious victim, place two fingers under his chin and a hand on his forehead. Tilt his head back to open his airway. Remove any obstructions from his mouth.
2. Listen and feel for victim's breathing. If he is breathing, place him in the recovery position. If he is not breathing, begin rescue breathing.
3. Check the victim's circulation by feeling for a pulse at the side of his windpipe (carotid artery). If there is no pulse, begin CPR immediately.

Fig. Steps of resuscitation

The Recovery Position

1. If a victim is unconscious but breathing, bend his near arm up at a right angle to his body. Hold the back of his far hand to his near cheek. With the near leg straight, pull the far knee toward you.
2. With the victim on his side, place his uppermost leg at a right angles to his body. His head will be supported by the hand of the uppermost arm. Tilt his head back so that he will not choke if he vomits.

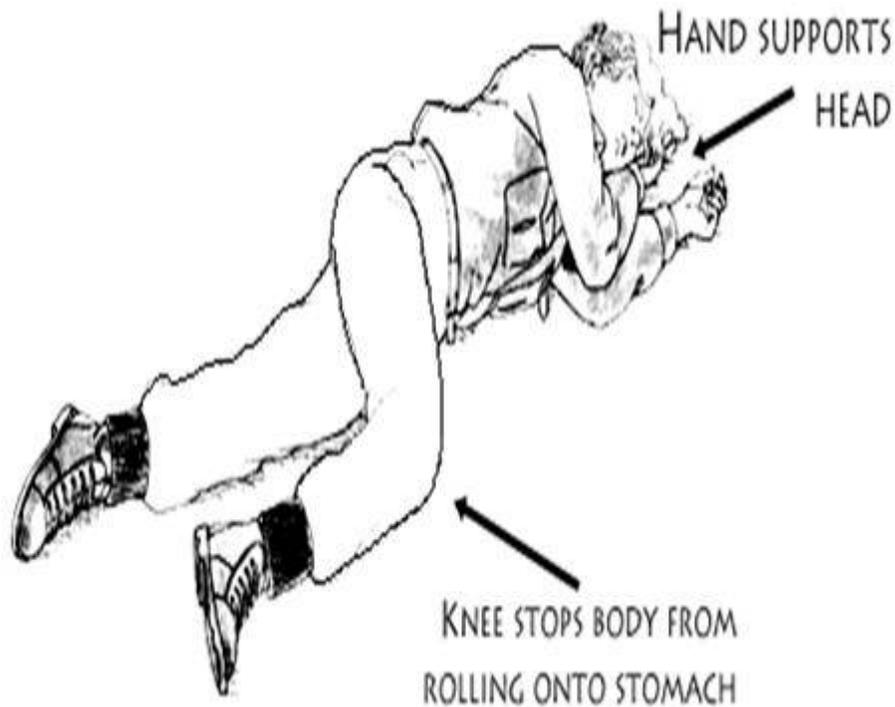

Fig. Position of patient during resuscitation

Rescue Breathing

1. To ensure an open airway, first clear the victim's mouth of obstructions, then place one hand under his chin and one on his forehead, and tilt his head back.
2. Pinching the victim's nose shut, clamp your mouth over his mouth, and blow steadily for about two seconds until his chest rises. Remove your mouth and let his chest fall, then repeat.
3. Listen for the victim's breathing and check his pulse. If he still has a pulse, give 10 breaths per minute until help arrives or the victim is breathing by himself. If the pulse has stopped, combine rescue breathing with chest compressions.

Fig. First step of resuscitation

Cardiopulmonary Resuscitation (CPR)

If a person's heart has stopped, give cardiopulmonary resuscitation (CPR). This consists of chest compressions to maintain the blood flow to the brain, combined with rescue breathing to oxygenate the blood. Give chest compressions at a rate of 80 per minute, counting "one-and-two-and..."

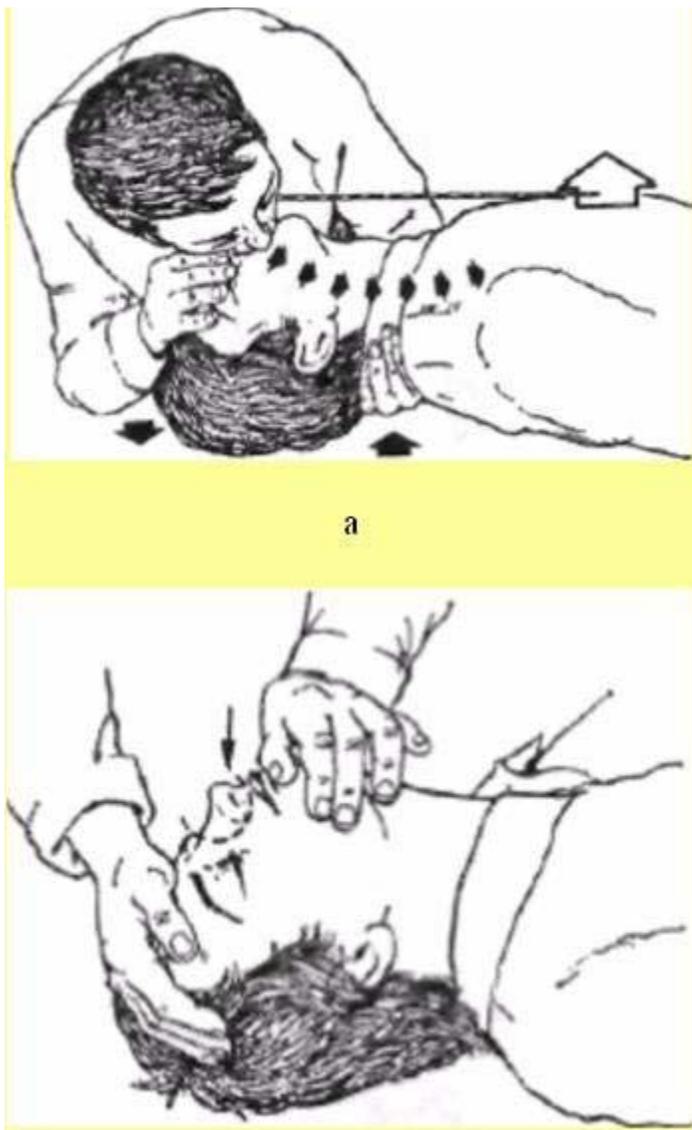

Fig. Artificial lung ventilation

1. Place the heel of your hand two finger-widths up from the end of the sternum and your other hand on top of the first. Press down firmly, then release.
2. Check for a pulse. After 15 chest compressions, give the victim two breaths of rescue breathing. Repeat until the pulse restarts, professional help arrives, or you are too exhausted to continue.

Control of the airway is the single most important task for emergency resuscitation. If the patient has inadequate oxygenation or ventilation, inability to protect the airway due to altered sensorium from illness or drugs, or external forces compromising the airway (i.e., trauma), he or she may need advanced airway techniques as described in this chapter.

CPR is now a days is called as CPCPR.

Cardiac arrest is defined as 'inability of heart to sustain effective cardiac output, impairing tissue perfusion.

Cardiac arrest may be witnessed (monitored) or unwitnessed (unmonitored). It may be inside hospital or outside hospital.

Cardiac arrest may be of cardiac origin or non cardiac.

Cardiac arrest in adults is usually of cardiac origin and in children it is usually of respiratory origin and most common cause of arrest in adults is ventricular fibrillation.

Therefore unwitnessed cardiac arrest in adults should be considered due to ventricular fibrillation until proved otherwise and in children should be considered due to asystole until proved otherwise.

Rhythms in Cardiac Arrest

1. Ventricular fibrillation (or pulseless ventricular tachycardia) - most common rhythm.
2. Asystole - most common in children.
3. Electromechanical dissociation (pulse less electrical activity).

Management guidelines are based on the recent recommendation (2005) by American Heart Association (AHA) and Emergency Cardio Vascular care (ECC) with International Lesion Committee on Resuscitation (ICCOR).

The management of CPR should be done in sequence A (Airway)—Breathing (B)—Circulation (C) and must be followed in these sequence.

Management of CPR is done under three heads:

1. Basic life support.
2. Advance life support.
3. Post resuscitation life support.

AHA and ECC have given 4 link chain of survival: 1. Early recognition and activation of emergency medical services.

2. Immediate CPR (every minute delay decreases prognosis by 7-10%).
3. Early shock (CPR + shock within 5 minutes has survival rate of 49-75%).
4. Early advance life support.

BASIC LIFE SUPPORT (BLS) (Primary A, B, C, D)

Basic life support includes:

1. Airway management (manual).
2. Breathing by mouth to mouth, mouth to nose or bag and mask ventilation.

3. Circulation by cardiac massage.

4. Defibrillation by automatic external defibrillator (AED): AED are the devices which automatically detects rhythm and give shock if rhythm is shockable. Since they detect rhythm automatically and gives shock automatically they can be used even by lay rescuer. (In manual defibrillators rescuer has to detect rhythm, therefore not included as basic life support as they can be used only by health personnel).

ADVANCE LIFE SUPPORT (ALS)

Advance life support includes:

1. Airway management by equipments like Guedel 's airway, laryngeal mask airway or endotracheal tube.
2. Breathing by advanced airways e. endotracheal tube, laryngeal mask, combitube or tracheostomy.
3. Circulation by cardiac massage.
4. Defibrillation by manual defibrillators.
5. Drugs.

AIRWAY MANAGEMENT

The most common cause of airway obstruction in unconscious patient is tongue fall (e. tongue falling

Parameter	Basic life support (Primary A,B,C,D)	Advance life support (Secondary A,B,C,D)
Airway management	Manual	With equipments like Guedel's airway, endotracheal tube laryngeal mask airway (LMA) or tracheostomy tube.
Breathing	Mouth to mouth, mouth to LMA, nose or bag & mask	Advanced methods like endotracheal tube, combitube or tracheostomy tube.
Circulation	Cardiac massage.	Cardiac massage
Defibrillation	Automatic external defibrillator	Manual defibrillator
Drugs	- back on posterior pharyngeal wall and obstructing the airway).	

This tongue fall can be managed by:

A. Manually which includes:

Open mouth and clear airways (if something is clearly visible in oral cavity).

i Tilt head backwards (e. neck extension) and chin lift. Jaw thrust e. mandible is pulled forward. In patients with cervical spine fracture head tilt and chin lift is C/I and airway should be managed only by jaw thrust

Airway insertion: Most commonly used in Guedel's, other are Safar, nasopharyngeal, laryn-

geal mask airway (LMA),

C. Endotracheal tube: It is the most definitive method to maintain airway.

Management of Airway Obstruction Due to Foreign Body

1. Infant chest thrust: 4 blows given with thrust by heel of hand between the shoulders.
2. Back blows: 4 blows on the middle of back. Again performed for infants.
3. Heimlich manoeuvre: Manual thrust with the patient standing, rescuer behind the patient and compressing the abdomen 6 to 10 times. This method is for adults and older children.
4. Chest thrust (manual compression over lower sternum): Employed in very obese or pregnant patient where abdominal compression is not possible.
5. Finger sweep method: Possible in unconscious patients only.
6. Cricothyroidotomy: As a life saving procedure to secure airway.

Airway obstruction due to other causes like laryngeal edema, acute epiglottitis and laryngotracheobronchitis may require tracheostomy.

BREATHING (Ventilation)

Breathing can be accomplished by:

1. Mouth to mouth:

Method: Open airway — pinch victim's nose — create airtight seal — give breath over 1 sec with sufficient force to move chest (not excessive force) — provide 2nd breath in the same way if rescuer is hesitant in giving direct mouth to mouth he/she can use face shields/plastic or silicone sheets or even a handkerchief, if nothing is available.

2. Mouth to airway: By Safar or Brook airway.
3. Bag and mask. Disadvantage of bag and mask

ventilation are:

Difficult and exhausting.

Increased dead space.

Increased chances of aspiration.

4. Ventilation by advanced methods:

Endotracheal tube: Intubation is most definitive and best method for ventilation. Laryngeal mask airway, Combitube. Tracheostomy tube.

5. Ventilation by automatic ventilators.

CIRCULATION

This is accomplished by cardiac massage.

Method

It is done in supine position. But in very rare cases, where supine position is not possible it can be done in prone position also.

The rescuer stand (or bend on knee if the victim is on floor) on side (usually right side), lock one hand over other and provide compression over the lower third of sternum (2 fingers above xiphoid process).

The force generated during massage should be able to depress sternum by 1.5-2 inches (approx 73 of chest wall diameter). During massage compression relaxation (chest to recoil) should be equal.

Patient should lie flat on hard surface.

Physiological Considerations of Cardiac Massage

Heart compressed between sternum and spine results in ejection of blood from heart (cardiac pump theory) but another convincing theory is thoracic pump theory which states that cardiac compression raises intrathoracic pressure forcing blood out of chest and dynamic venous compression preventing backward flow, heart acting only as a passive conduit.

Chest compression can generate a systolic BP of 80-100 mmHg but diastolic only 10-40 mmHg (which may compromise coronary flow). Effective cardiac output generated by successful massage is only 30% of normal. So all efforts to restore spontaneous cardiac activity should be started immediately.

Monitoring of CPR

1. Capnography: It is considered as most reliable and best Indicator to see the effectiveness of CPR. Successful cardiac massage should be able to produce ETCO₂ of at least 20 mmHg and ETCO₂ becoming normal (40 mmHg), is the earliest indicator of return of normal circulation.
2. Palpation of pulses (carotid): It is the most effective clinical monitor to see the effectiveness of cardiac massage. A successful cardiac massage should be able to generate a major peripheral pulse especially carotid.
3. Coronary perfusion pressure: Good guide but very difficult to measure.

COMPRESSION (C) TO VENTILATION (V) RATIO

Before advanced airway (e. by mouth to mouth, bag and mask ventilation), the ratio should be 30:2 (30 compressions followed by 2 breaths) irrespective of duration of resuscitation (previously this ratio was 15:2). The reason for change in ratio is to minimize interruption in chest compression (this is the most important goal of latest recommendations).

After advanced airway (e. endotracheal tube, LMA or combitube): Compression will be

continued at a rate of 100 compressions/minute and breathing at a rate of 8-10 breaths/min. with no synchronization e. no pause for ventilation. The aim is again same e. uninterrupted compressions. Previous ratio of 5:1 now is obsolete, rather ventilation rate should not exceed more than 12 breaths/min. as high rate (more ventilation will increase intrathoracic pressure which decreases venous return thereby decreasing cardiac output and hence coronary and cerebral perfusion). Therefore low tidal volume (6-7 ml/kg) is preferred over large tidal volume (10-12 ml/kg) and one breath should not exceed more than 1 second.

If there are 2 rescuers they should rotate after 2 minutes (or 5 cycles of 30:2) to avoid fatigue of one person providing compression (because studies have shown that after 2 minutes the performance of compression start decreasing because of fatigue), but this change over should not take more than 5 seconds.

Therefore it can concluded that key guidelines for present day CPR are (i) push hard () push fast (Hi) allow full chest recoil and (iv) minimize interruption in chest compressions.

ADVANCED LIFE SUPPORT (Secondary ABCD)

As described earlier in advanced life support airway and ventilation are maintained by advance airway method and circulation by continuing cardiac massage, recognising arrhythmias and managing them by defibrillators and drugs or any other intervention done beyond basic life support is included in advance life support. Therefore advanced life support is employed in hospital arrest.

Airway management and ventilation employed in advance life support has been described in detail in chapter on instrument (chapter no. 6).

Defibrillation: Done for ventricular fibrillation, pulseless ventricular tachycardia and polymorphic ventricular tachycardia.

Defibrillators have been classified as: Monophasic (delivers current of one polarity only) and biphasic (delivers current of two polarities), Manual or automatic (AED).

Biphasic are considered superior to monophasic and that is why most of the defibrillators which are manufactured today are biphasic.

POSITION OF DEFIBRILLATION PADDLES

The ideal position would be like that the heart is sandwiched between paddles e., one is placed anteriorly at the precordial region and second one posteriorly but this is not possible because patient lies supine so usually 1 st paddle is put on right side of chest just below the clavicle and 2nd at precordial region. Paddle should be applied with pressure equivalent to 10 kg.

Paddle size

- For adults: 13 cm.
- For children: 8 cm.
- For infants :4.5cm.

Latest Recommendations for Energy selection and shock protocol.

1. Contrary to previous recommendation of 3 successive shocks (200,300 & 360 J) now a days Only Single Shock of 360J by monophasic defibrillators, and 150-200J withbiphasic [biphasic 150-200J is equivalent to 360 J of monophasic) is given.

2. Immediately after giving shock, give 5 cycles of 30:2 (without advance airway) or 2 minutes of CPR (with advance airway) before checking rhythm [Earlier rhythm was checked just after giving shock]. The rationale for this recommendation is that it actually takes around 2 minutes for heart to recover completely after ventricular fibrillation so CPR during this 2 minutes is required to maintain coronary and cerebral perfusion.

So the protocol for advance life support maybe in continuation of basic life support (where BLS is provided by lay rescuers/paramedicals) or fresh management in hospital arrest.

Consider termination of efforts if there is no response after 20 minutes.

MANAGEMENT OF PULSELESS ELECTRICAL ACTIVITY AND ASYSTOLE

PULSELESS ELECTRICAL ACTIVITY (PEA)

Also called as electromechanical dissociation (EMD). It is the condition in which peripheral pulses are not palpable but heart shows some electrical activity on ECG other than ventricular tachycardia and ventricular fibrillation.

Causes are

1. Hypovolemia (most common cause).
2. Cardiac tamponade.
3. Tension pneumothorax.
4. Pulmonary embolism.
5. Hypoxia.
6. Hyperkalemia.
7. Hypothermia.
8. Acidosis.
9. Overdosage of digitalis, (5 blockers, calcium channel blockers.

(Conditions 6 to 9 show idioventricular rhythm).

Treatment

Treatment of PEA lies in treating the cause, adrenaline

PROTOCOL FOR ADVANCED LIFE SUPPORT

Assess responsiveness

Call for help (Activate EMS)

Manage airway and breathing⁸

Asses circulation -> if present give breaths at a rate of 10-12/min

Absent

Start

CPR with compression rate of 100/min and ventilation with 8-10 breath/min

with advance airway and 30:2 without advance airway

a. whenever possible defibrillation should precede intubation and IV access (should not delay defibrillation if ventilation is achieved without intubation, like bag & mask)

Assess Rhythm

Shockable (VF, pulseless V tachy)

1. Give one shock (360 J with monophasic & 200 J with biphasic)

Continue CPR for 2 min (or 5 cycles of 30:2 if airway is still not maintained by advance methods)

Check Rythm

Still shockable rhythm

(Asystole)

Non shockable (Asystole, PEA)

Continue CPR

Adrenaline 1 mg IV and repeat every 3-5 minutes (if IV access not possible than use intraoss-eous or endotracheal route) Consider vasopressin 40U after 1st or 2nd dose of adrenaline Atropine 1 mg, repeat every 3-5 minutes (to a max. of 3 doses) Keep on checking rhythm every 2 min, if non shockable, continue same treatment and if becomes shockable treat like shockable.

2. • Continue CPR ~* • Give adrenaline (1:10,000) 1 mg IV, endotracheal or Intraosseous

Give shock (again 360 J with monophasic & 200 J with biphasic)

Continue CPR for 2 min.

Check rhythm

Still shockable

Recovered

Non shockable

3.
 - Continue CPR
 - Repeat adrenaline 1 mg or vasopressin 40 U (as an alternative to adrenaline)

1 Shock (360 J - Monophasic, 200 J - Biphasic)

Continue CPR for 2 minutes

- Continue CPR
- Give amiodarone / lignocaine / magnesium sulphate

Shock (with 360 J - monophasic with 200 J biphasic)

- Proceed like non shockable

Recovered Shockable

Go back to stage 2 and continue same protocol

Non shockable

Treat like non shockable and pacing as immediate measures to tide over the crisis.

MANAGEMENT OF ASYSTOLE

Asystole is the terminal event of all arrhythmias.

Management

Intubate immediately and start pulmonary ventilation and cardiac massage

Consider possible causes like hyperkalemia, hypokalemia, hypothermia, hypoxia, acidosis,

I Adrenaline 1 mg IV and repeat every 3 minutes Vasopressin 40 Units after 1s' or 2nd dose of adrenaline Atropine 1 mg IV and repeat every 3 minutes to a total of 0.04 mg/kg

Transcutaneous pacing

No response Consider termination of efforts

PAEDIATRIC CPR (excluding NEWBORN)

Age classification: From CPR point of view.

- Neonate: First 4 weeks after birth.
- Infants: 4 weeks to 1 year.
- Child: 1-14 years (previously children were considered 1 -8 years) for medical staff but for lay rescuers children still mean 1-8 years.
- Adults: > 14 years for medical staff. > 8 years for lay rescuers.

Differences from Adults

- Ratio of compression to breathing without advance airway: 30:2 for one rescuer and 15:2 for 2 rescuers. (While for adults it is 30:2 irrespective of rescuers).
- With Advance airway: 100 compressions per minute (even for infants which was earlier 120/min) with 8-10 breaths/min. and unsynchronized e. no pause for ventilation (similar to adults) [contrary to previous 5:1 ratio and synchronized].
- If pulses are palpable then give breath at a rate of 12-20/min (Adults 10-12/min).
- Pulse check:
 - Infants: Brachial/Femoral.
 - Children: Carotid.
 - Adult: Carotid/Femoral.
- In emergency cuffed tubes can be used in paediatric age group if inflation pressure is less than 20 cmH₂O.
- If heart rate is <60/min with signs of poor perfusion (pallor/cyanosis) start compressions.
- Cardiac arrest in children is not usually because of ventricular fibrillation and cause is usually asphyxial (respiratory) so the difference from adults in protocol of basic life support is that after assessing responsiveness immediately start CPR and give five cycle of 30:2 and then call for Emergency medical system (EMS) while in adults (see algorithm for BLS) first step after assessing responsiveness is activation of EMS and then start CPR, further protocol for BLS remains same.
- Advance life support protocol for paediatric patient remains same with some differences like:
 1. Energy selection for shock (manual) is 2 J/kg for first shock and 4 J/kg subsequently. If AED is used it automatically select energy and do attenuation accordingly. Paediatric AED are only recommended for children < 8yrs (or <25 kg). Children > 8 years (> 25 kg) should be defibrillated with adult defibrillators.
 2. Another important difference from adults in management of asystole is that atropine and vasopressin are not recommended for paediatric age group.
 3. Endotracheal concentration of adrenaline for adults is 1:10,000 but for paediatric 1 : 1000.

NEWBORN CPR

The detailed discussion of newborn CPR is beyond the scope of this book but some of the notable differences are:

1. Rate of ventilation (breathing) is 40-60 breaths/ min (if only ventilation is given).
2. The primary measure for successful ventilation is increase in heart rate.
3. Indication of chest compression is HR (Heart rate) < 60 /min. inspite of adequate ventilation with 100% oxygen for 30 seconds.
4. 2 thumbs with encircled chest is preferred method for compression over only 2 thumb technique.
5. Compression ventilation ratio is 3:1 (90 compression with 30 breaths) and synchronized.
6. Reassessment to be made every 30 sec. and continue compression till HR > 60 /min.
7. Adrenaline indicated if HR < 60 /min.
8. Stop resuscitation if no signs of life after 10 minutes.

Lay Rescuers

1. Pulse check not expected from them therefore they can start compression even if not able to palpate pulse of an unresponsive victim.
2. Paediatric means 1-8 years (for health care professionals pead. means 1-14 years).

CPR IN PREGNANCY

1. External cardiac massage should be combined with lateral tilt.
2. Sodium bicarbonate administration is advocated early.
3. Early insertion of endotracheal tube (as pregnant patients are very vulnerable for aspiration) therefore during mask ventilation continously apply cricoid pressure till patient is intubated.
4. More prone for hypoxia so use high FIO₂.
5. Chest compression should be performed harder.
6. Emergency LSCS (cesarean section) should be considered only if:
 - Fetus > 25 week.
 - Uterine decompression is mandatory for patients life (fetus can be saved only if LSCS is performed within 5 min. of arrest).

OPEN CHEST MASSAGE

Indications are:

1. Cardiac tamponade.
2. Penetrating blunt trauma.
3. Air embolism.
4. Arrest during intrathoracic procedures.
5. Chest deformities.

COMPLICATIONS OF CPR

1. Rib fracture.
2. Pneumothorax.
3. Pneumopericardium.
4. Pneumomediastinum.
5. Injury to diaphragm.
6. Gastric injury.
7. Lung injury.
8. Injury to major vessels particularly by fractured rib.
9. Injury to abdominal organs: Liver, spleen and stomach.

OUTCOME OF CPR

Depends on the:

1. Cause.
2. The time of initiation of CPR and
3. Duration for which CPR is performed.

Survival is better, if basic life support (BLS) is

initiated within 4 minutes of arrest and ALS within 8 minutes.

Fortunately most common cause of cardiac arrest is ventricular fibrillation which if detected in time can have 50 to 60% success rate. Average survival rate of in hospital arrest is 8 to 21 %.

Survival is better if arrest time (onset of arrest to start of CPR) is less than 6 minutes and CPR time (time required for successful CPR) is less than 30 minutes.

NEWER TECHNIQUES OF CPR

1. Simultaneous abdominal compression: Limits caudal movement of diaphragm and limits dissipation of intrathoracic pressure.
2. Vest CPR: Increasing intrathoracic pressure by physically inflating the bladder around chest.
3. Simultaneous ventilation with every compression.
4. Cardiopulmonary bypass.
5. Cough CPR (applicable to conscious patient having VF): If a patient cough during VF, increase in intrathoracic pressure can maintain cerebral (perfusion (e. consciousness) for 90 sec. So ask him to cough every 1-3 sec. till he/she is defibrillated.
6. High frequency (120/min) CPR: Not better than standard CPR.

INITIAL APPROACH

The initial approach to airway management is simultaneous assessment and management of the adequacy of airway patency (the A of ABCs) and oxygenation and ventilation (the B of ABCs).

1. The patient's color and respiratory rate must be assessed; marked hypoventilation with or without cyanosis may be an indication for immediate intubation.
2. The airway should be opened with head tilt–chin lift maneuver (jaw thrust should be used if C-spine injury is suspected). If needed, the patient should be bagged with the bag-valve-mask device, including an O₂ reservoir. For a good seal, the proper size mask should be ensured. This technique may require an oral or nasal airway or two rescuers to both seal the mask (two hands) and bag the patient.
3. The patient should be placed on a cardiac monitor, pulse oximetry, and possibly capnography (end-tidal CO₂), while the remaining vitals, pulse, and blood pressure (temperature is important but can be delayed to assure the ABCs) can be collected.
4. The need for invasive airway management techniques must be determined as described later. It is essential to not wait for arterial blood gas analyses (ABG) if the initial assessment declares the need for invasive airway management. If the patient does not require immediate airway or ventilation control, he or she should be administered oxygen by face mask, as necessary, to assure an O₂ saturation of 95%. Laboratory studies should be collected as needed. Do not remove a patient from oxygen to draw an ABG unless deemed safe from the initial assessment.

OROTRACHEAL INTUBATION

The most reliable means to ensure a patent airway, prevent aspiration, and provide oxygenation and ventilation is endotracheal (ET) intubation. Many conscious patients require intubation (see the section, “Rapid Sequence Induction” later). Selection of the blade should be considered in advance, if possible. The curved blade rests in the vallecula above the epiglottis and indirectly lifts it off the larynx because of traction on the frenulum. The straight blade is used to lift the epiglottis directly. The curved blade does a better job of clearing the tongue

from view and may be less traumatic and reflex-stimulating. The straight blade is mechanically easier to insert in many patients.

Emergency Department Care and Disposition

1. Adequate ventilation must be ensured while the equipment is prepared. The patient should be preoxygenated, with or without a bag-valve-mask device, depending on the clinical need. Vital signs must be monitored and pulse oximetry used throughout the procedure.

2. The blade type and size (usually #3 or #4 curved blade, or #2 or #3 straight blade) should be selected; the blade light should be tested. The tube size (usually 7.5 to 8.0 in women, 8.0 to 8.5 in men) must be selected and the balloon cuff tested. The end of the tube should be lubricated with lidocaine jelly or similar lubricant. The use of a flexible stylet should be considered; the distal end should be bent upward if the patient's anatomy requires it. The tube and tonsillar tip suction should be placed within easy reach. If there is an assistant, he or she should be asked to pass the items when needed.

3. The patient should be positioned with the head extended and neck flexed, possibly with a rolled towel under the occiput. If C-spine injury is suspected, the head or neck should not be moved. Rapid sequence induction with in-line traction, nasotracheal intubation, or cricothyrotomy should be considered.

4. The blade should be inserted on the right and slowly advanced in search of the epiglottis. The patient should be suctioned as necessary. If the curved blade is used, the tip should be slid into the vallecula and lifted (indirectly lifting the epiglottis); if a straight blade is used, the epiglottis should be lifted directly in the direction the handle points, that is, 90° to the blade. It is important to not rock back on the teeth.

5. Once the vocal cords are visualized, it is important to not lose sight of them. The assistant should be asked to place the tube in the physician's hand. Pass the tube between the cords, avoiding force. The stylet should be removed, the balloon cuff inflated. Ventilate the patient with a bag-valve device and check for bilateral breath sounds. Placement should be confirmed with an end-tidal CO₂ detector (not reliable if the patient is in cardiac arrest) or capnography. Tube length should be checked; the usual distance (marked on the tube) from the corner of the

mouth to 2 cm above the carina is 23 cm in men and 21 cm in woman.

6.The tube should be taped in place and a bite block inserted. Correct intubation and tube placement can be verified with a portable chest x-ray.

7.If unsuccessful, reoxygenation should be performed with bag-valve-mask device. The technique can be changed by possibly using a smaller tube, different blade type or size, or repositioning the patient and reattempting intubation.

Short-term complications from orotracheal intubation (trauma to surrounding structures) are unusual, as long as correct position is confirmed. Failure to confirm position immediately can result in hypoxia and neurologic injury. Endobronchial intubation is usually on the right side and is corrected by withdrawing the tube 2 cm and listening for equal breath sounds.

NASOTRACHEAL INTUBATION

Nasotracheal intubation is indicated in situations where laryngoscopy is difficult, neuromuscular blockade is hazardous, or crico-thyrotomy unnecessary. Severely dyspneic, awake patients with congestive heart failure, chronic obstructive pulmonary disease, or asthma often cannot remain supine for other airway maneuvers but do tolerate nasotracheal intubation in the sitting position. Relative contraindications for this technique include complex nasal and massive midface fractures and bleeding disorders.

Emergency Department Care and Disposition

1.Both nares should be sprayed with a topical vasoconstrictor and anesthetic. Between 4 to 10% cocaine solution is an appropriate single agent, but may cause unwanted systemic cardiovascular effects. Topical neosynephrine is an effective vasoconstrictor, and tetracaine is a safe effective topical anesthetic.

2.The tube size must be chosen, usually between 7.0 to 7.5 in women and 7.5 to 8.0 in men. The balloon cuff of the tube should be checked for leaks. The tube should be lubricated with lidocaine jelly or similar lubricant.

3. The largest nares should be used or the right side if the nares are equal. Some operators recommend dilating the nares with a lubricated nasal airway. The patient may be sitting up or supine.

4. An assistant can immobilize the patient's neck. The physician should stand to the patient's side, with one hand on the tube and with the thumb and index finger of the other hand straddling the larynx. The tube should be advanced slowly, with steady gentle pressure. The tube should be twisted to help move past obstructions in the nose and nasopharynx. The tube should be advanced until maximal airflow is heard through the tube; this means the larynx is now close by.

5. The physician should listen carefully to the rhythm of inspiration and expiration. The tube should then be gently but swiftly advanced during the beginning of inspiration. Entrance into the larynx may initiate a cough, and most expired air should exit the tube even though the cuff is uninflated. If the tube is foggy the cuff should be inflated.

6. If intubation is unsuccessful, the physician should carefully look for a bulge lateral to the larynx (usually the tip of the tube is in the pyriform fossa on the same side as the nares used). If found, the tube must be retracted until maximal breath sounds are heard and then intubation should be reattempted by manually displacing the larynx toward the bulge. If no bulge is seen, it is possible that the tube has gone posteriorly into the esophagus. In this case, the tube should be withdrawn until maximal breath sounds are heard. Intubation should again be reattempted after the patient's head is extended and a Sellick's maneuver performed. Another option is to use a directional control tip (Endotrol) or fiberoptic laryngoscope. The head should not be moved if C-spine injury is suspected.

Complications other than local bleeding are rare. Occasionally, marked bleeding will prompt the need for orotracheal intubation or cricothyrotomy.

CRICOTHYROTOMY

Indications for immediate cricothyrotomy include severe, ongoing tracheobronchial hemorrhage, massive midface trauma, and inability to control the airway with the usual less-invasive maneuvers. Cricothyrotomy is relatively contraindicated in patients with acute

laryngeal disease due to trauma or infection or recent prolonged intubation and should not be used in children below the age of 12.

Emergency Department Care and Disposition

1. Sterile technique should be used. The cricothyroid membrane should be palpated with digital stabilization of the larynx (see With a #11 scalpel, a vertical 3 to 4 cm incision should be started at the superior border of the thyroid cartilage and incised caudally toward the suprasternal notch.

2. The membrane should be repalpated and a horizontal stab should be made through its inferior aspect. The blade should be kept temporarily in place.

3. The larynx should be stabilized by inserting the tracheal hook into the cricothyroid space and retracting upon the inferior edge of the thyroid cartilage (an assistant should hold after the hook is placed). Leaving the blade tip in the space, a slightly open hemostat should be inserted straddling the blade and spread open horizontally.

4. The scalpel should be removed and a dilator inserted (LaBorde or Trousseau). The tracheal hook can then be removed.

5. A Shiley tracheostomy tube should be introduced (or the largest tube that will fit). Alternatively, a small cuffed endotracheal tube may be used (#6 or the largest tube that will fit). The balloon should be inflated and the tube secured in place.

6. The physician should check for bilateral breath sounds. Make sure subcutaneous air is not introduced. Placement can be checked with an end-tidal CO₂ detector and chest x-ray.

RAPID SEQUENCE INDUCTION

Complex airway emergencies in select nonfasted patients may require rapid sequence induction. This technique couples sedation to induce unconsciousness (induction) with muscular paralysis. Intubation follows laryngoscopy while maintaining cricoid pressure to prevent aspiration. The principle contraindication is any condition preventing mask ventilation

or intubation.

- 1.The cardiac monitor, oximetry, and capnography should be set up, if available. Equipment should be checked.
- 2.The patient should be preoxygenated with 100% oxygen.
- 3.Lidocaine (1.5 mg/kg intravenously) should be considered in a head trauma patient to prevent increased intracranial pressure. Atropine (0.4 mg/kg intravenously) should be considered to prevent reflex bradycardia, but is not essential.
- 4.Medication for sedation or analgesia should be considered, if such agents are not being used for induction.
- 5.A defasciculating dose of a nondepolarizing agent (i.e., vecuronium at 0.02 mg/kg) is used if succinylcholine is given for paralysis.
- 6.The patient should be induced with thiopental (3 to 5 mg/kg), methohexital (1 to 2 mg/kg), or midazolam (0.1 mg/kg with 5 mg maximum dose). Barbiturates should not be used in a patient with hypotension or reactive airway disease (caution in head injury). Benzodiazepines may be inadequate for induction, however, midazolam is an excellent amnestic agent. Etomidate, 0.3 mg/kg, is an excellent alternative in a hypotensive patient. Ketamine, 1 to 2 mg/kg, should be considered for the induction of a patient who has active bronchospasm for its bronchodilator properties.
- 7.In a patient needing analgesia in addition to sedation, opiates should be considered for induction. These agents are reversible with naloxone. Fentanyl, 2 to 10 µg/kg, is commonly used.
- 8.Cricoid pressure should be applied before paralysis and maintained until intubation is accomplished.
- 9.Succinylcholine (1.0 mg/kg) is chosen for paralysis in many cases because of its rapid onset and short duration of action; it should not be used in a patient with preexisting paralysis or > 2

h after severe burns, as hyperkalemia may occur. A nondepolarizing agent such as vecuronium (0.2 mg/kg) may be chosen for a patient with increased intracranial pressure, one in status asthmaticus, or at operator discretion.

10. The trachea should be intubated and cricoid pressure released.

11. The physician should be prepared to bag the patient if intubation proves unsuccessful. Invasive airway techniques should be considered as indicated.

Alternative drugs for rapid sequence induction are listed in Chap. 15 of Emergency Medicine, A Comprehensive Study Guide, 5th ed. Airway management alternatives to the methods described earlier include retrograde tracheal intubation, translaryngeal ventilation, digital intubation, transillumination, fiberoptic assistance, and formal tracheostomy. Translaryngeal ventilation may be used to temporarily provide ventilation until a more definitive procedure is possible. When oral intubation is indicated but has been unsuccessful, and the patient can be temporarily ventilated with a bag-valve-mask unit, the following assist methods are warranted. Retrograde tracheal intubation, digital intubation, transillumination, or fiberoptic assistance may be helpful. Formal tracheostomy is reserved for those experienced in the technique when less-invasive or more-rapid methods (cricothyrotomy) are unsuccessful.

2 Dysrhythmia Management

Emergency Medicine Companion Handbook

If sustained junctional escape rhythms are producing symptoms, the underlying cause should be treated. Atropine can be used to accelerate temporarily the sinus node discharge rate and enhance AV nodal conduction.

VENTRICULAR DYSRHYTHMIAS

Aberrant Versus Ventricular Tachydysrhythmias

Differentiation between ectopic beats of ventricular origin and those of supraventricular origin that are conducted aberrantly, can be difficult, especially in sustained tachycardias with wide

QRS complexes (WCT). In general, the majority of patients with WCT have ventricular tachycardia, which should be approached as ventricular tachycardia, until proved otherwise. Several guidelines follow:

1. A preceding ectopic P wave is good evidence favoring aberrancy, although coincidental atrial and ventricular ectopic beats or retrograde conduction can occur. During a sustained run of tachycardia, AV dissociation favors a ventricular origin of the dysrhythmia.
2. Postectopic pause: A fully compensatory pause is more likely after a ventricular beat, but exceptions occur.
3. Fusion beats are good evidence for ventricular origin but, again, exceptions occur.
4. A varying bundle branch block pattern suggests aberrancy.
5. Coupling intervals are usually constant with ventricular ectopic beats, unless parasystole is present. Varying coupling intervals suggest aberrancy.
6. Response to carotid sinus massage or other vagal maneuvers will slow conduction through the AV node and may abolish reentrant SVT and slow the ventricular response in other supraventricular tachydysrhythmias. These maneuvers have essentially no effect on ventricular dysrhythmias.
7. A QRS duration of longer than 0.14 s is usually found in ventricular ectopy or tachycardia.
8. Historical criteria also have been found to be useful: a patient over 35 years old or a history of MI, CHF, or coronary artery bypass graft strongly suggest ventricular tachycardia in patients with WCT.

Emergency Department Care and Disposition

1. As with ventricular tachycardia lidocaine 1 to 1.5 mg/kg intravenously should be started and may be repeated up to 3 mg/kg.

2. Adenosine 6 mg intravenously may be tried prior to procainamide (see ventricular tachycardia management later for administration guidelines).

Premature Ventricular Contractions

Clinical Features

Premature ventricular contractions (PVCs) are due to impulses originating from single or multiple areas in the ventricles. The ECG characteristics of PVCs are (a) a premature and wide QRS complex; (b) no preceding P wave; (c) the ST-segment and T wave of the PVC are directed opposite the major QRS deflection; (d) most PVCs do not affect the sinus node, so there is usually a fully compensatory postectopic pause, or the PVC may be interpolated between 2 sinus beats; (e) many PVCs have a fixed coupling interval (within 0.04 s) from the preceding sinus beat; and (f) many PVCs are conducted into the atria, producing a retrograde P wave.

PVCs are common, occur in most patients with ischemic heart disease, and are universally found in patients with acute MI. Other common causes of PVCs include digoxin toxicity, CHF, hypokalemia, alkalosis, hypoxia, and sympathomimetic drugs.

Emergency Department Care and Disposition

1. Most acute patients with PVCs will respond to intravenous lidocaine (1 mg/kg intravenously), although some patients may require procainamide. Although single studies have suggested benefit, pooled data and meta-analysis find no reduction in mortality from either suppressive or prophylactic treatment of PVCs.

Accelerated Idioventricular Rhythm

Clinical Features

The ECG characteristics of accelerated idioventricular rhythm (AIVR) are (a) wide and regular QRS complexes; (b) rate between 40 and 100, often close to the preceding sinus rate; (c) most runs of short duration (3 to 30 beats); and (d) an AIVR often beginning with a fusion beat.

This condition is found most commonly with an acute MI.

Emergency Department Care and Disposition

1. Treatment is not necessary. On occasion, AIVR may be the only functioning pacemaker, and suppression with lidocaine can lead to cardiac asystole.

Ventricular Tachycardia

Clinical Features

Ventricular tachycardia is the occurrence of 3 or more beats from a ventricular ectopic pacemaker at a rate greater than 100. The ECG characteristics of ventricular tachycardia are (a) wide QRS complexes; (b) rate greater than 100 (most commonly 150 to 200); (c) usually regular rhythm, although there may be some beat-to-beat variation; and (d) usually constant QRS axis

Ventricular tachycardia is rare in patients without underlying heart disease. The most common causes of ventricular tachycardia are ischemic heart disease and acute MI. Ventricular tachycardia cannot be differentiated from SVT with aberrancy on the basis of clinical symptoms, blood pressure, or heart rate. Patients who are unstable should be cardioverted, which is effective for both dysrhythmias. In general, it is best to treat all wide complex tachycardias as ventricular tachycardia with lidocaine or procainamide. Adenosine appears to cause little harm in patients with ventricular tachycardia and has potential merit for the treatment of wide QRS complex tachycardias.

Emergency Department Care and Disposition

1. Unstable patients, or those in cardiac arrest, should be treated with synchronized cardioversion. Ventricular tachycardia can be converted with energies as low as 1 J, and over 90 percent can be converted with less than 10 J. ACLS guidelines recommend that pulseless ventricular tachycardia be defibrillated (unsynchronized cardioversion) with 200 J. Another alternative for unstable patients is intravenous amiodarone. (See treatment recommendations

under ventricular fibrillation.)

2. Clinically stable patients should be treated with intravenous antidysrhythmics.

a. Lidocaine 75 mg (1.0 to 1.5 mg/kg) intravenously over 60 to 90 s can be administered, followed by a constant infusion at 1 to 4 mg/min (10 to 40 $\mu\text{g}/\text{kg}/\text{min}$). A repeat bolus dose of 50 mg lidocaine may be required during the first 20 min to avoid a subtherapeutic dip in serum level due to the early distribution phase.

b. Procainamide can be administered intravenously at less than 30 mg/min until the dysrhythmia converts, the total dose reaches 15 to 17 mg/kg in normals (12 mg/kg in patients with CHF), or early signs of toxicity develop, with hypotension or QRS prolongation. The loading dose should be followed by a maintenance infusion of 2.8 mg/kg/h in normal subjects.

c. Bretylium 500 mg (5 to 10 mg/kg) intravenously over 10 min can be administered, followed by a constant infusion at 1 to 2 mg/min.

Torsades de Pointes

Atypical ventricular tachycardia (torsade de pointes, or twisting of the points) is where the QRS axis swings from a positive to negative direction in a single lead (Fig. 2-14).

FIG. 2-14 Two examples of short runs of atypical ventricular tachycardia showing sinusoidal variation in amplitude and direction of the QRS complexes: “Le torsade de pointes” (twisting of the points). Note that the top example is initiated by a late-occurring PVC (lead II).

Drugs that further prolong repolarization—quinidine, disopyramide, procainamide, phenothiazines, tricyclic antidepressants—exacerbate this dysrhythmia.

1. Reports have revealed that magnesium sulfate, 1 to 2 g intravenously over 60 to 90 s followed by an infusion of 1 to 2 g/h, is effective in abolishing torsades de pointes.

2. To date, treatment for torsades de pointes consisted of accelerating the heart rate (thereby shortening ventricular repolarization) with isoproterenol (2 to 8 $\mu\text{g}/\text{min}$), while making

arrangements for a ventricular pacemaker to overdrive the heart at rates of 90 to 120. Temporary pacing is the most effective and safest method to treat torsades de pointes and prevent its recurrence.

Ventricular Fibrillation

Clinical Features

Ventricular fibrillation is the totally disorganized depolarization and contraction of small areas of ventricular myocardium—there is no effective ventricular pumping activity. The ECG of ventricular fibrillation shows a fine-to-coarse zigzag pattern without discernible P waves or QRS complexes (Fig. 2-15). Ventricular fibrillation is never accompanied by a pulse or a measurable blood pressure.

Ventricular fibrillation is most commonly seen in patients with severe ischemic heart disease, with or without an acute MI. Primary ventricular fibrillation occurs suddenly, without preceding hemodynamic deterioration, whereas secondary ventricular fibrillation occurs after a prolonged period of left ventricular failure or circulatory shock.

Emergency Department Care and Disposition

1. Current ACLS guidelines recommend immediate electrical defibrillation with 200 J. If ventricular fibrillation persists, defibrillation should be repeated immediately, with 200 to 300 J at the second attempt, increased to 360 J at the third attempt.
2. If the initial 3 attempts at defibrillation are unsuccessful, cardiopulmonary resuscitation and intubation should be initiated.
3. Epinephrine in standard dose should be administered, 1 mg intravenously. If this is not successful, high-dose epinephrine may be subsequently given, 0.1 mg/kg, and repeated every 3 to 5 min.
4. Defibrillation should be attempted after each drug administration, at 360 J, unless lower energy levels have been previously successful.

5. Successive antidysrhythmics should then be administered with defibrillation attempted after each drug. The recommended sequence is lidocaine, 1.5 mg/kg, bretylium, 5 mg/kg, then possibly magnesium, 2 g intravenously, and procainamide (see preceding dosing guidelines).

6. Amiodarone, 150 mg over 10 min followed by 1 mg/min for 6 h, may become a preferred treatment for

Shock Overview

The word shock is used differently by the medical community and the general public. The connotation by the public is an intense emotional reaction to a stressful situation or bad news. The medical definition of shock is much different.

Medically, shock is defined as a condition where the tissues in the body don't receive enough oxygen and nutrients to allow the cells to function. This ultimately leads to cellular death, progressing to organ failure, and finally, if untreated, whole body failure and death.

How the body works

Cells need two things to function: oxygen and glucose. This allows the cells to generate energy and do their specific jobs.

Oxygen in the air enters the body through the lungs; where oxygen molecules cross into the smallest blood vessels, the capillaries, and are picked up by red blood cells and attached to [hemoglobin](#) molecules. The red blood cells are pushed through the body by the actions of the pumping heart and deliver the oxygen to cells in all the tissues of the body. The hemoglobin then picks up carbon dioxide, the waste product of metabolism, where it is then taken back to the lungs and breathed out into the air, whereby the whole cycle begins again.

Glucose is generated in the body from the foods we eat. Glucose travels in the blood stream and uses an insulin molecule to "open the door," where it then enters the cell to provide energy for cellular metabolism.

Shock Causes

When things go wrong

If cells are deprived of oxygen, instead of using aerobic (with oxygen) metabolism to function, the cells use the anaerobic (without oxygen) pathway to produce energy. Unfortunately, lactic acid is formed as a by product of anaerobic metabolism. This acid changes the acid-base balance in the blood, making it more acidic, and this leads to situation in which cells begin to leak toxic chemicals into the bloodstream, causing blood vessel walls to become damaged. The anaerobic process ultimately leads to the death of the cell. If enough cells die, organs start to fail, and the body starts to fail and death occurs.

Think of the cardiovascular system of the body as similar to the oil pump in your car. For efficient functioning, the electrical pump needs to work to pump the oil, there needs to be enough oil, and the oil lines need to be intact. If any of these components fail, oil pressure falls and the engine may be damaged. In the body, if the heart, blood vessels, or bloodstream (circulation) fail, then the body fails.

Where things go wrong

The **oxygen delivery system** to the body's cells can fail in a variety of ways.

- The amount of oxygen in the air that is inhaled can be decreased.
- Examples include [breathing at high altitude](#) or [carbon monoxide poisoning](#).

The **lung** may be injured and not be able to transfer oxygen to the blood stream. Examples of causes include:

- pneumonia (an infection of the lung),
- [congestive heart failure](#) (the lung fills with fluid or [pulmonary edema](#)), or
- trauma with [collapse or bruising of the lung](#), or
- [pulmonary embolism](#).

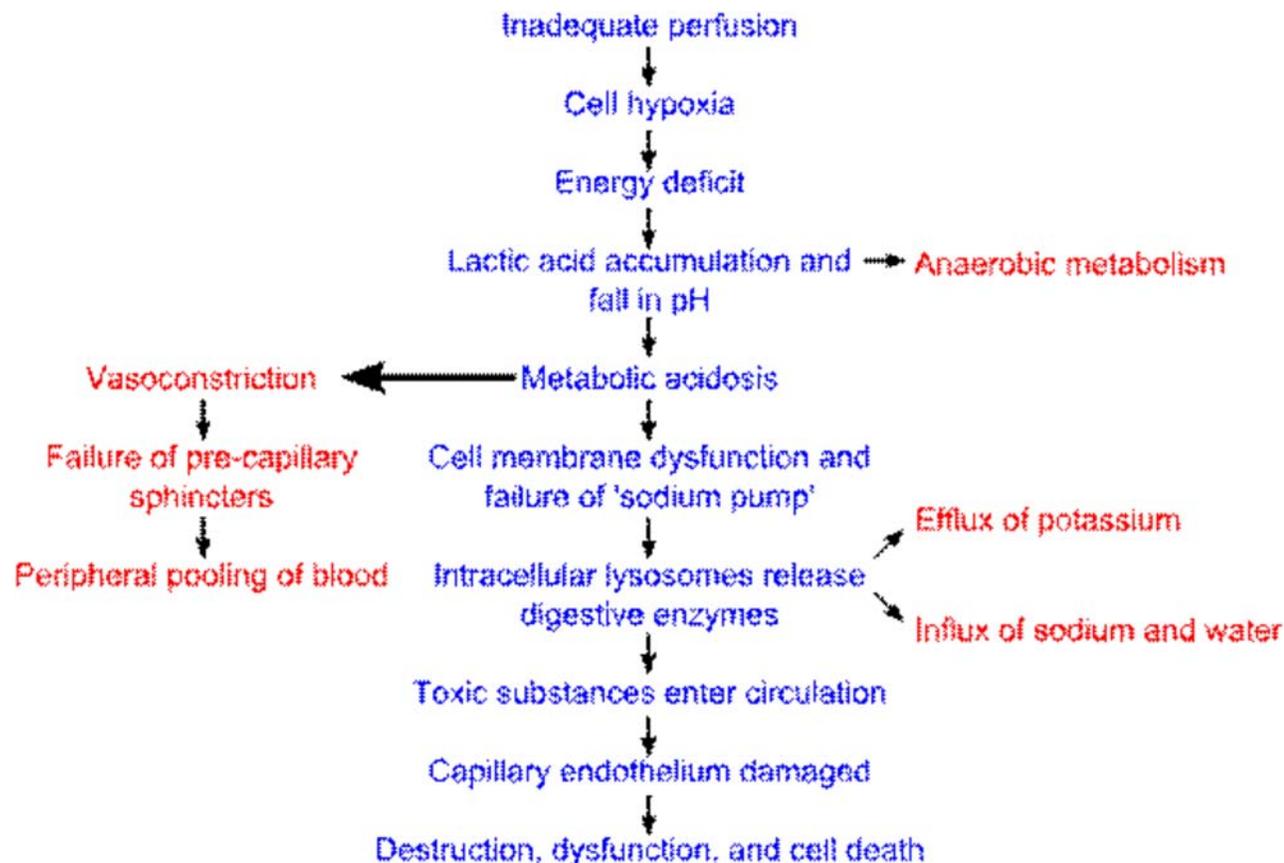

Fig. Effects of inadequate perfusion on cell function.

The **heart** may not be able to adequately pump the blood to the tissues of the body. Examples of causes examples include:

- [Heart attack](#) in which muscle tissue is lost and the heart cannot beat as strong and pump blood throughout the body.
- A [rhythm disturbance of the heart](#) occurs when the heart can't beat in a coordinated way.
- Inflammation of the sac around the heart ([pericarditis](#)) or inflammation of the heart muscle due to infections or other causes, in which the effective beating capabilities of the heart are lost.

There may **not be enough red blood cells** in the blood. If there aren't enough red blood cells ([anemia](#)), then not enough oxygen can be delivered to the tissues with each heart beat. Examples of causes may include:

- acute or chronic [bleeding](#),
- inability of the bone marrow to make red blood cells, or
- the increased destruction of red blood cells by the body (an example, [sickle cell disease](#)).

There may **not be enough other fluids** in the blood vessels. The blood stream contains the blood cells (red, white, and platelets), plasma (which is more than 90% water), and many important proteins and chemicals. Loss of body water or [dehydration](#) can cause shock.

The **blood vessels** may not be able to maintain enough pressure within their walls to allow blood to be pumped to the rest of the body. Normally, blood vessel walls have tension on them to allow blood to be pumped against gravity to areas above the level of the heart. This tension is under the control of the unconscious central nervous system, balanced between the action of two chemicals, adrenaline (epinephrine) and acetylcholine. If the adrenaline system fails, then the blood vessel walls dilate and blood pools in the parts of the body closest to the ground (lower extremities), and may have a difficult time returning to heart to be pumped around the body.

Since one of the steps in the cascade of events causing shock is damage to blood vessel walls, this loss of integrity can cause blood vessels to leak fluid, leading to dehydration which initiates a vicious circle of worsening shock.

Stages of shock

There are four stages of shock. As it is a complex and continuous condition there is no sudden transition from one stage to the next.

Initial

During this stage, the hypoperfusal state causes hypoxia, leading to the mitochondria being unable to produce adenosine triphosphate (ATP). Due to this lack of oxygen, the cell membranes become damaged, they become leaky to extra-cellular fluid, and the cells perform anaerobic respiration. This causes a build-up of lactic and pyruvic acid which results in systemic metabolic acidosis. The process of removing these compounds from the cells by the liver requires oxygen, which is absent.

Compensatory (Compensating)

This stage is characterised by the body employing physiological mechanisms, including neural, hormonal and bio-chemical mechanisms in an attempt to reverse the condition. As a result of the acidosis, the person will begin to hyperventilate in order to rid the body of carbon dioxide (CO₂). CO₂ indirectly acts to acidify the blood and by removing it the body is attempting to raise the pH of the blood. The baroreceptors in the arteries detect the resulting hypotension, and cause the release of adrenaline and noradrenaline.

- Baroreceptor reflexes
- Circulating vasoconstrictors
- Chemoreceptor reflexes
- Reabsorption of tissue fluids
- Renal reabsorption of sodium and water
- Activation of thirst mechanisms
- Cerebral ischemia
- Hemapoiesis

Fig. Compensatory mechanisms

Noradrenaline causes predominately vasoconstriction with a mild increase in heart rate, whereas adrenaline predominately causes an increase in heart rate with a small effect on the

vascular tone; the combined effect results in an increase in blood pressure. Renin-angiotensin axis is activated and arginine vasopressin is released to conserve fluid via the kidneys.

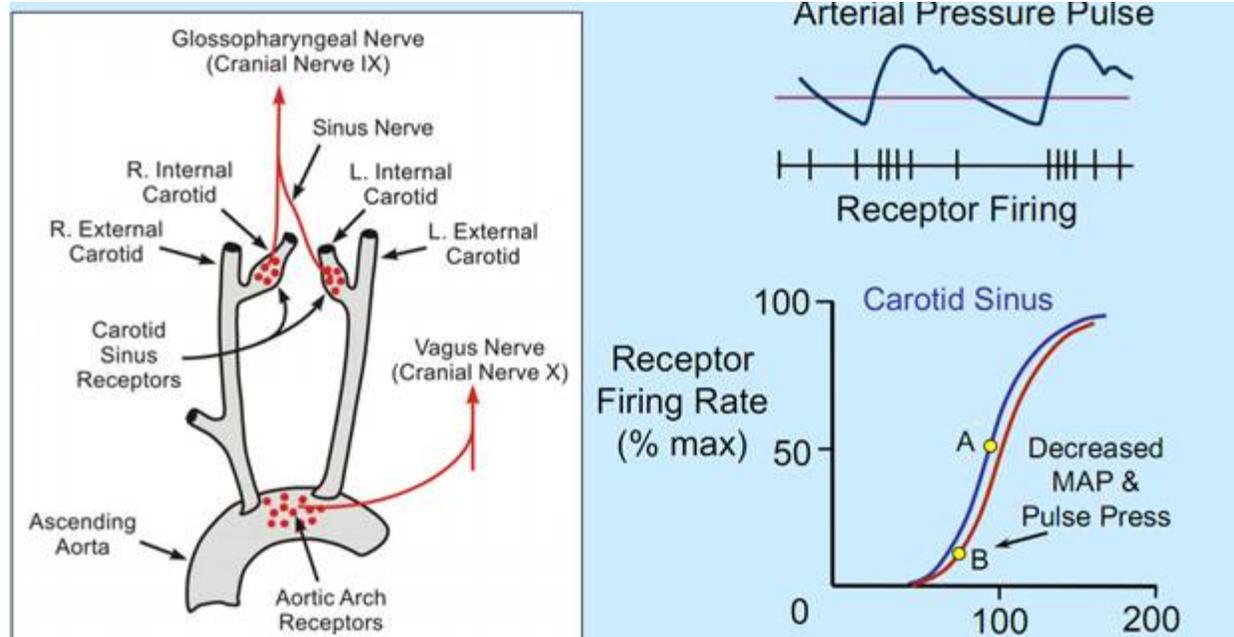

Fig. Compensatory mechanisms

Also, these hormones cause the vasoconstriction of the kidneys, gastrointestinal tract, and other organs to divert blood to the heart, lungs and brain. The lack of blood to the renal system causes the characteristic low urine production. However the effects of the Renin-angiotensin axis take time and are of little importance to the immediate homeostatic mediation of shock .

Progressive (Decompensating)

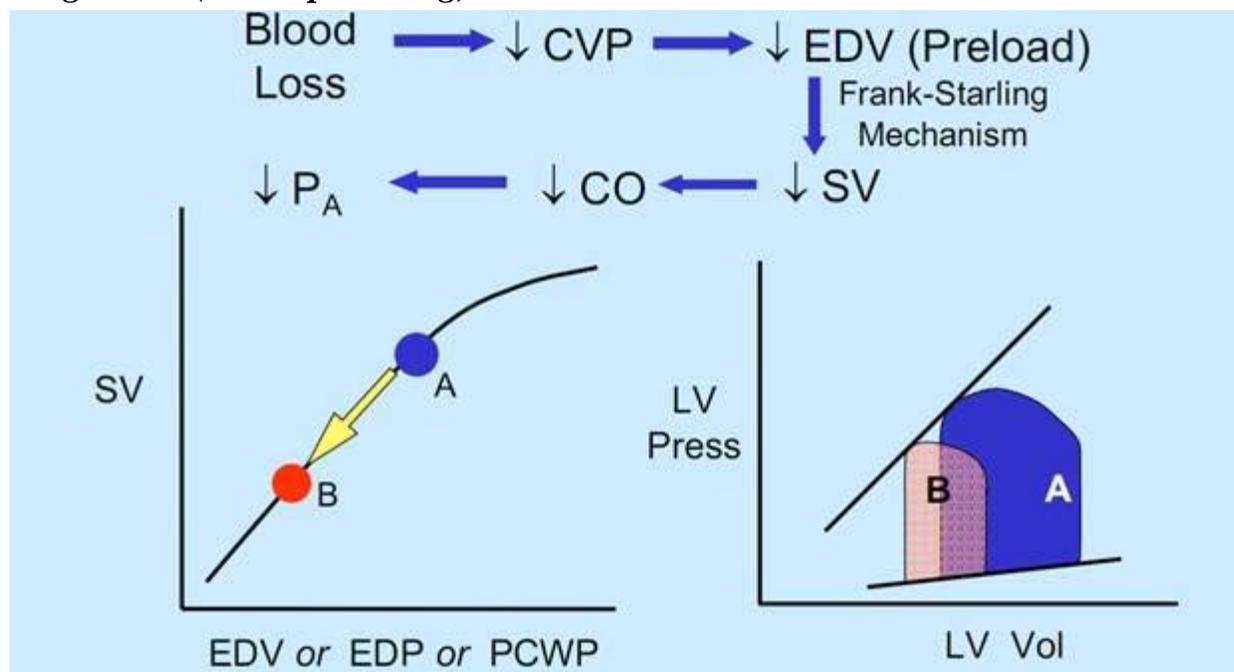

Fig. Compensatory mechanisms

Should the cause of the crisis not be successfully treated, the shock will proceed to the progressive stage and the compensatory mechanisms begin to fail. Due to the decreased perfusion of the cells, sodium ions build up within while potassium ions leak out. As anaerobic metabolism continues, increasing the body's metabolic acidosis, the arteriolar smooth muscle and precapillary sphincters relax such that blood remains in the capillaries. Due to this, the hydrostatic pressure will increase and, combined with histamine release, this will lead to leakage of fluid and protein into the surrounding tissues. As this fluid is lost, the blood concentration and viscosity increase, causing sludging of the micro-circulation. The prolonged vasoconstriction will also cause the vital organs to be compromised due to reduced perfusion. If the bowel becomes sufficiently ischemic, bacteria may enter the blood stream, resulting in the increased complication of endotoxic shock.

Refractory (Irreversible)

At this stage, the vital organs have failed and the shock can no longer be reversed. Brain damage and cell death have occurred. Death will occur imminently.

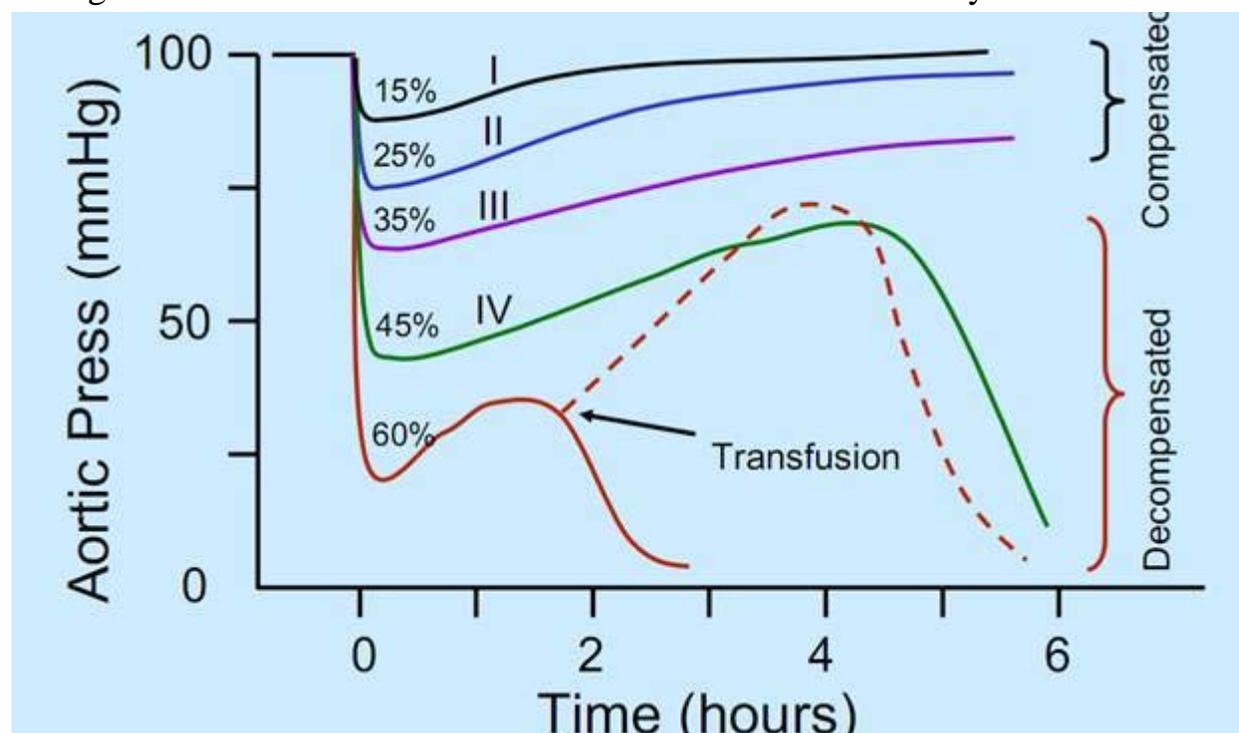

Fig. Effect of blood volume loss on arterial pressure

A medical emergency is an injury or illness that is acute and poses an immediate risk to a person's life or long term health. These emergencies may require assistance from another person, who should ideally be suitably qualified to do so, although some of these emergencies can be dealt with by the victim themselves. Dependent on the severity of the emergency, and the quality of any treatment given, it may require the involvement of multiple levels of care, from a

first aider to an emergency physician through to specialist surgeons.

Classification of shock

Shock is identified in most patients by hypotension and inadequate organ perfusion, which may be caused by either low cardiac output or low systemic vascular resistance. Circulatory shock can be subdivided into 4 distinct classes on the basis of underlying mechanism and characteristic hemodynamics, as follows:

- Hypovolemic shock
- Obstructive shock
- Distributive shock
- Cardiogenic shock

These classes of shock should be considered and systemically differentiated before establishing a definitive diagnosis of septic shock.

Hypovolemic shock results from the loss of blood volume caused by such conditions as gastrointestinal (GI) bleeding, extravasation of plasma, major surgery, trauma, and severe burns. The patient demonstrates tachycardia, cool clammy extremities, hypotension, dry skin and mucus membranes, and poor turgor.

Obstructive shock results from impedance of circulation by an intrinsic or extrinsic obstruction. Pulmonary embolism and pericardial tamponade both result in obstructive shock.

Distributive shock is caused by such conditions as direct arteriovenous shunting and is characterized by decreased resistance or increased venous capacity from the vasomotor dysfunction. These patients have high cardiac output, hypotension, large pulse pressure, a low diastolic pressure, and warm extremities with a good capillary refill. These findings on physical examination strongly suggest a working diagnosis of septic shock.

Cardiogenic shock is characterized by primary myocardial dysfunction, resulting in the inability of the heart to maintain adequate cardiac output. These patients demonstrate clinical signs of low cardiac output, while evidence exists of adequate intravascular volume. The patients have cool clammy extremities, poor capillary refill, tachycardia, narrow pulse pressure, and a low urine output.

Shock - Specific Types

Hypovolemic and Hemorrhagic Shock

Hypovolemic Shock

There needs to be enough red blood cells and water in the blood for the heart to push the fluids around within the blood vessels. When the body becomes dehydrated, there may be enough red blood cells, but the total volume of fluid is decreased, and pressure within the system decreases. Cardiac output is the amount of blood that the heart can pump out in one minute. It is calculated as the stroke volume (how much blood each heart beat can push out) multiplied by the heart rate (how fast the heart beats each minute). If there is less blood in the system to be pumped, the heart speeds up to try to keep its output steady.

Water makes up 90% of blood. If the body becomes dehydrated because water is lost or fluid intake is inadequate, the body tries to maintain cardiac output by making the heart beat faster. But as the fluid losses mount, the body's compensation mechanisms fail, and shock may ensue.

[Hypovolemic](#) (hypo=low + volemic=volume) shock due to water loss can be the endpoint of many illnesses, but the common element is the lack of fluid within the body.

[Gastroenteritis](#) can cause significant water loss from [vomiting](#) and [diarrhea](#), and is a common cause of death in third world countries. [Heat exhaustion and heat stroke](#) is caused by excessive water loss through sweating as the body tries to cool itself. Patients with infections can lose significant amounts of water from sweating. People with diabetes who have [diabetic ketoacidosis](#) lose significant water because of because of elevated blood sugar that cause excess water to be excreted in the urine.

Ultimately in hypovolemic shock, the patient cannot replace the amount of fluid that was lost by drinking enough water, and the body is unable to maintain blood pressure and cardiac output. In all shock states, when cells start to malfunction waste products build up, a downward spiral of cell death begins, increased acidosis occurs, and a worsening body environment leads to further cell death - and ultimately organ failure.

Hemorrhagic Shock

A subset of hypovolemic shock occurs when there is significant bleeding that occurs relatively quickly. Trauma is the most common example of bleeding or hemorrhage, but bleeding can

occur from medical conditions such as:

- Bleeding from the gastrointestinal tract is common; examples include [stomach or duodenal ulcers](#), [colon cancers](#) or [diverticulitis](#).
- In women, excessive bleeding can occur from the uterus.
- People with cancers or [leukemia](#) have the potential to bleed spontaneously from a variety of sources if their bone marrow does not make enough clotting factors.
- Patients who are taking blood thinners (anticoagulant medications) can bleed excessively as well.

Hemorrhage classes

Class	Blood loss	Response	Treatment
I	<15 % (0.75 l)	min. fast heart rate, normal blood pressure	minimal
II	15-30 % (0.75-1.5 l)	fast heart rate, min. low blood pressure	intravenous fluids
III	30-40 % (1.5-2 l)	very fast heart rate, low blood pressure, confusion	fluids and packed RBCs
IV	>40 % (>2 l)	critical blood pressure and heart rate	aggressive interventions

Blood loss has two effects on the body. First, there is a loss of volume within blood vessels to be pumped (see hypovolemic shock) and second, a reduced oxygen carrying capacity occurs because of the loss of red blood cells. Otherwise healthy people can lose up to 10% of their blood volume (about the amount that a person donates at a blood drive) without becoming symptomatic with weakness, lightheadedness, or shortness of breath.

The treatment of hemorrhagic shock depends on the cause. Finding and controlling the source of bleeding is of paramount importance. Intravenous fluids are used to help with resuscitation to increase the fluid volume within the blood vessel space, but blood transfusion is not always mandatory. If the bleeding is controlled and the patient becomes more stable, the bone marrow may be allowed to replenish the red blood cells that were lost.

If the red blood cell count in the blood decreases gradually over time, either because of bleeding or the inability of the body to make enough new red cells, the body can adjust to the lower levels to maintain adequate cell perfusion, but the individual's [exercise](#) tolerance may decrease. This means that they may do well in normal daily activities but find that routine exercise or household activities bring on weakness or shortness of breath. The treatment depends on the underlying diagnosis, since it isn't a total fluid problem as in hypovolemic shock.

Cardiogenic, Neurogenic, and Hypoglycemic Shock

Cardiogenic Shock

When the heart loses its ability to pump blood to the rest of the body, blood pressure decreases. Although there may be enough red blood cells and oxygen, they can't get to the cells that need them.

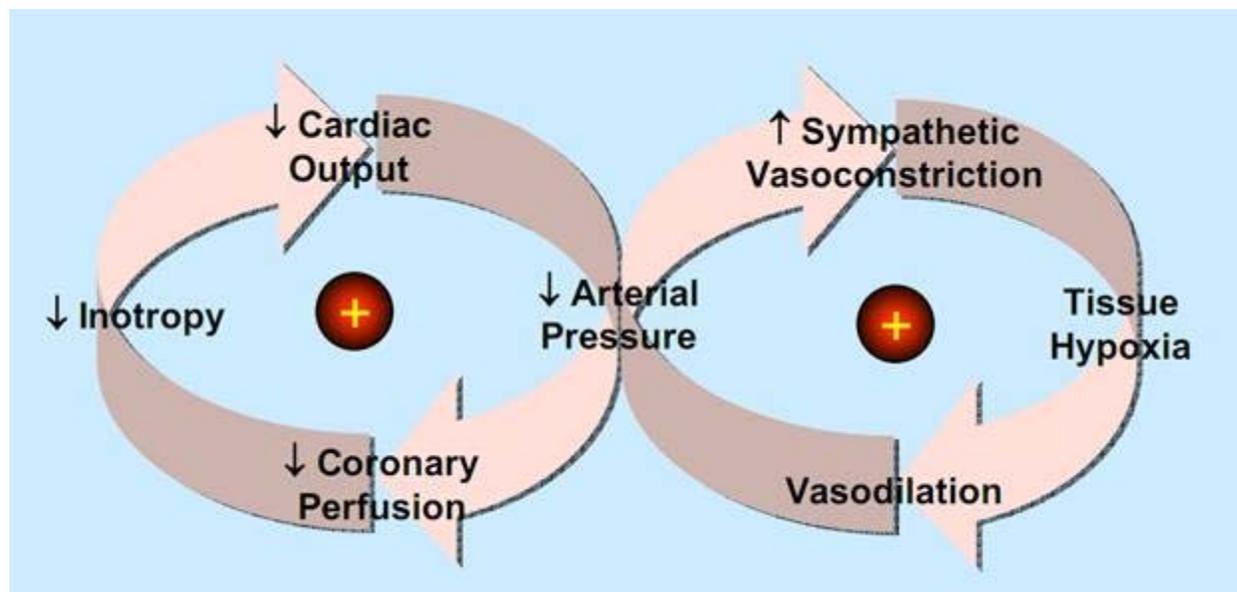

Fig. Mechanisms of cardiogenic shock

The heart is a muscle itself and needs blood supply to work. When a heart attack occurs, the blood supply to part of the heart is lost, and that can stun and irritate the heart muscle so that it isn't able to beat with an appropriate squeeze to push blood out to the rest of the body. This decreases stroke volume, and cardiac output falls.

Treatment includes trying to restore blood supply and the use of medications to support blood pressure. In more dire circumstances, machines can be used to assist the heart to support blood pressure.

Neurogenic Shock

There are involuntary muscles within blood vessel walls that maintain the squeeze so that the volume within the vessels stays constant even if the body changes position against gravity. As an analogy, is when you get up out of bed in the morning. If your blood vessels didn't squeeze a little tighter, gravity would make the blood flow to your feet, the lowest part of your body,

away from your brain, and you might pass out. The squeeze is maintained by signals from nerves in the sympathetic trunk, a long bundle of fibers running from the skull to the tailbone alongside the vertebral column.

In brain or spinal injury, the sympathetic trunk stops working and blood vessels dilate and result in blood pooling away from the heart. Since there isn't enough blood returning to the heart, the heart has a hard time pumping blood through the body.

Treatment includes fluids and medications to increase the tone in the blood vessel walls.

Hypoglycemic Shock and Hyperglycemia

High or low blood sugars are almost always associated with [diabetes](#). In people with diabetes, the body does not make enough insulin to permit glucose to enter the cells for aerobic metabolism. As treatment, insulin needs to be injected, or medication needs to be taken to boost the body's lower insulin production. There must be a balance between how much medication is taken and how much food is eaten.

If not enough food is ingested, then the blood sugar drops ([hypoglycemia](#)) and no glucose is available to enter the cells, even if there is enough insulin to permit glucose to enter the cells. The brain is very susceptible to low blood sugars, and [coma](#) has a very quick onset. Treatment is providing sugar. If the person is awake enough to swallow, a sugar solution by mouth is used, otherwise, intravenous fluids containing glucose are provided. If the lack of sugar was of short duration, the person will awaken almost immediately after treatment. If blood sugars remain low for prolonged periods of time, the brain's ability to recover is potentially lost.

When blood sugar levels spiral high out of control, there is risk of significant dehydration and shock. If there is not enough insulin in the blood stream, cells cannot use the glucose that is present, and instead turn to an alternative anaerobic metabolism to generate energy. Since glucose can't enter cells to be used, [hyperglycemia](#) (hyper= high + gly=sugar = emia) occurs as the glucose level builds up in the blood stream. The kidneys try to excrete excess sugar, but because of chemical concentration gradients between blood and urine, significant amounts of water also are lost. The body quickly becomes dehydrated and blood pressure drops, decreasing blood flow to cells. Cells which are now lacking glucose inside them are now starved of oxygen and turn to anaerobic metabolism, causing acid waste product build up. Excess acid in the body changes the metabolism for all organs, making it more difficult for oxygen to be used.

Conditions will continue worsen until insulin and significant fluids are given to the patient.

Anaphylactic Shock

When the body develops an [allergic reaction](#) to some outside chemical or substance, it can activate its immune system to combat that substance. On occasion, there can be an excess response and multiple organ systems in the body can be affected and fail. This is known as anaphylaxis. Mast cells and basophils (a type of white blood cell) that contain histamine become unstable and leak their contents to affect the muscles of the lung, heart and blood vessels. These are smooth muscles that are part of the regulatory system of the body and are not under conscious control.

- The muscles that surround bronchial tubes go into spasm and cause wheezing and shortness of breath.
- The muscles that surround blood vessels dilate, causing blood pressure to drop.
- The histamine also causes flushing of the skin, urticaria ([hives](#)), vomiting and diarrhea.
- A variety of mechanisms cause the heart muscle to pump weakly and blood vessels to leak fluid.

The combination of these effects decrease blood flow and oxygen supply to cells in the body and can result in shock.

The most common causes of anaphylactic shock include allergic reactions to foods (especially peanuts), [antibiotics](#), and [bee and wasp stings](#). Children are often allergic to eggs, [soy](#), and milk.

These allergens can cause the immune system to turn on the potential cascade to shock. Many patients have allergic reactions that are less severe and can just involve hives, but others can develop shortness of breath, wheezing, swelling of the tongue and mouth, and difficulty swallowing.

Medical interventions include injections of antihistamine like [diphenhydramine](#) (Benadryl), corticosteroids and adrenaline (epinephrine).

Patients with major allergic reactions must try to avoid the chemical trigger. They also often carry an Epipen ([epinephrine injection](#) kit) to inject themselves with epinephrine should an allergic reaction occur.

Shock Symptoms

Shock is defined as abnormal metabolism at the cellular level. Since it is not easy to directly measure cellular problems, the symptoms of shock are indirect measurements of cellular function. Shock is the end stage of all diseases, and symptoms will often be dependant on the underlying cause.

Vital signs

As the patient goes through the various stages of shock, vital signs change. In the early stages, the body tries to compensate by moving fluids around from within cells to the blood stream with an attempt to maintain blood pressure in a normal range. However, there may be a slight rise in the heart rate (tachycardia = tachy or fast + cardia or heart). For example, donating blood. A unit of blood (or about 10% of the bloods volume) is removed, yet the body compensates well, except for a little lightheadedness, which is often resolved by drinking fluids. Another example is exercising and forgetting to drink enough fluids and feeling a little tired at the end of the day.

As the body loses the ability to compensate, the breathing rate gets faster and the tachycardia increases as the body tries to pack as much oxygen onto the remaining red blood cells as possible and deliver them to the cells. Unfortunately, blood pressure starts to drop (hypotension=hypo or low + tension= pressure) as compensation mechanisms fail.

Body function

Cells don't receive enough oxygen and the organs that they comprise begin to fail. All organs may be affected.

- As the brain is affected, the patient may become confused or lose consciousness (coma).
- There may be [chest pain](#) as the heart itself doesn't get an adequate oxygen supply.
- Diarrhea may occur as the large intestine becomes irritated due to hypotension.
- [Kidneys may fail](#) and the body may stop producing urine.
- The skin becomes clammy and pale.

Shock Diagnosis

The approach to the patient in shock requires that treatment occur at the same time as the

diagnosis occurs. The source of the underlying disease needs to be found. Sometimes it is obvious, for example, a trauma victim bleeding from a wound. Other times, the diagnosis is elusive. The type of tests will depend upon the underlying condition.

The diagnosis is most often found through the medical history. A thorough physical examination will be undertaken and the patients vital signs monitored.

- **Patient vital signs monitored** might include continual blood pressure and heart rate monitoring, and oxygen measurement. Special catheters may be inserted into the large veins in the neck, chest, arm, or groin and threaded near the heart or into the pulmonary artery, to measure pressures close to the heart, which may be a better indicator of the body's fluid status. Other catheters may be inserted into arteries (arterial lines) to measure blood pressures more directly. Tubes may be placed in the bladder ([Foley catheter](#)) to measure urine output.
- **Blood laboratory tests** will be performed (the type dependent on the underlying disease or condition).
- **Radiologic tests** may be performed dependent on the underlying illness.

Differential diagnosis

Shock is a common end point of many medical conditions. It has been divided into four main types based on the underlying cause: hypovolemic, distributive, cardiogenic and obstructive. A few additional classifications are occasionally used including: endocrinologic shock.

Hypovolemic

This is the most common type of shock and is caused by insufficient circulating [volume](#). Its primary cause is hemorrhage (internal and/or external), or loss of fluid from the [circulation](#). [Vomiting](#) and [diarrhea](#) are the most common cause in children. With other causes including burns, environmental exposure and excess urine loss due to [diabetic ketoacidosis](#) and [diabetes insipidus](#).

Cardiogenic

This type of shock is caused by the failure of the heart to pump effectively. This can be due to damage to the heart muscle, most often from a large [myocardial infarction](#). Other causes of cardiogenic shock include [dysrhythmias](#), [cardiomyopathy/myocarditis](#), [congestive heart failure](#) (CHF), [contusio cordis](#), or [cardiac valve](#) problems.

Obstructive

Obstructive shock is due to obstruction of blood flow outside of the heart. Several conditions can result in this form of shock.

- [Cardiac tamponade](#) in which fluid in the pericardium prevents inflow of blood into the heart (venous return). [Constrictive pericarditis](#), in which the [pericardium](#) shrinks and hardens, is similar in presentation.
- [Tension pneumothorax](#) Through increased intrathoracic pressure, bloodflow to the heart is prevented (venous return).
- [Pulmonary embolism](#) is the result of a thromboembolic incident in the blood vessels of the [lungs](#) and hinders the return of blood to the heart.
- [Aortic stenosis](#) hinders circulation by obstructing the [ventricular outflow tract](#)

Distributive

Distributive shock is due to impaired utilization of oxygen and thus production of energy by the cell. Examples of this form of shock are:

- [Septic shock](#) is the most common cause of distributive shock. Caused by an overwhelming systemic infection resulting in [vasodilation](#) leading to hypotension. Septic shock can be caused by [Gram negative](#) bacteria such as (among others) [Escherichia coli](#), Proteus species, [Klebsiella pneumoniae](#) which release an [endotoxin](#) which produces adverse biochemical, immunological and occasionally neurological effects which are harmful to the body, and other [Gram-positive](#) cocci, such as [pneumococci](#) and [streptococci](#), and certain fungi as well as Gram-positive bacterial toxins. Septic shock also includes some elements of cardiogenic shock. In 1992, the ACCP/SCCM Consensus Conference Committee defined septic shock: ". . .sepsis-induced hypotension (systolic blood pressure <90 mm Hg or a reduction of 40 mm Hg from baseline) despite adequate fluid resuscitation along with the presence of perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status. Patients who are receiving inotropic or vasopressor agents may have a normalized blood pressure at the time that perfusion abnormalities are identified."
- [Anaphylactic shock](#) Caused by a severe [anaphylactic reaction](#) to an [allergen](#), [antigen](#), [drug](#) or foreign protein causing the release of [histamine](#) which causes widespread vasodilation, leading to hypotension and increased capillary permeability.
- High spinal injuries may cause [neurogenic shock](#). The classic symptoms include [a slow heartrate](#) due to loss of cardiac [sympathetic tone](#) and warm skin due to dilation of the

peripheral blood vessels. (This term can be confused with [spinal shock](#) which is a recoverable loss of function of the [spinal cord](#) after injury and does not refer to the haemodynamic instability per se.)

Endocrine

Based on [endocrine](#) disturbances such as:

- [Hypothyroidism](#) (Can be considered a form of [Cardiogenic shock](#)) in critically ill patients, reduces [cardiac output](#) and can lead to [hypotension](#) and respiratory insufficiency.
- [Thyrotoxicosis](#) ([Cardiogenic shock](#))
 - may induce a reversible cardiomyopathy.
- Acute [adrenal insufficiency](#) ([Distributive shock](#)) is frequently the result of discontinuing [corticosteroid](#) treatment without tapering the dosage. However, surgery and intercurrent disease in patients on corticosteroid therapy without adjusting the dosage to accommodate for increased requirements may also result in this condition.
- Relative adrenal insufficiency ([Distributive shock](#)) in critically ill patients where present [hormone levels](#) are insufficient to meet the higher demands

Shock Treatment

Shock Self-Care at Home

If you come upon a person in shock, the initial response should be to call 101 in Ukraine (911 in Usa) and activate the emergency response system. Self-care at home is not appropriate.

Lay the person down in a safe place and try to keep them warm and comfortable.

If the patient is not awake, is not breathing, and has no heartbeat, it is appropriate to start chest compressions following the American Heart Association guidelines. It is important to send someone to get an AED if one is available.

Shock Medical Treatment

- EMS personnel are well trained in the initial assessment of the patient in shock. The first course of action is to make certain that the **ABCs** have been assessed. The so-called ABCs are:

- **Airway:** assessment of whether the patient is awake enough to try to take their own breaths and/or if there is anything blocking the mouth or nose.
- **Breathing:** assessment of the adequacy of breathing and whether it may need to be assisted with mouth-to-mouth resuscitation or more aggressive interventions like a bag and mask or intubation with an [endotracheal tube](#) and a ventilator.
- **Circulation:** assessment of the adequacy of the blood pressure and determination of whether intravenous lines are needed for delivery of fluid or medications to support the blood pressure.

- **Reducing reperfusion injury & systemic inflammatory response syndrome (SIRS)**
 - Anti-inflammatory drugs
 - NO scavenging and antioxidant drugs
- **Resuscitation fluids**
 - Crystalloid vs. non-crystalloid solutions
 - Isotonic vs. hypertonic solutions
 - Whole blood vs. packed red cells
 - Hemoglobin-based solutions
 - Perfluorocarbon-based solutions
 - Fluid volume-related issues

Fig. Shock resuscitation

- If there is bleeding that is obvious, attempts to control it with direct pressure will be attempted.
- A fingerstick blood sugar will be checked to make certain that hypoglycemia ([low blood sugar](#)) does not exist.
- In the emergency department, diagnosis and treatment will occur at the same time.
- Patients will be treated with oxygen supplementation through nasal cannulae, a face mask, or endotracheal intubation. The method and amount of oxygen will be titrated to make certain enough oxygen is available for the body to use. Again, the goal will be to pack each hemoglobin molecule with oxygen.
- Blood may be transfused if bleeding (hemorrhage) is the cause of the shock state. If

bleeding is not the case, intravenous fluids will be given to bolster the volume of fluids within the blood vessels.

- Intravenous drugs can be used to try to maintain blood pressure (vasopressors). They work by stimulating the heart to beat stronger and by squeezing blood vessels to increase the flow within them.

Shock Prognosis

Shock is a culmination of multiple organ systems in the body that have failed or are in the process of failing. Even with the best of care, there is a significant risk of death. The mortality rate for shock depends upon the type and reason for the shock, and the age and underlying health condition of the patient.

Hemorrhagic Shock

Background

Shock is a state of inadequate perfusion, which does not sustain the physiologic needs of organ tissues. Many conditions, including blood loss but also including nonhemorrhagic states such as dehydration, sepsis, impaired autoregulation, obstruction, decreased myocardial function, and loss of autonomic tone, may produce shock or shocklike states.

Pathophysiology

In hemorrhagic shock, blood loss exceeds the body's ability to compensate and provide adequate tissue perfusion and oxygenation. This frequently is due to trauma, but it may be caused by spontaneous hemorrhage (eg, GI bleeding, childbirth), surgery, and other causes.

Most frequently, clinical hemorrhagic shock is caused by an acute bleeding episode with a discrete precipitating event. Less commonly, hemorrhagic shock may be seen in chronic conditions with subacute blood loss.

- Class I hemorrhage (loss of 0-15%)
 - Little tachycardia
 - Usually no significant change in BP, pulse pressure, respiratory rate
- Class II hemorrhage (loss of 15-30%)
 - HR >100 beats per minute, tachypnea, decreased pulse pressure
- Class III hemorrhage (loss of 30-40%)
 - Marked tachycardia and tachypnea, decreased systolic BP, oliguria
- Class IV hemorrhage (loss of >40%)
 - Marked tachycardia and decreased systolic BP, narrowed pulse pressure, markedly decreased (or no) urinary output
 - Immediately life threatening

Fig. Classes of hemorrhagic shock

Physiologic compensation mechanisms for hemorrhage include initial peripheral and mesenteric vasoconstriction to shunt blood to the central circulation. This is then augmented by a progressive tachycardia. Invasive monitoring may reveal an increased cardiac index, increased oxygen delivery (ie, DO_2), and increased oxygen consumption (ie, VO_2) by tissues. Lactate levels, acid-base status, and other markers also may provide useful indicators of physiologic status. Age, medications, and comorbid factors all may affect a patient's response to hemorrhagic shock.

Failure of compensatory mechanisms in hemorrhagic shock can lead to death. Without intervention, a classic trimodal distribution of deaths is seen in severe hemorrhagic shock. An initial peak of mortality occurs within minutes of hemorrhage due to immediate exsanguination. Another peak occurs after 1 to several hours due to progressive decompensation. A third peak occurs days to weeks later due to sepsis and organ failure.

Epidemiology

Frequency

United States

Accidental injuries remain the leading cause of death in individuals aged 1-44 years. Hemorrhagic shock is a leading cause of death among trauma patients.

History

History taking should address the following:

- Specific details of the mechanism of trauma or other cause of hemorrhage are essential.
- Inquire about a history of bleeding disorders and surgery.
- Prehospital interventions, especially the administration of fluids, and changes in vital signs should be determined. Emergency medical technicians or paramedics should share this information.

Physical

Findings at physical examination may include the following:

- Head, ears, eyes, nose, and throat
 - Sources of hemorrhage usually are apparent.
 - The blood supply of the scalp is rich and can produce significant hemorrhage.
 - Intracranial hemorrhage usually is insufficient to produce shock, except possibly in very young individuals.
- Chest
 - Hemorrhage into the thoracic cavities (pleural, mediastinal, pericardial) may be discerned at physical examination. Ancillary studies often are required for confirmation.
 - Signs of hemothorax may include respiratory distress, decreased breath sounds, and dullness to percussion.
 - Tension hemothorax, or hemothorax with cardiac and contralateral lung compression, produces jugular venous distention and hemodynamic and respiratory decompensation.
 - With pericardial tamponade, the classic triad of muffled heart sounds, jugular venous distention, and hypotension often is present, but these signs may be difficult to appreciate in the setting of an acute resuscitation.
- Abdomen
 - Injuries to the liver or spleen are common causes of hemorrhagic shock. Spontaneous rupture of abdominal aortic aneurysm (AAA) may also cause severe intra-abdominal hemorrhage and shock.
 - Blood irritates the peritoneal cavity; diffuse tenderness and peritonitis are common

when blood is present. However, the patient with altered mental status or multiple concomitant injuries may not have the classic signs and symptoms at physical examination.

- Progressive abdominal distention in hemorrhagic shock is highly suggestive of intra-abdominal hemorrhage.
- Pelvis
 - Fractures can produce massive bleeding. Retroperitoneal bleeding must be suspected.
 - Flank ecchymosis may indicate retroperitoneal hemorrhage.
- Extremities
 - Hemorrhage from extremity injuries may be apparent, or tissues may obscure significant bleeding.
 - Femoral fractures may produce significant blood loss.
- Nervous system
 - Agitation and combativeness may be seen in the initial stages of hemorrhagic shock.
 - These signs are followed by a progressive decline in level of consciousness due to cerebral hypoperfusion or concomitant head injury.

Differential Diagnoses

- Abdominal Trauma, Blunt
- Abdominal Trauma, Penetrating
- Abortion, Complications
- Anemia, Acute
- Anemia, Chronic
- Blast Injuries
- Disseminated Intravascular Coagulation
- Pneumothorax, Tension and Traumatic
- Pregnancy, Ectopic
- Pregnancy, Postpartum Hemorrhage
- Pregnancy, Trauma
- Shock, Cardiogenic
- Shock, Hypovolemic
- Shock, Septic
- Spinal Cord Injuries

Laboratory Studies

- Laboratory studies are essential in management of many forms of hemorrhagic shock. Baseline levels are determined frequently, but these infrequently change the initial management after trauma. Serial evaluations of the following can help guide ongoing therapy.
 - CBC
 - Prothrombin time and/or activated partial thromboplastin time
 - Urine output rate can help guide adequacy of perfusion.
 - ABGs (Levels reflect acid-base and perfusion status.)
 - Lactate and base deficit are used in some centers to indicate the degree of metabolic debt. Clearance of these markers over time can reflect the adequacy of resuscitation.
- Typed and crossmatched packed red blood cells should be ordered immediately based on clinical suspicion of hemorrhagic shock. Fresh frozen plasma and platelets also may be required to correct or prevent coagulopathies that develop in severe hemorrhagic shock.

Imaging Studies

Cervical spine, chest, and pelvis radiographs are the standard screening images for severe trauma. Other radiographs may be indicated for orthopedic injuries.

Computed tomography can be used to image the appropriate region of suspected injury. CT scanning frequently is the method of choice for evaluating possible intra-abdominal and/or retroperitoneal sources of hemorrhage in stable patients (see the image below). Oral contrast material may not increase the diagnostic yield of abdominal CT scanning in blunt trauma. Scanning should not be delayed to administer oral contrast material.

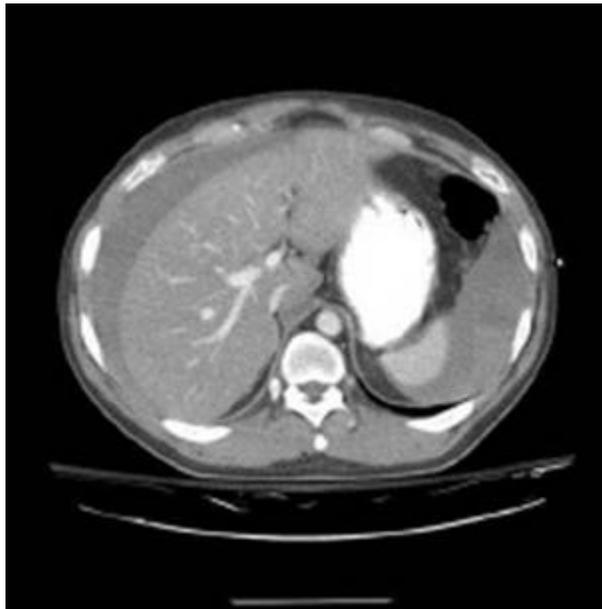

Fig. CT scan of a 26-year-old man after a motor vehicle crash shows a significant amount of intra-abdominal bleeding.

Bedside ultrasonography abdominal ultrasonography can be very useful for the rapid detection of AAA and free intra-abdominal fluid. Thoracic ultrasonographic findings can immediately confirm hemothorax or pericardial tamponade.

Directed angiography may be diagnostic and therapeutic. Interventional radiologists have had good success achieving hemostasis in hemorrhage caused by a variety of vessels and organs.

Other Tests

- An ECG can be useful for detecting dysrhythmias and cardiac sequelae of shock.
- Tissue oximetry using Near Infrared Spectroscopy (NIRS) shows promise for continuous noninvasive measurement of perfusion in hemorrhagic shock and other conditions.

Procedures

- Tube thoracostomy is necessary in significant hemothorax with or without pneumothorax.
- Central venous access facilitates fluid resuscitation and monitoring of central venous pressure and is necessary if peripheral intravenous access is inadequate or impossible to obtain.
- Diagnostic peritoneal lavage is used to detect intra-abdominal blood, fluid, and intestinal contents. It is sensitive but not specific for abdominal injury. It is not used to evaluate the retroperitoneum, which can hold significant hemorrhage, and does not identify the source

of hemorrhage.

Prehospital Care

The standard care consists of rapid assessment and expeditious transport to an appropriate center for evaluation and definitive care.

Intravenous access and fluid resuscitation are standard. However, this practice has become controversial.

- For many years, aggressive fluid administration has been advocated to normalize hypotension associated with severe hemorrhagic shock. Recent studies of urban patients with penetrating trauma have shown that mortality increases with these interventions; these findings call these practices into question.
- Reversal of hypotension prior to the achievement of hemostasis may increase hemorrhage, dislodge partially formed clots, and dilute existing clotting factors. Findings from animal studies of uncontrolled hemorrhage support these postulates. These provocative results raise the possibility that moderate hypotension may be physiologically protective and should be permitted, if present, until hemorrhage is controlled.
- These findings should not yet be clinically extrapolated to other settings or etiologies of hemorrhage. The ramifications of permissive hypotension in humans remain speculative, and safety limits have not been established yet.

Emergency Department Care

Management of hemorrhagic shock should be directed toward optimizing perfusion of and oxygen delivery to vital organs.

Diagnosis and treatment of the underlying hemorrhage must be performed rapidly and concurrently with management of shock.

Supportive therapy, including oxygen administration, monitoring, and establishment of intravenous access (eg, 2 large-bore catheters in peripheral lines, central venous access), should be initiated.

- Intravascular volume and oxygen-carrying capacity should be optimized.
- In addition to crystalloids, some colloid solutions, hypertonic solutions, and oxygen-carrying solutions (eg, hemoglobin-based and perfluorocarbon emulsions) are used or

being investigated for use in hemorrhagic shock.

- Blood products are often required in severe hemorrhagic shock. Replacement of lost components using red blood cells (RBCs), fresh frozen plasma (FFP), and platelets may be essential. The ideal ratio of RBCs to FFP remains undetermined. Recent combat experience has suggested that aggressive use of FFP may reduce coagulopathies and improve outcomes.

Determination of the site and etiology of hemorrhage is critical to guide further interventions and definitive care.

Control of hemorrhage may be achieved in the ED, or control may require consultations and special interventions.

Consultations

Consult a general or specialized surgeon, gastroenterologist, obstetrician-gynecologist, interventional radiologist, and others as required.

Medication Summary

Achievement of hemostasis, fluid resuscitation, and use of blood products are the mainstays of treatment. Pressor agents may be useful in some settings (eg, spinal shock), but these agents should not be substitutes for adequate volume resuscitation and blood product replacement.

Tranexamic acid (TXA) is an inexpensive antifibrinolytic drug that promotes blood clotting by preventing blood clots from breaking down. It has been shown to reduce mortality in trauma patients with uncontrolled hemorrhage. Further studies are planned to determine specific recommendations for TXA administration.

Vasopressors

Class Summary

These agents augment both coronary and cerebral blood flow during the low-flow state associated with shock.

[Dopamine \(Intropin\)](#)

Stimulates both adrenergic and dopaminergic receptors. Hemodynamic effect is dependent on the dose. Lower doses predominantly stimulate dopaminergic receptors that in turn produce renal and mesenteric vasodilation. Higher doses produce cardiac stimulation and renal vasodilation

Norepinephrine (Levophed)

Used in protracted hypotension following adequate fluid-volume replacement. Stimulates beta1-adrenergic and alpha-adrenergic receptors, which, in turn, increase cardiac muscle contractility and heart rate, as well as vasoconstriction; result is increased systemic BP and coronary blood flow.

Vasopressin (Pitressin)

Has vasopressor and ADH activity. Increases water resorption at distal renal tubular epithelium (ADH effect) and promotes smooth muscle contraction throughout the vascular bed of the renal tubular epithelium (vasopressor effects); however, vasoconstriction also is increased in splanchnic, portal, coronary, cerebral, peripheral, pulmonary, and intrahepatic vessels.

Epinephrine (Adrenalin, Bronitin)

Used for hypotension refractory to dopamine. Alpha-agonist effects include increased peripheral vascular resistance, reversed peripheral vasodilatation, systemic hypotension, and vascular permeability. Beta2-agonist effects include bronchodilatation, chronotropic cardiac activity, and positive inotropic effects.

Further Inpatient Care

- Admit the patient to an ICU, surgical ICU, or pediatric ICU.

- Patients with hemorrhagic shock should be admitted to an intensive care or monitored setting appropriate for the underlying condition and physiologic state.

Transfer

- In hospitals without facilities to provide definitive care, patients should be stabilized as much as possible and transferred to a facility with a higher level of care.

Complications

- Coagulopathies may occur in severe hemorrhage. Fluid resuscitation, while necessary, may exacerbate coagulopathies.
- Sepsis and multiple organ system failure occur days after acute hemorrhagic shock.
- Death is a possible complication.

Hypovolemic Shock

Hypovolemic shock refers to a medical or surgical condition in which rapid fluid loss results in multiple organ failure due to inadequate circulating volume and subsequent inadequate perfusion. Most often, hypovolemic shock is secondary to rapid blood loss (hemorrhagic shock).

Acute external blood loss secondary to penetrating trauma and severe GI bleeding disorders are 2 common causes of hemorrhagic shock. Hemorrhagic shock can also result from significant acute internal blood loss into the thoracic and abdominal cavities.

Two common causes of rapid internal blood loss are solid organ injury and rupture of an abdominal aortic aneurysm. Hypovolemic shock can result from significant fluid (other than blood) loss. Two examples of hypovolemic shock secondary to fluid loss include refractory gastroenteritis and extensive burns. The remainder of this article concentrates mainly on hypovolemic shock secondary to blood loss and the controversies surrounding the treatment of this condition. The reader is referred to other articles for discussions of the pathophysiology and treatment for hypovolemic shock resulting from losses of fluid other than blood.

The many life-threatening injuries experienced during the wars of the 1900s have significantly affected the development of the principles of hemorrhagic shock resuscitation. During World War I, W.B. Cannon recommended delaying fluid resuscitation until the cause of the hemorrhagic shock was repaired surgically. Crystalloids and blood were used extensively

during World War II for the treatment of patients in unstable conditions. Experience from the Korean and Vietnam wars revealed that volume resuscitation and early surgical intervention were paramount for surviving traumatic injuries resulting in hemorrhagic shock. These and other principles helped in the development of present guidelines for the treatment of traumatic hemorrhagic shock. However, recent investigators have questioned these guidelines, and today, controversies exist concerning the optimal treatment of hemorrhagic shock.

For more information, see Medscape's [Trauma Resource Center](#).

Pathophysiology

The human body responds to acute hemorrhage by activating the following major physiologic systems: the hematologic, cardiovascular, renal, and neuroendocrine systems.

The hematologic system responds to an acute severe blood loss by activating the coagulation cascade and contracting the bleeding vessels (by means of local thromboxane A₂ release). In addition, platelets are activated (also by means of local thromboxane A₂ release) and form an immature clot on the bleeding source. The damaged vessel exposes collagen, which subsequently causes fibrin deposition and stabilization of the clot. Approximately 24 hours are needed for complete clot fibrination and mature formation.

The cardiovascular system initially responds to hypovolemic shock by increasing the heart rate, increasing myocardial contractility, and constricting peripheral blood vessels. This response occurs secondary to an increased release of norepinephrine and decreased baseline vagal tone (regulated by the baroreceptors in the carotid arch, aortic arch, left atrium, and pulmonary vessels). The cardiovascular system also responds by redistributing blood to the brain, heart, and kidneys and away from skin, muscle, and GI tract.

The renal system responds to hemorrhagic shock by stimulating an increase in renin secretion from the juxtaglomerular apparatus. Renin converts angiotensinogen to angiotensin I, which subsequently is converted to angiotensin II by the lungs and liver. Angiotensin II has 2 main effects, both of which help to reverse hemorrhagic shock, vasoconstriction of arteriolar smooth muscle, and stimulation of aldosterone secretion by the adrenal cortex. Aldosterone is responsible for active sodium reabsorption and subsequent water conservation.

The neuroendocrine system responds to hemorrhagic shock by causing an increase in circulating antidiuretic hormone (ADH). ADH is released from the posterior pituitary gland in

response to a decrease in BP (as detected by baroreceptors) and a decrease in the sodium concentration (as detected by osmoreceptors). ADH indirectly leads to an increased reabsorption of water and salt (NaCl) by the distal tubule, the collecting ducts, and the loop of Henle.

The pathophysiology of hypovolemic shock is much more involved than what was just listed. To explore the pathophysiology in more detail, references for further reading are provided in the bibliography. These intricate mechanisms list above are effective in maintaining vital organ perfusion in severe blood loss. Without fluid and blood resuscitation and/or correction of the underlying pathology causing the hemorrhage, cardiac perfusion eventually diminishes, and multiple organ failure soon follows.

History

- In a patient with possible shock secondary to hypovolemia, the history is vital in determining the possible causes and in directing the workup. Hypovolemic shock secondary to external blood loss typically is obvious and easily diagnosed. Internal bleeding may not be as obvious as patients may complain only of weakness, lethargy, or a change in mental status.
- Symptoms of shock, such as weakness, lightheadedness, and confusion, should be assessed in all patients.
- In the patient with trauma, determine the mechanism of injury and any information that may heighten suspicion of certain injuries (eg, steering wheel damage or extensive passenger compartment intrusion in a motor vehicle accident).
- If conscious, the patient may be able to indicate the location of pain.
- Vital signs, prior to arrival in the ED, should also be noted.
- Chest, abdominal, or back pain may indicate a vascular disorder.
- The classic sign of a thoracic aneurysm is a tearing pain radiating to the back. Abdominal aortic aneurysms usually result in abdominal, back pain, or flank pain.
- In patients with GI bleeding, inquiry about hematemesis, melena, alcohol drinking history, excessive nonsteroidal anti-inflammatory drug use, and coagulopathies (iatrogenic or otherwise) is very important.
 - The chronology of vomiting and hematemesis should be determined.
 - The patient who presents with hematemesis after multiple episodes of forceful vomiting is more likely to have Boerhaave syndrome or a Mallory-Weiss tear,

whereas a patient with a history of hematemesis from the start is more likely to have peptic ulcer disease or esophageal varices.

- If a gynecologic cause is being considered, gather information about the following: last menstrual period, risk factors for ectopic pregnancy, vaginal bleeding (including amount and duration), vaginal passage of products of conception, and pain. All women of childbearing age should undergo a pregnancy test, regardless of whether they believe that they are pregnant. A negative pregnancy test typically excludes ectopic pregnancy as a diagnosis.

Physical

The physical examination should always begin with an assessment of the airway, breathing, and circulation. Once these have been evaluated and stabilized, the circulatory system should be evaluated for signs and symptoms of shock.

Do not rely on systolic BP as the main indicator of shock; this practice results in delayed diagnosis. Compensatory mechanisms prevent a significant decrease in systolic BP until the patient has lost 30% of the blood volume. More attention should be paid to the pulse, respiratory rate, and skin perfusion. Also, patients taking beta-blockers may not present with tachycardia, regardless of the degree of shock.

Classes of hemorrhage have been defined, based on the percentage of blood volume loss. However, the distinction between these classes in the hypovolemic patient often is less apparent. Treatment should be aggressive and directed more by response to therapy than by initial classification.

- Class I hemorrhage (loss of 0-15%)
 - In the absence of complications, only minimal tachycardia is seen.
 - Usually, no changes in BP, pulse pressure, or respiratory rate occur.
 - A delay in capillary refill of longer than 3 seconds corresponds to a volume loss of approximately 10%.
- Class II hemorrhage (loss of 15-30%)
 - Clinical symptoms include tachycardia (rate >100 beats per minute), tachypnea, decrease in pulse pressure, cool clammy skin, delayed capillary refill, and slight anxiety.
 - The decrease in pulse pressure is a result of increased catecholamine levels, which

causes an increase in peripheral vascular resistance and a subsequent increase in the diastolic BP.

- Class III hemorrhage (loss of 30-40%)
 - By this point, patients usually have marked tachypnea and tachycardia, decreased systolic BP, oliguria, and significant changes in mental status, such as confusion or agitation.
 - In patients without other injuries or fluid losses, 30-40% is the smallest amount of blood loss that consistently causes a decrease in systolic BP.
 - Most of these patients require blood transfusions, but the decision to administer blood should be based on the initial response to fluids.
- Class IV hemorrhage (loss of >40%)
 - Symptoms include the following: marked tachycardia, decreased systolic BP, narrowed pulse pressure (or immeasurable diastolic pressure), markedly decreased (or no) urinary output, depressed mental status (or loss of consciousness), and cold and pale skin.
 - This amount of hemorrhage is immediately life threatening.
- In the patient with trauma, hemorrhage usually is the presumed cause of shock. However, it must be distinguished from other causes of shock. These include cardiac tamponade (muffled heart tones, distended neck veins), tension pneumothorax (deviated trachea, unilaterally decreased breath sounds), and spinal cord injury (warm skin, lack of expected tachycardia, neurological deficits).
- The 4 areas in which life-threatening hemorrhage can occur are as follows: chest, abdomen, thighs, and outside the body.
 - The chest should be auscultated for decreased breath sounds, because life-threatening hemorrhage can occur from myocardial, vessel, or lung laceration.
 - The abdomen should be examined for tenderness or distension, which may indicate intraabdominal injury.
 - The thighs should be checked for deformities or enlargement (signs of femoral fracture and bleeding into the thigh).
 - The patient's entire body should then be checked for other external bleeding.
- In the patient without trauma, the majority of the hemorrhage is in the abdomen. The abdomen should be examined for tenderness, distension, or bruits. Look for evidence of an aortic aneurysm, peptic ulcer disease, or liver congestion. Also check for other signs of bruising or bleeding.

- In the pregnant patient, perform a sterile speculum examination. However, with third-trimester bleeding, the examination should be performed as a "double set-up" in the operating room. Check for abdominal, uterine, or adnexal tenderness.

Causes

The causes of hemorrhagic shock are traumatic, vascular, GI, or pregnancy related.

- Traumatic causes can result from penetrating and blunt trauma. Common traumatic injuries that can result in hemorrhagic shock include the following: myocardial laceration and rupture, major vessel laceration, solid abdominal organ injury, pelvic and femoral fractures, and scalp lacerations.
- Vascular disorders that can result in significant blood loss include aneurysms, dissections, and arteriovenous malformations.
- GI disorders that can result in hemorrhagic shock include the following: bleeding esophageal varices, bleeding peptic ulcers, Mallory-Weiss tears, and aortointestinal fistulas.
- Pregnancy-related disorders include ruptured ectopic pregnancy, placenta previa, and abruption of the placenta. Hypovolemic shock secondary to an ectopic pregnancy is common. Hypovolemic shock secondary to an ectopic pregnancy in a patient with a negative urine pregnancy test is rare but has been reported.

Differential Diagnoses

- Abruptio Placentae
- Aneurysm, Abdominal
- Aneurysm, Thoracic
- Fractures, Femur
- Fractures, Pelvic
- Gastritis and Peptic Ulcer Disease
- Placenta Previa
- Pregnancy, Ectopic
- Pregnancy, Postpartum Hemorrhage
- Pregnancy, Trauma
- Shock, Hemorrhagic
- Shock, Hypovolemic

- Toxicity, Iron

Laboratory Studies

- After the history is taken and the physical examination is performed, further workup depends on the probable cause of the hypovolemia, as well as on the stability of the patient's condition.
- Initial laboratory studies should include analysis of the CBC, electrolyte levels (eg, Na, K, Cl, HCO₃, BUN, creatinine, glucose levels), prothrombin time, activated partial thromboplastin time, ABGs, urinalysis (in patients with trauma), and a urine pregnancy test. Blood should be typed and cross-matched.

Imaging Studies

- Patients with marked hypotension and/or unstable conditions must first be resuscitated adequately. This treatment takes precedence over imaging studies and may include immediate interventions and immediately taking the patient to the operating room.
- The workup for the patient with trauma and signs and symptoms of hypovolemia is directed toward finding the source of blood loss.
- The atraumatic patient with hypovolemic shock requires ultrasonographic examination in the ED if an abdominal aortic aneurysm is suspected. If GI bleeding is suspected, a nasogastric tube should be placed, and gastric lavage should be performed. An upright chest radiograph should be obtained if a perforated ulcer or Boerhaave syndrome is a possibility. Endoscopy can be performed (usually after the patient has been admitted) to further delineate the source of bleeding.
- A pregnancy test should be performed in all female patients of childbearing age. If the patient is pregnant and in shock, surgical consultation and the consideration of bedside pelvic ultrasonography should be immediately performed in the ED. Hypovolemic shock secondary to an ectopic pregnancy is common. Hypovolemic shock secondary to an ectopic pregnancy in a patient with a negative pregnancy test, although rare, has been reported.
- If thoracic dissection is suspected because of the mechanism and initial chest radiographic findings, the workup may include transesophageal echocardiography, aortography, or CT scanning of the chest.
- If a traumatic abdominal injury is suspected, a focused abdominal sonography for trauma (FAST) ultrasonography examination may be performed in the stable or unstable patient.

Computed tomography (CT) scanning typically is performed in the stable patient.

- If long-bone fractures are suspected, radiographs should be obtained.

Prehospital Care

The treatment of patients with hypovolemic shock often begins at an accident scene or at home. The prehospital care team should work to prevent further injury, transport the patient to the hospital as rapidly as possible, and initiate appropriate treatment in the field. Direct pressure should be applied to external bleeding vessels to prevent further blood loss.

- Prevention of further injury applies mostly to the patient with trauma. The cervical spine must be immobilized, and the patient must be extricated, if applicable, and moved to a stretcher. Splinting of fractures can minimize further neurovascular injury and blood loss.
- Although in selected cases stabilization may be beneficial, rapid transport of sick patients to the hospital remains the most important aspect of prehospital care. Definitive care of the hypovolemic patient usually requires hospital, and sometimes surgical, intervention. Any delay in definitive care, eg, such as delayed transport, is potentially harmful.
- Most prehospital interventions involve immobilizing the patient (if trauma is involved), securing an adequate airway, ensuring ventilation, and maximizing circulation.
 - In the setting of hypovolemic shock, positive-pressure ventilation may diminish venous return, diminish cardiac output, and worsen the shock state. While oxygenation and ventilation are necessary, excessive positive-pressure ventilation can be detrimental for a patient suffering hypovolemic shock.
 - Appropriate treatment usually can be initiated without delaying transport. Some procedures, such as starting intravenous (IV) lines or splinting of extremities, can be performed while a patient is being extricated. However, procedures in the field that prolong transportation should be delayed. Benefits to giving IV fluids prior to departure from the scene are not clear; however, IV lines and fluid resuscitation should be started and continued once the patient is en route to definitive care.
- In recent years, there has been considerable debate regarding the use of military antishock trousers (MAST). MAST were introduced in the 1960s and, based mostly on anecdotal reports of success, their use became standard therapy in the prehospital treatment of hypovolemic shock in the late 1970s. By the 1980s, the American College of Surgeons Committee on Trauma included their use in the standard of care for all patients with trauma and signs or symptoms of shock. Since that time, studies have failed to show

improved outcome with the use of MAST. The American College of Surgeons Committee on Trauma no longer recommends the use of MAST.

Emergency Department Care

Three goals exist in the emergency department treatment of the patient with hypovolemic shock as follows: (1) maximize oxygen delivery - completed by ensuring adequacy of ventilation, increasing oxygen saturation of the blood, and restoring blood flow, (2) control further blood loss, and (3) fluid resuscitation. Also, the patient's disposition should be rapidly and appropriately determined.

Maximizing oxygen delivery

The patient's airway should be assessed immediately upon arrival and stabilized if necessary. The depth and rate of respirations, as well as breath sounds, should be assessed. If pathology (eg, pneumothorax, hemothorax, flail chest) that interferes with breathing is found, it should be addressed immediately. High-flow supplemental oxygen should be administered to all patients, and ventilatory support should be given, if needed. Excessive positive-pressure ventilation can be detrimental for a patient suffering hypovolemic shock and should be avoided.

Two large-bore IV lines should be started. The Poiseuille law states that flow is inversely related to the length of the IV catheter and directly related to its radius to the fourth power. Thus, a short large-caliber IV catheter is ideal; the caliber is much more significant than the length. IV access may be obtained by means of percutaneous access in the antecubital veins, cutdown of saphenous or arm veins, or access in the central veins by using the Seldinger technique. If central lines are obtained, a large-bore single-lumen catheter should be used. Intraosseous access has and continues to be used for hypotensive children younger than 6 years. Intraosseous access has also been used in hypotensive adults. The most important factor in determining the route of access is the practitioner's skill and experience.

Placement of an arterial line should be considered for patients with severe hemorrhage. For these patients, the arterial line will provide continuous blood pressure monitoring and also ease arterial blood gas testing.

Once IV access is obtained, initial fluid resuscitation is performed with an isotonic crystalloid, such as lactated Ringer solution or normal saline. An initial bolus of 1-2 L is given in an adult (20 mL/kg in a pediatric patient), and the patient's response is assessed.

If vital signs return to normal, the patient may be monitored to ensure stability, and blood should be sent for typed and cross-matched. If vital signs transiently improve, crystalloid infusion should continue and type-specific blood obtained. If little or no improvement is seen, crystalloid infusion should continue, and type O blood should be given (type O Rh-negative blood should be given to female patients of childbearing age to prevent sensitization and future complications).

If a patient is moribund and markedly hypotensive (class IV shock), both crystalloid and type O blood should be started initially. These guidelines for crystalloid and blood infusion are not rules; therapy should be based on the condition of the patient.

The position of the patient can be used to improve circulation; one example is raising the hypotensive patient's legs while fluid is being given. Another example of useful positioning is rolling a hypotensive gravid patient with trauma onto her left side, which displaces the fetus from the inferior vena cava and increases circulation. The Trendelenburg position is no longer recommended for hypotensive patients, as the patient is predisposed to aspiration. In addition, the Trendelenburg position does not improve cardiopulmonary performance and may worsen gas exchange.

Autotransfusion may be a possibility in some patients with trauma. Several devices that allow for the sterile collection, anticoagulation, filtration, and retransfusion of blood are available. In the trauma setting, this blood almost always is from a hemothorax collected by means of tube thoracostomy.

Controlling further blood loss

Control of further hemorrhage depends on the source of bleeding and often requires surgical intervention. In the patient with trauma, external bleeding should be controlled with direct pressure; internal bleeding requires surgical intervention. Long-bone fractures should be treated with traction to decrease blood loss.

In the patient whose pulse is lost in the ED or just prior to arrival, an emergency thoracotomy with cross-clamping of the aorta may be indicated to preserve blood flow to the brain. This procedure is palliative at best and requires immediate transfer to the operating room.

In the patient with GI bleeding, intravenous vasopressin and H₂ blockers have been used. Vasopressin commonly is associated with adverse reactions, such as hypertension, arrhythmias,

gangrene, and myocardial or splanchnic ischemia. Therefore, it should be considered secondary to more definitive measures. H₂ blockers are relatively safe but have no proven benefit.

Somatostatin and octreotide infusions have been shown to reduce gastrointestinal bleeding from varices and peptic ulcer disease. These agents possess the advantages of vasopressin without the significant side effects.

In patients with variceal bleeding, use of a Sengstaken-Blakemore tube can be considered. These devices have a gastric balloon and an esophageal balloon. The gastric one is inflated first, and then the esophageal one is inflated if bleeding continues. The use of this tube has been associated with severe adverse reactions, such as esophageal rupture, asphyxiation, aspiration and mucosal ulceration. For this reason, its use should be considered only as a temporary measure in extreme circumstances.

Virtually all causes of acute gynecological bleeding that cause hypovolemia (eg, ectopic pregnancy, placenta previa, abruptio placenta, ruptured cyst, miscarriage) require surgical intervention.

Early consultation and definitive care are the keys. The goal in the ED is to stabilize the hypovolemic patient, determine the cause of bleeding, and provide definitive care as quickly as possible. If transfer to another hospital is necessary, resources should be mobilized early.

In patients with trauma, if the emergency medical services personnel indicate potential serious injury, the surgeon (or trauma team) should be notified prior to the patient's arrival. In a 55-year-old patient with abdominal pain, for example, emergency ultrasonography of the abdomen may be necessary to identify an abdominal aortic aneurysm before the vascular surgeon is notified. Every patient should be individually evaluated, because delaying definitive care can increase morbidity and mortality.

Resuscitation

Whether crystalloids or colloids are best for resuscitation continues to be a matter for discussion and research. Many fluids have been studied for use in resuscitation; these include isotonic sodium chloride solution, lactated Ringer solution, hypertonic saline, albumin, purified protein fraction, fresh frozen plasma, hetastarch, pentastarch, and dextran 70.

Proponents of colloid resuscitation argue that the increased oncotic pressure produced with

these substances decreases pulmonary edema. However, the pulmonary vasculature allows considerable flow of material, including proteins, between the intravascular space and interstitium. Maintenance of the pulmonary hydrostatic pressure at less than 15 mm Hg appears to be a more important factor in preventing pulmonary edema.

Another argument is that less colloid is needed to increase the intravascular volume. Studies have shown this to be true. However, they still have not demonstrated any difference in outcome with colloids compared with crystalloids.

Synthetic colloid solutions, such as hetastarch, pentastarch, and dextran 70, have some advantages compared with natural colloids such as purified protein fraction, fresh frozen plasma, and albumin. They have the same volume-expanding properties, but because of their structures and high molecular weights, they remain mostly in the intravascular space, reducing the occurrence of interstitial edema. Although theoretic advantages exist, studies have failed to show a difference in ventilatory parameters, pulmonary function test results, days using a ventilator, total hospital days, or survival.

The European Society of Intensive Care Medicine (ESICM) advises against the use of colloids-hydroxyethyl starches (HES) in patients with severe sepsis or risk of acute kidney injury. Physicians should also avoid using colloids in patients with head injury and refrain from administering gelatins and HES in organ donors

The combination of hypertonic saline and dextran also has been studied because of previous evidence that it may improve cardiac contractility and circulation. Studies in the US and Japan have failed to show any difference when this combination was compared with isotonic sodium chloride solution or lactated Ringer solution. Thus, despite the many available resuscitation fluids, current recommendations still advocate the use of normal saline or lactated Ringer solution. In the US, one reason for the predominant use of crystalloids over the other resuscitative fluids is cost.

Recent literature suggests that the early administration of FFP and platelets improves survival and decreases overall PRBC need in patients undergoing a massive transfusion

Restoring normal circulating volume and BP prior to definitive control of bleeding

Although some data indicate that a systolic BP of 80-90 mm Hg may be adequate in penetrating truncal trauma without head injury, further studies are needed.

Current recommendations are for aggressive fluid resuscitation with lactated Ringer solution or normal saline in all patients with signs and symptoms of shock, regardless of underlying cause.

Medication Summary

The goals of pharmacotherapy are to reduce morbidity and prevent complications.

Antisecretory agents

Class Summary

These agents have vasoconstrictive properties and can reduce blood flow to portal systems.

Somatostatin (Zecnil)

Naturally occurring tetradecapeptide isolated from the hypothalamus and pancreatic and enteric epithelial cells. Diminishes blood flow to portal system because of vasoconstriction. Has similar effects as vasopressin but does not cause coronary vasoconstriction. Rapidly cleared from the circulation, with an initial half-life of 1-3 min.

Octreotide (Sandostatin)

Synthetic octapeptide. Compared to somatostatin, has similar pharmacological actions with greater potency and longer duration of action.

Used as adjunct to nonoperative management of secreting cutaneous fistulas of the stomach, duodenum, small intestine (jejunum and ileum), or pancreas.

Complications

- Neurologic sequelae
- Death

Prognosis

- The prognosis is dependent on the degree of volume loss.

Cardiogenic Shock

Background

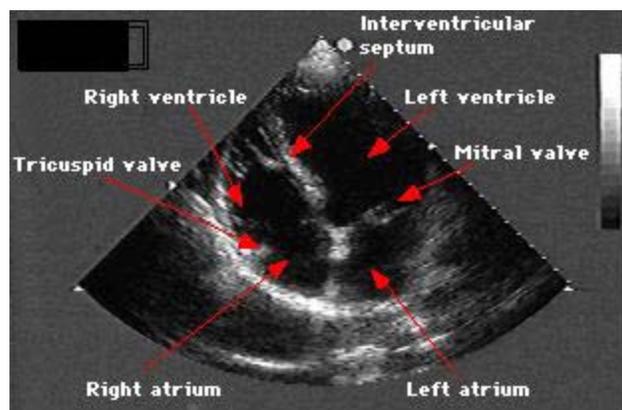

Cardiogenic shock is a physiologic state in which inadequate tissue perfusion results from cardiac dysfunction, most often systolic. It is a major, and frequently fatal, complication of a variety of acute and chronic disorders, occurring most commonly following acute [myocardial infarction \(MI\)](#). (See Pathophysiology, Etiology, and Prognosis.)

Although ST-segment elevation MI (STEMI, previously termed Q-wave MI) is encountered in most patients, cardiogenic shock may also develop in patients with non-ST-segment elevation [acute coronary syndrome](#) (NSTEMI, NSTACS, or [unstable angina](#)). (See the images below.)

Patient with an acute anterolateral myocardial infarction who developed cardiogenic shock. Coronary angiography images showed severe stenosis of the left anterior descending

coronary artery, which was dilated by percutaneous transluminal coronary angioplasty.

Echocardiogram image from a patient with cardiogenic shock shows enlarged cardiac chambers; the motion study showed poor left ventricular function. Courtesy of R. Hoeschen, MD.

The clinical definition of cardiogenic shock is decreased cardiac output and evidence of tissue hypoxia in the presence of adequate intravascular volume. Hemodynamic criteria for cardiogenic shock are sustained hypotension (systolic blood pressure < 90 mm Hg for at least 30 min) and a reduced cardiac index (< 2.2 L/min/m²) in the presence of elevated pulmonary capillary wedge pressure (>15 mm Hg). (See DDX, Workup.)

The diagnosis of cardiogenic shock can sometimes be made at the bedside by observing hypotension, absence of hypovolemia, and clinical signs of poor tissue perfusion, which include oliguria, cyanosis, cool extremities, and altered mentation. These signs usually persist after attempts have been made to correct hypovolemia, arrhythmia, hypoxia, and acidosis. (See Presentation, DDX.)

Pathophysiology

Cardiogenic shock is recognized as a low cardiac output state secondary to extensive left ventricular infarction, development of a mechanical defect (eg, ventricular septal defect or [papillary muscle rupture](#)), or right ventricular infarction.

Disorders that can result in the acute deterioration of cardiac function and lead to cardiogenic

shock include myocardial infarction (MI) or myocardial ischemia, acute myocarditis, sustained arrhythmia, severe valvular dysfunction, and decompensation of end-stage cardiomyopathy from multiple etiologies. Autopsy studies show that cardiogenic shock is generally associated with the loss of more than 40% of the left ventricular myocardial muscle.

Myocardial pathology

Cardiogenic shock is characterized by systolic and diastolic dysfunction. Patients who develop cardiogenic shock from acute MI consistently have evidence of progressive myocardial necrosis with infarct extension. Decreased coronary perfusion pressure and increased myocardial oxygen demand play a role in the vicious cycle that leads to cardiogenic shock.

Patients suffering from cardiogenic shock often have multivessel coronary artery disease with limited coronary blood flow reserve. Ischemia remote from the infarcted zone is an important contributor to shock. Myocardial diastolic function is also impaired, because ischemia causes decreased myocardial compliance, thereby increasing left ventricular filling pressure, which may lead to pulmonary edema and hypoxemia.

Cellular pathology

Tissue hypoperfusion, with consequent cellular hypoxia, causes anaerobic glycolysis, the accumulation of lactic acid, and intracellular acidosis. Also, myocyte membrane transport pumps fail, which decreases transmembrane potential and causes intracellular accumulation of sodium and calcium, resulting in myocyte swelling.

If ischemia is severe and prolonged, myocardial cellular injury becomes irreversible and leads to myonecrosis, which includes mitochondrial swelling, the accumulation of denatured proteins and chromatin, and lysosomal breakdown. These events induce fracture of the mitochondria, nuclear envelopes, and plasma membranes.

Additionally, apoptosis (programmed cell death) may occur in peri-infarcted areas and may contribute to myocyte loss. Activation of inflammatory cascades, oxidative stress, and stretching of the myocytes produces mediators that overpower inhibitors of apoptosis, thus activating the apoptosis.

Reversible myocardial dysfunction

Large areas of myocardium that are dysfunctional but still viable can contribute to the development of cardiogenic shock in patients with MI. This potentially reversible dysfunction is often described as myocardial stunning or as hibernating myocardium. Although hibernation is considered a different physiologic process than myocardial stunning, the conditions are difficult to distinguish in the clinical setting and they often coexist.

Myocardial stunning represents postischemic dysfunction that persists despite restoration of normal blood flow. By definition, myocardial dysfunction from stunning eventually resolves completely. The mechanism of myocardial stunning involves a combination of oxidative stress, abnormalities of calcium homeostasis, and circulating myocardial depressant substances.

Hibernating myocardium is a state of persistently impaired myocardial function at rest, which occurs because of the severely reduced coronary blood flow. Hibernation appears to be an adaptive response to hypoperfusion that may minimize the potential for further ischemia or necrosis. Revascularization of the hibernating (and/or stunned) myocardium generally leads to improved myocardial function.

Cardiovascular mechanics of cardiogenic shock

The main mechanical defect in cardiogenic shock is a shift to the right for the left ventricular end-systolic pressure-volume curve, because of a marked reduction in contractility. As a result, at a similar or even lower systolic pressure, the ventricle is able to eject less blood volume per beat. Therefore, the end-systolic volume is usually greatly increased in persons with cardiogenic shock.

The stroke volume is decreased, and to compensate for this, the curvilinear diastolic pressure-volume curve also shifts to the right, with a decrease in diastolic compliance. This leads to increased diastolic filling, which is associated with an increase in end-diastolic pressure. The attempt to enhance cardiac output by this mechanism comes at the cost of having a higher left ventricular diastolic filling pressure, which ultimately increases myocardial oxygen demand and causes pulmonary edema.

As a result of decreased contractility, the patient develops elevated left and right ventricular

filling pressures and low cardiac output. Mixed venous oxygen saturation falls because of the increased tissue oxygen extraction, which is due to the low cardiac output. This, combined with the intrapulmonary shunting that is often present, contributes to substantial arterial oxygen desaturation.

Systemic effects

When a critical mass of left ventricular myocardium becomes ischemic and fails to pump effectively, stroke volume and cardiac output are curtailed. Myocardial ischemia is further exacerbated by compromised myocardial perfusion due to hypotension and tachycardia.

The pump failure increases ventricular diastolic pressures concomitantly, causing additional wall stress and thereby elevating myocardial oxygen requirements. Systemic perfusion is compromised by decreased cardiac output, with tissue hypoperfusion intensifying anaerobic metabolism and instigating the formation of lactic acid, which further deteriorates the systolic performance of the myocardium.

Depressed myocardial function also leads to the activation of several physiologic compensatory mechanisms. These include sympathetic stimulation, which increases the heart rate and cardiac contractility and causes renal fluid retention, hence augmenting the left ventricular preload. The raised heart rate and contractility increases myocardial oxygen demand, further worsening myocardial ischemia.

Fluid retention and impaired left ventricular diastolic filling triggered by tachycardia and ischemia contribute to pulmonary venous congestion and hypoxemia. Sympathetically mediated vasoconstriction to maintain systemic blood pressure amplifies myocardial afterload, which additionally impairs cardiac performance. Finally, excessive myocardial oxygen demand with simultaneous inadequate myocardial perfusion worsens myocardial ischemia, initiating a vicious cycle that ultimately ends in death, if uninterrupted.

Usually, a combination of systolic and diastolic myocardial dysfunction is present in patients with cardiogenic shock. Metabolic derangements that impair myocardial contractility further compromise systolic ventricular function. Myocardial ischemia decreases myocardial compliance, thereby elevating left ventricular filling pressure at a given end-diastolic volume (diastolic dysfunction), which leads to pulmonary congestion and congestive heart failure.

Shock state

Shock state, irrespective of the etiology, is described as a syndrome initiated by acute systemic hypoperfusion that leads to tissue hypoxia and vital organ dysfunction. All forms of shock are characterized by inadequate perfusion to meet the metabolic demands of the tissues. A maldistribution of blood flow to end organs begets cellular hypoxia and end organ damage, the well-described multisystem organ dysfunction syndrome. The organs of vital importance are the brain, heart, and kidneys.

A decline in higher cortical function may indicate diminished perfusion of the brain, which leads to an altered mental status ranging from confusion and agitation to flaccid coma. The heart plays a central role in propagating shock. Depressed coronary perfusion leads to worsening cardiac dysfunction and a cycle of self-perpetuating progression of global hypoperfusion. Renal compensation for reduced perfusion results in diminished glomerular filtration, causing oliguria and subsequent renal failure.

Etiology

Cardiogenic shock can result from the following types of cardiac dysfunction:

- Systolic dysfunction
- Diastolic dysfunction
- Valvular dysfunction
- Cardiac arrhythmias
- Coronary artery disease
- Mechanical complications

The vast majority of cases of cardiogenic shock in adults are due to acute myocardial ischemia. Indeed, cardiogenic shock is generally associated with the loss of more than 40% of the left ventricular myocardium, although in patients with previously compromised left ventricular function, even a small infarction may precipitate shock. Cardiogenic shock is more likely to develop in people who are elderly or diabetic or in persons who have had a previous inferior myocardial infarction (MI).

Complications of acute MI, such as acute mitral regurgitation, large right ventricular infarction, and [rupture](#) of the interventricular septum or left ventricular free wall, can result in cardiogenic shock. Conduction abnormalities (eg, atrioventricular blocks, sinus bradycardia) are also risk factors.

Many cases of cardiogenic shock occurring after acute coronary syndromes may be due to medication administration. The use of beta blockers and angiotensin-converting enzyme (ACE) inhibitors in acute coronary syndromes must be carefully timed and monitored.

In children, preceding viral infection may cause [myocarditis](#). In addition, children and infants may have unrecognized congenital structural heart defects that are well compensated until there is a stressor. These etiologies plus toxic ingestions make up the 3 primary causes of cardiogenic shock in children.

A systemic inflammatory response syndrome–type mechanism has also been implicated in the etiology of cardiogenic shock. Elevated levels of white blood cells, body temperature, complement, interleukins, and C-reactive protein are often seen in large myocardial infarctions. Similarly, inflammatory nitric oxide synthetase (iNOS) is also released in high levels during myocardial stress. Nitric oxide production induced by iNOS may uncouple calcium metabolism in the myocardium resulting in a stunned myocardium. Additionally, iNOS leads to the expression of interleukins, which may themselves cause hypotension.

Left ventricular failure

Systolic dysfunction

The primary abnormality in systolic dysfunction is abated myocardial contractility. Acute MI or ischemia is the most common cause; cardiogenic shock is more likely to be associated with anterior MI. The causes of systolic dysfunction leading to cardiogenic shock can be summarized as follows:

- Ischemia/MI
- Global hypoxemia
- Valvular disease
- Myocardial depressant drugs - Eg, beta blockers, calcium channel blockers, and antiarrhythmics
- Myocardial contusion
- Respiratory acidosis
- Metabolic derangements - Eg, acidosis, hypophosphatemia, and hypocalcemia
- Severe myocarditis
- End-stage cardiomyopathy - Including valvular causes

- Prolonged cardiopulmonary bypass.
- Cardiotoxic drugs - Eg, doxorubicin (Adriamycin)

Diastolic dysfunction

Increased left ventricular diastolic chamber stiffness contributes to cardiogenic shock during cardiac ischemia, as well as in the late stages of hypovolemic shock and septic shock. Increased diastolic dysfunction is particularly detrimental when systolic contractility is also depressed. The causes of cardiogenic shock due primarily to diastolic dysfunction can be summarized as follows:

- Ischemia
- Ventricular hypertrophy
- Restrictive cardiomyopathy
- Prolonged hypovolemic or septic shock
- Ventricular interdependence
- External compression by pericardial tamponade

Greatly increased afterload

Increased afterload, which can impair cardiac function, can be caused by the following:

- Aortic stenosis
- Hypertrophic cardiomyopathy
- Dynamic aortic outflow tract obstruction
- Coarctation of the aorta
- Malignant hypertension

Valvular and structural abnormality

Valvular dysfunction may immediately lead to cardiogenic shock or may aggravate other etiologies of shock. Acute mitral regurgitation secondary to papillary muscle rupture or dysfunction is caused by ischemic injury. Rarely, acute obstruction of the mitral valve by a left atrial thrombus may result in cardiogenic shock by means of severely decreased cardiac output. Aortic and mitral regurgitation reduce forward flow, raise end-diastolic pressure, and aggravate shock associated with other etiologies.

Valvular and structural abnormalities associated with cardiogenic shock include the following:

- Mitral stenosis
- Endocarditis
- Mitral aortic regurgitation
- Obstruction due to atrial myxoma or thrombus
- Papillary muscle dysfunction or rupture
- Ruptured septum or free wall arrhythmias
- Tamponade

Decreased contractility

Reduced myocardial contractility can result from the following:

- Right ventricular infarction
- Ischemia
- Hypoxia
- Acidosis

Right ventricular failure

Greatly increased afterload

Afterload increase associated with right ventricular failure can result from the following:

- Pulmonary embolism
- Pulmonary vascular disease - Eg, pulmonary arterial hypertension and veno-occlusive disease
- Hypoxic pulmonary vasoconstriction
- Peak end-expiratory pressure
- High alveolar pressure
- Acute respiratory distress syndrome
- Pulmonary fibrosis
- Sleep disordered breathing
- Chronic obstructive pulmonary disease

Arrhythmias

Ventricular tachyarrhythmias are often associated with cardiogenic shock. Furthermore, bradyarrhythmias may cause or aggravate shock due to another etiology. Sinus tachycardia

and atrial tachyarrhythmias contribute to hypoperfusion and aggravate shock.

Epidemiology

International occurrence

Several multicenter thrombolytic trials in Europe reported a prevalence rate of cardiogenic shock following MI of approximately 7%.

Race-, sex-, and age-related demographics

Race-stratified mortality rates from cardiogenic shock are as follows (race-based mortality differences disappear with revascularization):

- Hispanics - 74%
- African Americans - 65%
- Whites - 56%
- Asians/others - 41%

The overall incidence of cardiogenic shock is higher in men than in women, with females accounting for 42% of patients with cardiogenic shock. This difference results from the increased prevalence of coronary artery disease in males. However, a higher percentage of female patients with MI develop cardiogenic shock than do males with MI.

Median age for cardiogenic shock mirrors the bimodal distribution of disease. For adults, the median age ranges from 65-66 years. For children, cardiogenic shock presents as a consequence of fulminant myocarditis or congenital heart disease.

Prognosis

Cardiogenic shock is the leading cause of death in acute myocardial infarction (MI). In the absence of aggressive, highly experienced technical care, mortality rates among patients with cardiogenic shock are exceedingly high (up to 70-90%). The key to achieving a good outcome is rapid diagnosis, prompt supportive therapy, and expeditious coronary artery revascularization in patients with myocardial ischemia and infarction.

Morbidity and mortality

Complications of cardiogenic shock may include the following:

- Cardiopulmonary arrest
- Dysrhythmia
- Renal failure
- Multisystem organ failure
- Ventricular aneurysm
- Thromboembolic sequelae
- Stroke
- Death

The following predictors of mortality were identified from the Global Utilization of Streptokinase and Tissue-Plasminogen Activator for Occluded Coronary Arteries (GUSTO-I) trial-:

- Increasing age
- Prior MI
- Altered sensorium
- Cold, clammy skin
- Oliguria

Echocardiographic findings such as left ventricular ejection fraction and mitral regurgitation are independent predictors of mortality. An ejection fraction of less than 28% is associated with a survival rate of 24% at 1 year, compared with a survival rate of 56% with a higher ejection fraction. Moderate or severe mitral regurgitation was found to be associated with a 1-year survival rate of 31%, compared with a survival rate of 58% in patients with no regurgitation.

Outcomes in cardiogenic shock significantly improve only when rapid revascularization can be achieved. The SHOCK (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock?) trial demonstrated that overall mortality when revascularization occurs is 38%. When rapid revascularization is not attempted, mortality rates approach 70%. Rates vary depending on the procedure (eg, percutaneous transluminal coronary angioplasty, stent placement, thrombolytic therapy).

Physical Examination

Characteristics of patients with cardiogenic shock include the following:

- Patients in shock usually appear ashen or cyanotic and have cool skin and mottled extremities
- Peripheral pulses are rapid and faint and may be irregular if arrhythmias are present
- Jugular venous distention and crackles in the lungs are usually (but not always) present; peripheral edema also may be present.
- Heart sounds are usually distant, and third and fourth heart sounds may be present
- The pulse pressure may be low, and patients are usually tachycardic
- Patients show signs of hypoperfusion, such as altered mental status and decreased urine output

A systolic murmur is generally heard in patients with acute mitral regurgitation or ventricular septal rupture. The associated parasternal thrill indicates the presence of a ventricular septal defect, whereas the murmur of mitral regurgitation may be limited to early systole.

The systolic murmur, which becomes louder upon Valsalva and prompt standing, suggests hypertrophic obstructive cardiomyopathy (idiopathic hypertropic subaortic stenosis).

Diagnostic Considerations

Conditions to consider in the differential diagnosis of cardiogenic shock include the following:

- Systemic inflammatory response syndrome
- Acute coronary syndrome
- Aortic regurgitation
- Dilated cardiomyopathy
- Restrictive cardiomyopathy
- Congestive heart failure and pulmonary edema
- Mitral regurgitation
- Pericarditis and cardiac tamponade
- Hypovolemic shock
- Papillary muscle rupture
- Acute valvular dysfunction

Right ventricular infarction

Right ventricular infarction occurs in up to 30% of patients with inferior myocardial infarction (MI) and becomes hemodynamically unstable in 10% of these patients. The diagnosis is made by identifying an ST-segment elevation in the right precordial leads (V₃ or V₄ R) and/or typical hemodynamic findings after right heart catheterization. These are elevated right atrial and right ventricular end-diastolic pressures with normal to low pulmonary artery wedge pressure and low cardiac output.

Echocardiography findings can also be very helpful in the diagnosis of right ventricular infarction. Patients with cardiogenic shock due to this condition have a better prognosis than do patients when compared to those with cardiogenic shock due to left ventricular systolic failure.

Regarding the management of cardiogenic shock due to right ventricular infarction, supportive therapy begins with the restoration and maintenance of right ventricular preload with fluid administration. However, excessive fluid resuscitation may compromise left ventricular filling by introducing an interventricular septal shift.

Inotropic therapy with dobutamine may be effective in increasing cardiac output in patients with right ventricular infarction. Maintenance of systemic arterial pressure in order to maintain adequate coronary artery perfusion may require vasoconstricting agents, such as norepinephrine. In unstable patients, an intra-aortic balloon pump (IABP) may be useful for ensuring adequate blood supply to the already compromised right ventricle.

Revascularization of the occluded coronary artery, preferably by percutaneous transluminal coronary angioplasty (PTCA), is crucial for management and has shown to dramatically improve outcome.

Acute mitral regurgitation

Acute mitral regurgitation is usually associated with inferior MI due to ischemia or infarction of the papillary muscle. It occurs in approximately 1% of MIs, and posteromedial papillary muscle is involved more frequently than anterolateral muscle. Acute mitral regurgitation usually happens 2-7 days following acute MI and manifests with an abrupt onset of pulmonary edema, hypotension, and cardiogenic shock.

Echocardiography findings are extremely useful in making a diagnosis. The 2-dimensional (2-D) echocardiographic image shows the malfunctioning mitral valve, and findings from a

Doppler study can be used to document the severity of mitral regurgitation. Right heart catheterization is often required for stabilizing the patient. Tall V waves identified on pulmonary arterial and wedge pressure waveforms indicate acute mitral regurgitation. However, the diagnosis must be confirmed based on echocardiography or left ventriculography findings before definitive therapy or surgery is initiated.

Hemodynamic stabilization by reducing afterload, either with nitroprusside or an IABP, is often instituted. Definitive therapy requires revascularization, if ischemia is present, and/or surgical valve repair or replacement, if a structural valvular lesion is present. The mortality rate in the presurgical era was 50% in the first 24 hours, with a 2-month survival rate of 6%.

Cardiac rupture

Rupture of the free wall of the left ventricle occurs within 2 weeks of the MI and may occur within the first 24 hours. The rupture may involve the anterior, posterior, or lateral wall of the ventricle.

Cardiac rupture often presents as sudden cardiac death. Premortem symptoms include chest pain, agitation, tachycardia, and hypotension. This diagnosis should be considered in patients with electromechanical dissociation who have a history of anginal pain. Patients rarely, if ever, survive cardiac rupture.

Ventricular septal rupture

Approximately 1-3% of acute MIs are associated with ventricular septal rupture. Most septal ruptures occur within the week following MI. Patients with acute ventricular septal rupture develop acute heart failure and/or cardiogenic shock, with physical findings of a harsh holosystolic murmur and left parasternal thrill.

A left-to-right intracardiac shunt, as demonstrated by a step-up (>5% increase in oxygen saturation) between the right atrium and right ventricle, confirms the diagnosis. Alternatively, 2-D and Doppler echocardiographic findings can be used to identify the location and severity of the left-to-right shunt.

Rapid stabilization using an IABP and pharmacologic measures, followed by emergent surgical repair, is lifesaving. The timing of surgical intervention is controversial, but most experts suggest operative repair within 48 hours of the rupture.

Ventricular septal rupture portends a poor prognosis unless management is aggressive. Immediate surgical repair of patients with ventricular septal rupture is reported to be associated with survival rates of 42-75%; therefore, prompt surgical therapy is imperative as soon as possible after the diagnosis of ventricular septal rupture is confirmed.

Reversible myocardial dysfunction

Other causes of severe, reversible myocardial dysfunction are sepsis-associated myocardial depression, myocardial depression following cardiopulmonary bypass, and inflammatory myocarditis. In older literature, this presentation is often referred to as cold septic shock. In these situations, myocardial dysfunction occurs from the effects of inflammatory cytokines, such as tumor necrosis factor and interleukin 1.

Myocardial dysfunction may vary from mild to severe and may lead to cardiogenic shock. For patients in cardiogenic shock, cardiovascular support with inotropic agents may be required until recovery, which generally occurs after the underlying disease process resolves.

- [Shock, Hemorrhagic](#)

Resuscitation, Ventilation, and Pharmacologic Intervention

Initial management includes fluid resuscitation to correct hypovolemia and hypotension, unless pulmonary edema is present. Central venous and arterial lines are often required. Swan-Ganz catheterization and continuous percutaneous oximetry are routine.

Oxygenation and airway protection are critical; intubation and mechanical ventilation are

commonly required. However, although positive pressure ventilation may improve oxygenation, it may also compromise venous return, preload, to the heart. In any event, the patient should be treated with high-flow oxygen. Studies in patients with acute cardiogenic pulmonary edema have shown noninvasive ventilation to improve hemodynamics and reduce the intubation rate. Mortality is, however, unaffected.

A study by Shin et al suggested that patients who receive extracorporeal cardiopulmonary resuscitation (CPR) versus conventional CPR for longer than 10 minutes following in-hospital arrest have a greater chance of survival. [\[12\]](#)

Pharmacologic therapy

Patients with myocardial infarction (MI) or acute coronary syndrome are given aspirin and heparin. Both of these medications have been shown to be effective in reducing mortality in separate studies. Before initiating therapy, however, care should be taken to ensure that the patient does not have a myocardial wall rupture that is amenable to surgery.

The glycoprotein IIb/IIIa inhibitors improve the outcome of patients with non-ST-segment elevation acute coronary syndrome (NSTACS). They have been found to reduce recurrent MI following percutaneous coronary intervention (PCI) and in cardiogenic shock.

Hemodynamic Support

Dopamine, norepinephrine, and epinephrine are vasoconstricting drugs that help to maintain adequate blood pressure during life-threatening hypotension and help to preserve perfusion pressure for optimizing flow in various organs. The mean blood pressure required for adequate splanchnic and renal perfusion (mean arterial pressure [MAP] of 60 or 65 mm Hg) is based on clinical indices of organ function.

In patients with inadequate tissue perfusion and adequate intravascular volume, initiation of inotropic and/or vasopressor drug therapy may be necessary. Dopamine increases myocardial contractility and supports the blood pressure; however, it may increase myocardial oxygen demand. Dobutamine may be preferable if the systolic blood pressure is higher than 80 mm Hg; it has the advantage of not affecting myocardial oxygen demand as much as dopamine does. However, the resulting tachycardia may preclude the use of this inotropic agent in some patients.

Dopamine is usually initiated at a rate of 5-10 mcg/kg/min intravenously, and the infusion rate is adjusted according to the blood pressure and other hemodynamic parameters. Often, patients may require high doses of dopamine (as much as 20 mcg/kg/min).

If the patient remains hypotensive despite moderate doses of dopamine, a direct vasoconstrictor (eg, norepinephrine) should be started at a dose of 0.5 mcg/kg/min and titrated to maintain an MAP of 60 mm Hg. The potent vasoconstrictors (eg, norepinephrine) have traditionally been avoided because of their adverse effects on cardiac output and renal perfusion.

Vasopressor supportive therapy

Dopamine

At doses of approximately 10 mcg/kg/min, alpha-adrenergic effects lead to arterial vasoconstriction and an elevation in blood pressure. The blood pressure increases primarily as a result of the inotropic effect. The undesirable effects are tachycardia and increased pulmonary shunting, as well as the potential for decreased splanchnic perfusion and increased pulmonary arterial wedge pressure.

Norepinephrine

The dose of norepinephrine may vary from 0.2-1.5 mcg/kg/min, and large doses, as high as 3.3 mcg/kg/min, have been used because of the alpha-receptor down-regulation in persons with sepsis.

Epinephrine

Administration of this agent is associated with an increase in systemic and regional lactate concentrations. The use of epinephrine is recommended only in patients who are unresponsive to traditional agents. The undesirable effects are an increase in lactate concentration, a potential to produce myocardial ischemia, the development of arrhythmias, and a reduction in splanchnic flow.

Inotropic supportive therapy

Dobutamine

In the setting of acute myocardial infarction (MI), dobutamine use could increase the size of the infarct because of the increase in myocardial oxygen consumption that may ensue. In general, avoid dobutamine in patients with moderate or severe hypotension (eg, systolic blood pressure < 80 mm Hg) because of the peripheral vasodilation.

Phosphodiesterase inhibitors

Phosphodiesterase inhibitors (PDIs), which include inamrinone (formerly amrinone) and milrinone, are inotropic agents with vasodilating properties and long half-lives. The hemodynamic properties of PDIs are (1) a positive inotropic effect on the myocardium and peripheral vasodilation (decreased afterload) and (2) a reduction in pulmonary vascular resistance (decreased preload).

PDIs are beneficial in persons with cardiac pump failure, but they may require concomitant vasopressor administration. Unlike catecholamine inotropes, these drugs are not dependent on adrenoceptor activity; therefore, patients are less likely to develop tolerance to these medications.

Thrombolytic Therapy

Although thrombolytic therapy (TT) reduces mortality rates in patients with acute myocardial infarction (MI), its benefits for patients with cardiogenic shock secondary to MI are disappointing. When used early in the course of MI, TT reduces the likelihood of subsequent development of cardiogenic shock after the initial event.

In the Gruppo Italiano Per lo Studio Della Streptokinase Nell'Infarto Miocardio trial, 30-day mortality rates were 69.9% in patients with cardiogenic shock who received streptokinase, compared to 70.1% in patients who received a placebo.

Similarly, other studies employing a tissue plasminogen activator did not show reductions in mortality rates from cardiogenic shock. Lower rates of reperfusion of the infarct-related artery in patients with cardiogenic shock may help to explain the disappointing results from TT. Other reasons for the decreased efficacy of TT are the existence of hemodynamic, mechanical, and metabolic causes of cardiogenic shock that are unaffected by TT.

Intra-Aortic Balloon Pump

The use of the IABP reduces systolic left ventricular afterload and augments diastolic coronary perfusion pressure, thereby increasing cardiac output and improving coronary artery blood flow. The IABP is effective for the initial stabilization of patients with cardiogenic shock. However, an IABP is not definitive therapy; the IABP stabilizes patients so that definitive diagnostic and therapeutic interventions can be performed. [\[18, 19\]](#)

The IABP also may be a useful adjunct to thrombolysis for initial stabilization and transfer of patients to a tertiary care facility. Some studies have shown lower mortality rates in patients with myocardial infarction (MI) and cardiogenic shock treated with an IABP and subsequent revascularization, as previously mentioned.

Complications may be documented in up to 30% of patients who undergo IABP therapy; these relate primarily to local vascular problems, embolism, infection, and hemolysis.

The impact of treatment with an IABP on long-term survival is controversial and depends on the patient's hemodynamic status and the etiology of the cardiogenic shock. Patient selection is the key issue; inserting the IABP early, rather than waiting until full-blown cardiogenic shock has developed, may result in clinical benefit.

Ramanathan et al found that rapid and complete reversal of systemic hypoperfusion with IABP counterpulsation in the SHOCK trial and SHOCK registry was independently associated with improved inhospital, 30-day, and 1-year survival, regardless of early revascularization. This suggests that complete reversal of systemic hypoperfusion with IABP counterpulsation is an important early prognostic feature.

In the IABP-SHOCK II study, 600 patients with cardiogenic shock complicating acute myocardial infarction were randomized to intraaortic balloon counterpulsation or no intraaortic balloon counterpulsation. All patients were expected to undergo early revascularization. Use of intraaortic balloon counterpulsation did not significantly reduce 30-day mortality in these patients.

Ventricular Assist Devices

In recent years, left ventricular assist devices (LVADs) capable of providing complete short-term hemodynamic support have been developed. The application of LVAD during reperfusion, after acute coronary occlusion, causes reduction of the left ventricular preload,

increases regional myocardial blood flow and lactate extraction, and improves general cardiac function. The LVAD makes it possible to maintain the collateral blood flow as a result of maintaining the cardiac output and aortic pressure, keeping wall tension low and reducing the extent of microvascular reperfusion injury.

A pooled analysis from 17 studies showed that the mean age of this group of patients with LVADs was 59.5 ± 4.5 years and that mean support duration was 146.2 ± 60.2 hours. In 78.5% of patients (range, 53.8-100%), adjunctive reperfusion therapy, mainly percutaneous transluminal coronary angioplasty (PTCA), was used. Mean weaning and survival rates were 58.5% (range, 46-75%) and 40% (range, 29-58%), respectively.

In any case, comparing studies is difficult because important data are usually missing, mean age of patients were different, and time to treatment is not standardized. Hemodynamic presentation seems to be worse compared with data reported in the SHOCK trial, with lower cardiac index, lower systolic aortic pressure, and higher serum lactates. Taking these considerations into account, LVAD support seems to give no survival improvement in patients with cardiogenic shock complicating acute myocardial infarction (MI), compared with early reperfusion alone or in combination with IABP.

However, LVADs as a bridging option for patients with cardiogenic shock must be considered cautiously and must be avoided in patients who are unlikely to survive or are not likely to be transplant candidates. Further investigations are required to better define indications, support modalities, and outcomes.

The indications for insertion of a ventricular assist device are controversial. Such an aggressive approach to support the circulatory system in cardiogenic shock is appropriate (1) after the failure of medical treatment and an IABP, (2) when the cause of cardiogenic shock is potentially reversible, or (3) if the device can be used as a bridging option.

Percutaneous Transluminal Coronary Angioplasty

The retrospective and prospective data favor aggressive mechanical revascularization in patients with cardiogenic shock secondary to myocardial infarction (MI).

Reestablishing blood flow in the infarct-related artery may improve left ventricular function and survival following MI. In acute MI, studies show that percutaneous transluminal coronary angioplasty (PTCA) can achieve adequate flow in 80-90% of patients, compared with 50-60%

of patients after thrombolytic therapy (TT).

Several retrospective clinical trials have shown that patients with cardiogenic shock due to myocardial ischemia benefitted (reduction in 30d mortality rates) when treated with angioplasty. A study of direct (primary) PTCA in patients with cardiogenic shock reported lower mortality rates in patients treated with angioplasty combined with the use of stents than in patients treat with medical therapy.

Coronary Artery Bypass Grafting

Critical left main artery disease and 3-vessel coronary artery disease are common findings in patients who develop cardiogenic shock. The potential contribution of ischemia in the noninfarcted zone contributes to the deterioration of already compromised myocardial function.

Coronary artery bypass grafting (CABG) in the setting of cardiogenic shock is generally associated with high surgical morbidity and mortality rates. Because the results of percutaneous interventions can be favorable, routine bypass surgery is often discouraged for these patients.

Shock states

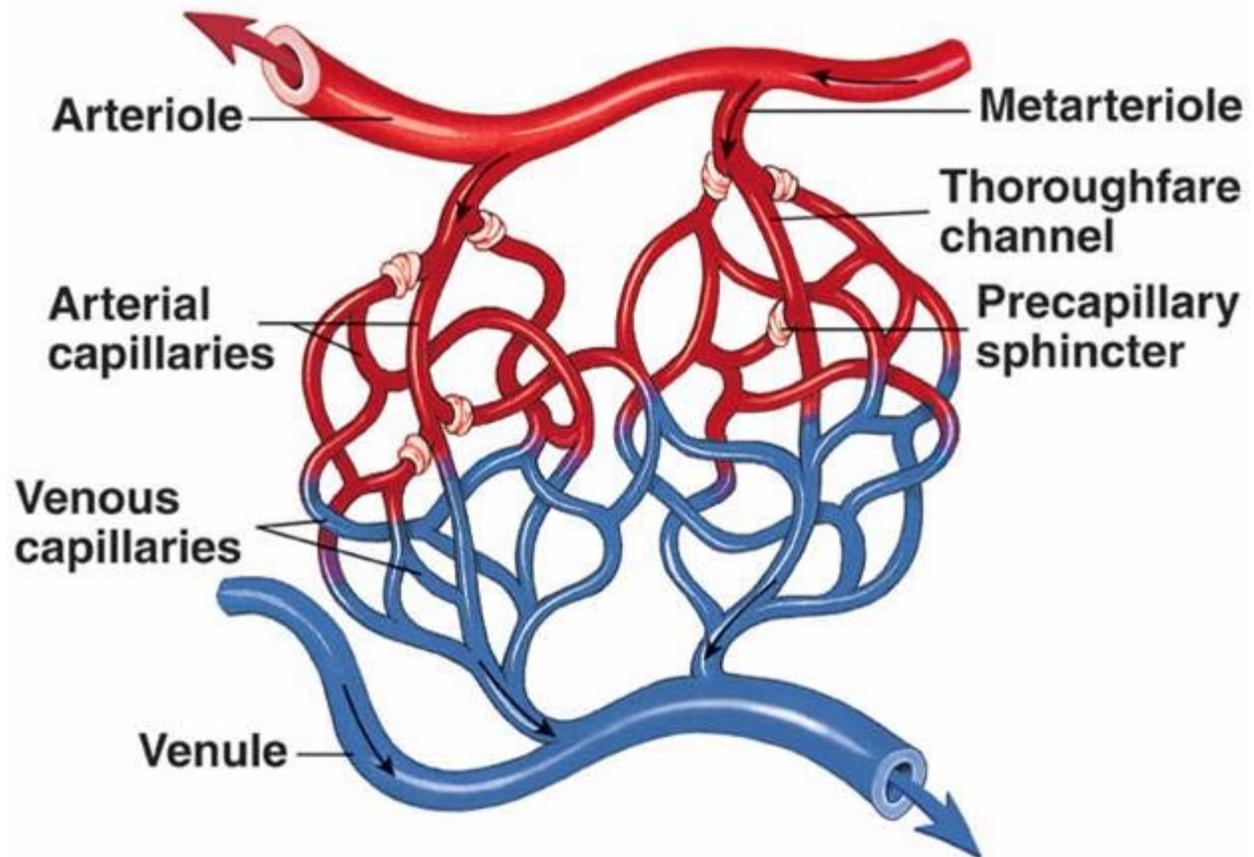

Acute circulatory insufficiency

4.1 Anatomy and physiology

Life is provided through a variety of mechanisms, however all of them depend on proper circulation. Circulation itself consists of 2 parts: work of heart (pump of the body) and vessels, through which blood is pumped to the most remote organs and tissues. During every systolic contraction heart pump 70-80 ml of blood (so called stroke volume). Thus in case of heart rate 70 beats per minute heart pumps nearly 5 liters of blood, what makes more than 7 tones per day.

From the left ventricle blood gets to the arterial system of the systemic circuit. Arteries contain 15% of the whole circulating blood volume; they carry blood from the heart to their distal departments – arterioles (vessels of resistance). Arterioles themselves are defining blood distribution: in condition of constriction (spasm) they make blood supply of the capillaries impossible (ischemia appears). On the contrary, in condition of dilatation they provide maximal oxygenation. When arterioles are blocked due to the spasm blood is flowing through the arterio-venous anastomosis directly to the venous system.

Copyright © The McGraw-Hill Companies, Inc. Permission required for reproduction or display.

Distribution of blood in the vascular bed (% of CBV).

- a. heart cavity 3%
- b. arteries 15%
- c. capillaries 12%
- d. venous system 70%

Among the natural vasoconstrictors (agents, which cause constriction of the blood vessel) are epinephrine, norepinephrine, serotonin, angiotensin II. Stress enhances the secretion of catecholamines, their blood concentration increases and arterioles constrict. Spasm of the arterioles is the basis of blood flow centralization: peripheral flow is disregarded in order to provide brain with the oxygenated blood as long as possible. To the group of vasodilators (agents, which provide dilatation of the vessels) belong “acid” metabolites (lactate, pyruvate, adenylic acid, inosinic acid), bradykinin, acetylcholine, different medicines (neuroleptics, α -adrenergic antagonists, peripheral vasodilators, ganglionic blocking agents, etc.), some exogenous poisons. All of them cause blood flow decentralization: opening of arterioles and distribution of the blood from central vessels to the capillary bed.

Capillaries are the interweaving network of the smallest body vessels with the general length of 90-100 thousands of kilometers. However simultaneously work only 20-25% of them. They provide metabolic exchange bringing oxygen and nutrients to the tissues and take back wastes of metabolism. Periodically, every 30-40 seconds one of them get closed and others open (vasomotion effect). Capillaries contain 12% of the whole circulating blood volume, but different pathological conditions can increase this amount even 3 and more times.

“Used” blood from the capillaries flows to the venous system. Veins are the blood reservoir, which contains 70% of the total circulating blood volume. Unlike arteries they are capable of volume control and thus they influence the amount of blood, which returns to the heart.

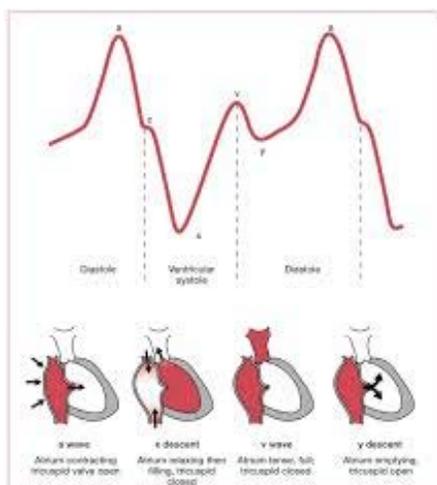

The most important haemodynamic index of venous system is central venous pressure. CVP represents the pressure which blood causes to the walls of cava veins and right atrium. This parameter is an integral index of circulating blood volume, systemic vascular resistance and pump function of the heart. It can be measure with a special device called “phlebotonometer” (pic. 4.9) or with a usual infusion set and a ruler. Normally CVP measured from the sternum point is 0-14 cm H₂O and from midaxillary line is 8-15 cm H₂O.

Central venous pressure decreases (sometimes even to negative) in case of:

- blood loss
- excessive water loss (dehydration)
- distributive shock (decrease of peripheral resistance due to venous and arterial

dilatation)

In those conditions decreases volume of blood returning to the heart and thus suffers cardiac output. In case of negative CVP cardiac arrest is highly probable.

Central venous pressure increases in case of:

- heart failure (insufficiency of left or right ventricle)
- hypervolemia (excessive blood infusion, improper infusion therapy)
- obstructions to blood flow (pulmonary embolism, cardiac tamponade, etc.)

When CVP over 15-16 cm H₂O is combined with left ventricle insufficiency the risk of pulmonary edema is very high.

Blood pressure is an integral index of arterial part of systemic haemodynamics. Talking about blood pressure we may refer to systolic, diastolic, pulse and mean arterial pressure. Systolic (P_{syst}) and diastolic (P_{diast}) pressures are measured with the manometer (method with the usage of phonendoscope was invented by M.Korotkoff). Pulse pressure (PP) is a difference between systolic and diastolic blood pressure.

Mean arterial pressure (MAP) is calculated according to the formula:

$$\text{MAP} = P_{\text{dias}} + 1/3 \text{ PP} \quad \text{mm Hg}$$

MAP defines the level of pressure necessary for the metabolic exchange in the tissues. Its measurement allows the evaluation of tissue perfusion level.

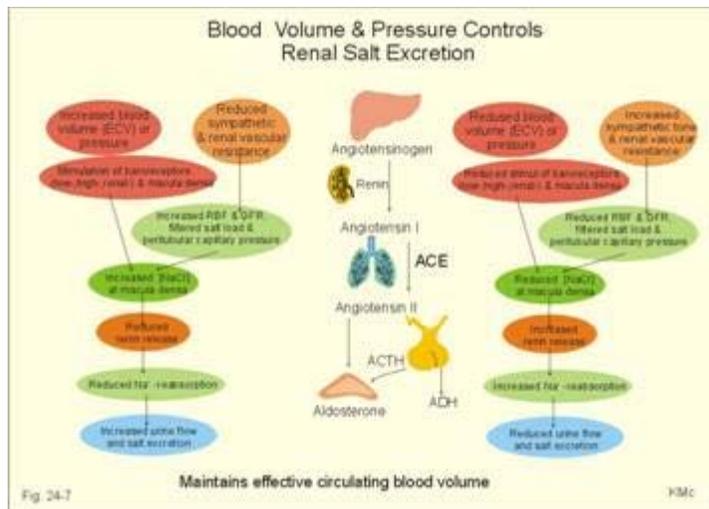

Blood pressure depends on different factors, but the most important are cardiac output and vascular resistance (mostly arterioles). This dependence is direct, thus you can increase blood pressure using:

- infusion of vasoconstrictors - solutions of

epinephrine, phenylephrine (mesaton), etc. (they will increase the vascular resistance);

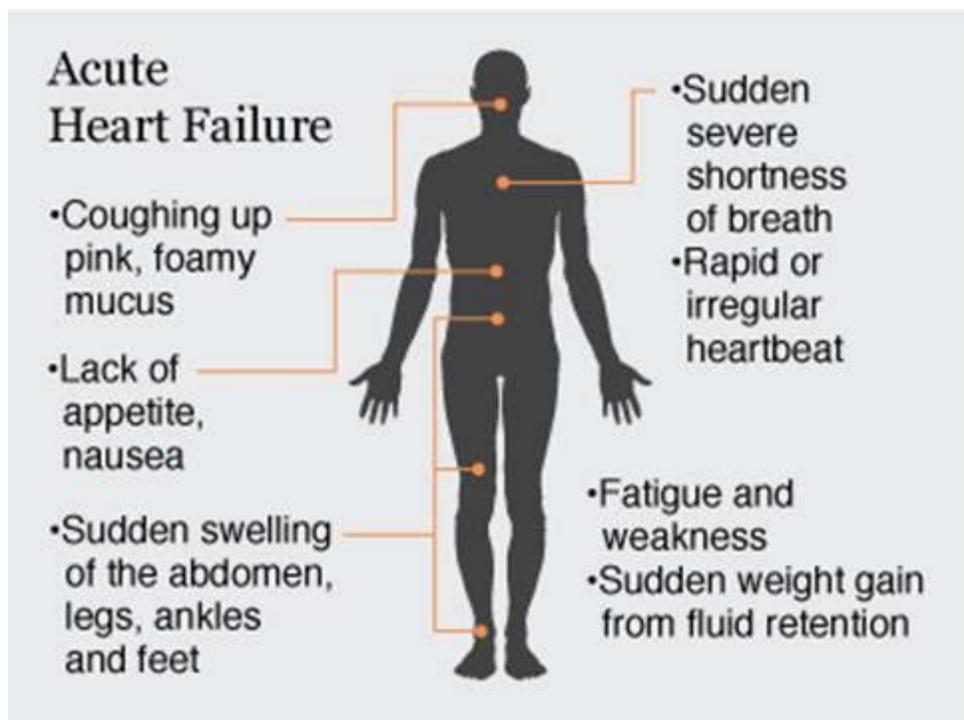

- infusion of hydroxyethyl starch solutions or saline (they will increase circulating blood volume)

- infusion of cardiac glycosides or other medicine which stimulate myocardium

General volume of blood in the body of a healthy adult is nearly 7% from the body weight: 70 ml per kilogram for male and 65 ml per kilogram of body weight for female. Of course circulating blood volume is lower, because part of blood is out of metabolic processes as a reserve. CBV can be measured with the infusion of coloring substance to the blood flow (Evans blue, polyglucin) and later evaluation of its dissolution degree.

Therefore measurement of CVP, BP, cardiac output and circulating blood volume allow to evaluate condition of circulation system of the patients and to provide adequate correction.

Acute heart failure; shock and collapse.

Acute cardiovascular failure is a state of cardiac and vascular inability to provide adequate supply of tissue metabolic needs with oxygenated blood and nutrients. This, earlier or later, causes cellular death.

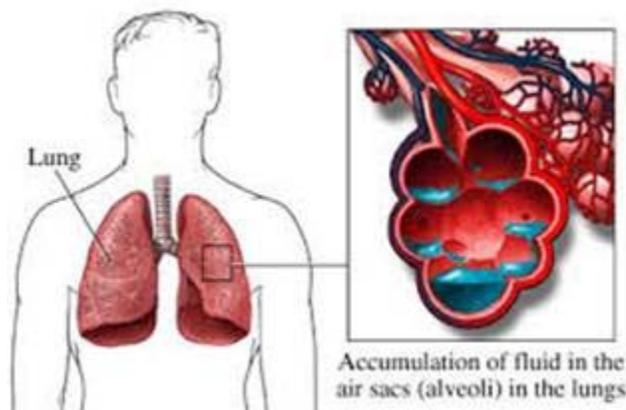

The reasons of the failure vary greatly: mechanic injuries, blood loss, burns, dehydration, exogenous and endogenous intoxications, immediate hypersensitivity reaction, ischemic heart disease, neural and humoral regulation disorders of vascular tone.

Acute cardiac failure is a disorder of heart pumping action. It develops due to primary heart problems or secondary, under the influence of extracardiac factors such as infection or intoxication. There are two types of heart failure: left-sided and right-sided.

Left-sided heart failure is an inability of left ventricle to pump blood from the pulmonary circuit to the systemic circuit. The most common reasons of it are myocardial infarction, mitral insufficiency, left AV valve stenosis, aortic valve stenosis, aortal insufficiency, hypertonic disease, coronary sclerosis, acute pneumonia.

Coronary circulation is possible only during the diastole and in those conditions every violation of coronary passability decreases cardiac output. This way during the systole part of the blood is not injected into aorta, but stays in the left ventricle. Diastolic pressure in the left ventricle increases and blood is literally forced to stagnate in the left atrium. At the same time right ventricle functions normally and continues to pump usual amounts of blood to the pulmonary circuit. Thus hydrostatic pressure in the vessels of pulmonary circulation increases, fluid part of the blood moves first to the lung tissue and then, through alveolar-capillary membrane, to the alveolar lumen.

Clinically pulmonary edema begins with dyspnea (during physical activity or rest). Later attacks of dyspnea are connected with persistent cough with white or pink blood-tinged phlegm. During the attack patient tries to sit as in this position breathing is easier. This condition is called "heart asthma". When hydrostatic pressure is over 150-200 mm Hg, fluid part of blood moves to the alveolar lumen causing development of pulmonary edema.

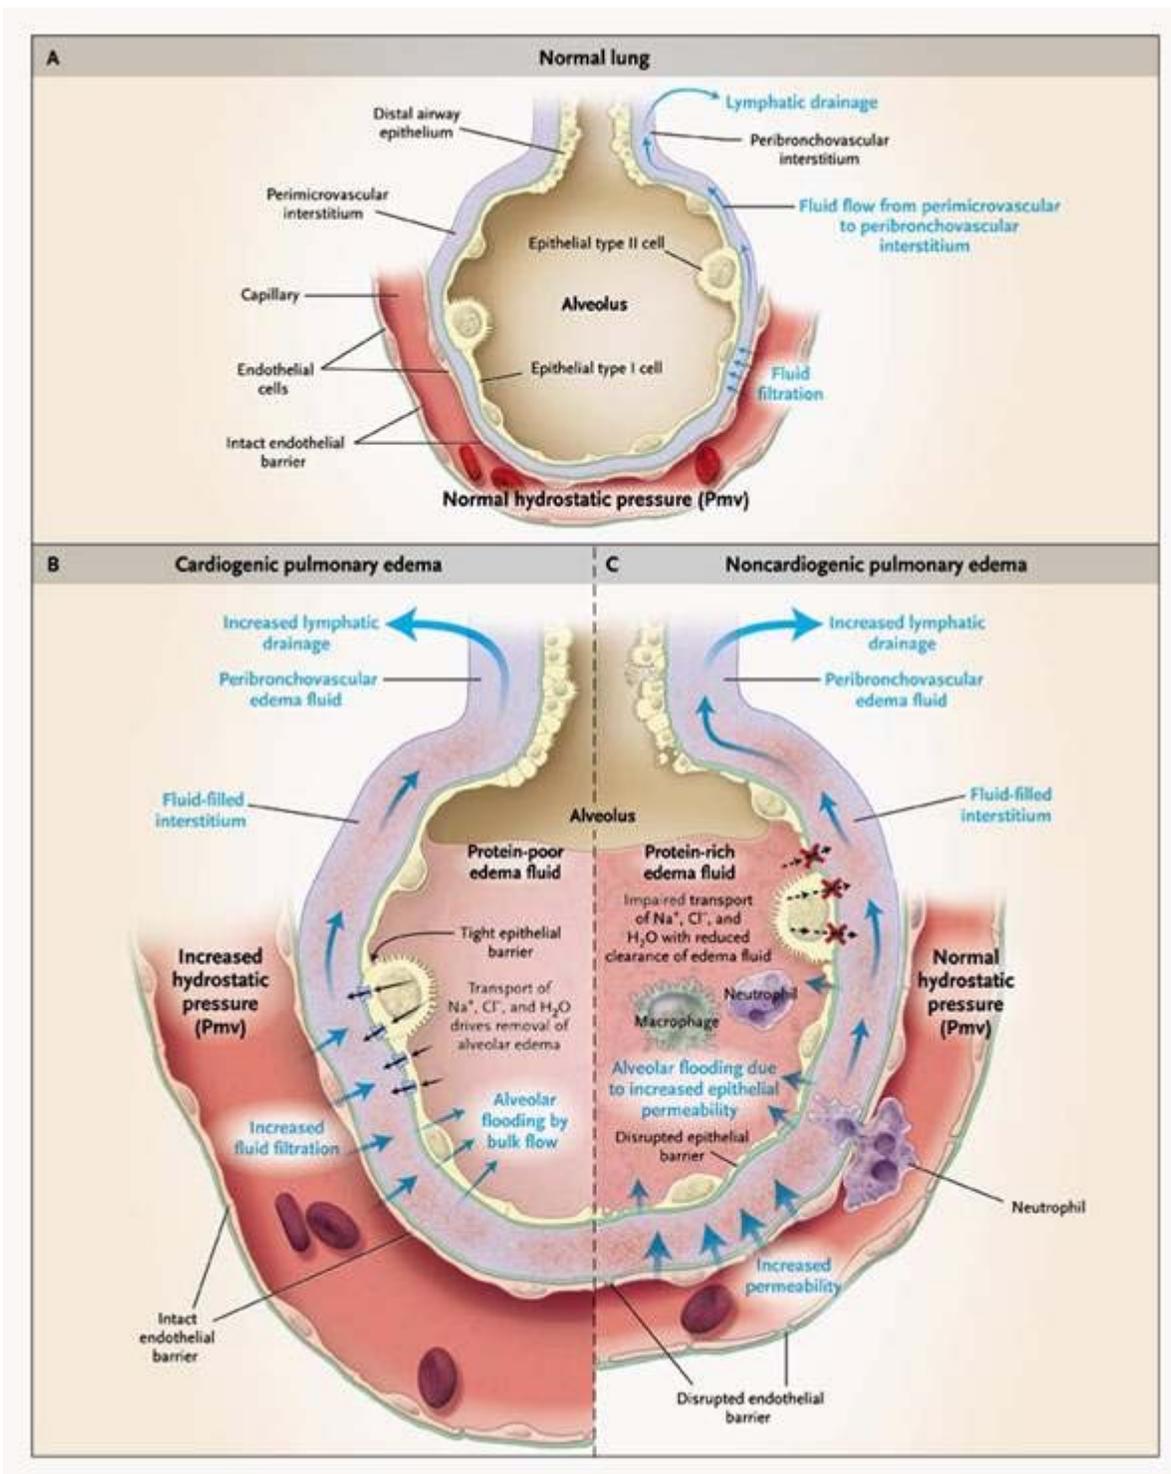

Pulmonary edema is divided into interstitial and alveolar edema.

Interstitial edema is a condition during which serous part of stagnated in the pulmonary circuit blood infiltrates the lung tissue, including peribronchial and perivascular spaces.

During alveolar edema not only the plasma, but also blood components (red and white blood cells, platelets) get out from the vessels. During the respiratory act blood mixes with the air creating large amount of “foam”, which violates gas exchange. This way, in addition to circulatory hypoxia, hypoxic hypoxia appears.

Condition of the patient gets worse quickly. Sitting position is optimal, but not as helping as previously. Respiratory rate is nearly 30-35 breathes per minute, but attacks of breathlessness are constant. Skin is pale with acrocyanosis. Hypoxia of central nervous system usually causes psychomotor agitation. Respiratory acts are noisy; during cough pink blood-tinged phlegm is released. Auscultation allows you to hear different wet rales, sometimes it's even possible to hear them standing aside the patient without phonendoscope.

Pulmonary edema can be also divided according to the blood pressure level: the one with elevated pressure is caused by a hypertonic disease, aorta valve insufficiency or disorders of cerebral perfusion; another one is caused by total myocardial infarction, acute inflammation of myocardial muscle, terminal valve defects, severe pneumonia and is characterized with normal or low blood pressure.

Immediate aid

- make sure patient is sitting with his legs down (orthopnea)
- provide oxygenation through nasal catheter (before placing oil it with

glycerin, insert it to the depth of 10-12 cm – distance from the wing of the nose to auricle) or face mask. Do not use Vaseline, because it can burn in atmosphere with high concentration of oxygen.

However if catheter is not deep enough patient will suffer from an unpleasant “burning” feeling, because oxygen flow will dry mucosa layer of the nasal cavity; also in this situation concentration of oxygen will be lower than expected.

- put venous tourniquets on the limbs in order to reduce amount of blood returning to heart: venous bed of limbs can reserve up to 1,7 liters of blood;
- constantly control heart and kidney activity (ECG, SaO₂ , and blood pressure are checked automatically trough the monitor; to control diuresis you should insert Foley catheter;
- catheterize central vein, because amount of infusions should be based on central venous pressure;
- use medical “defoamers” if they are available (ethyl alcohol or antiphomsylan solution) combined with oxygen inhalation

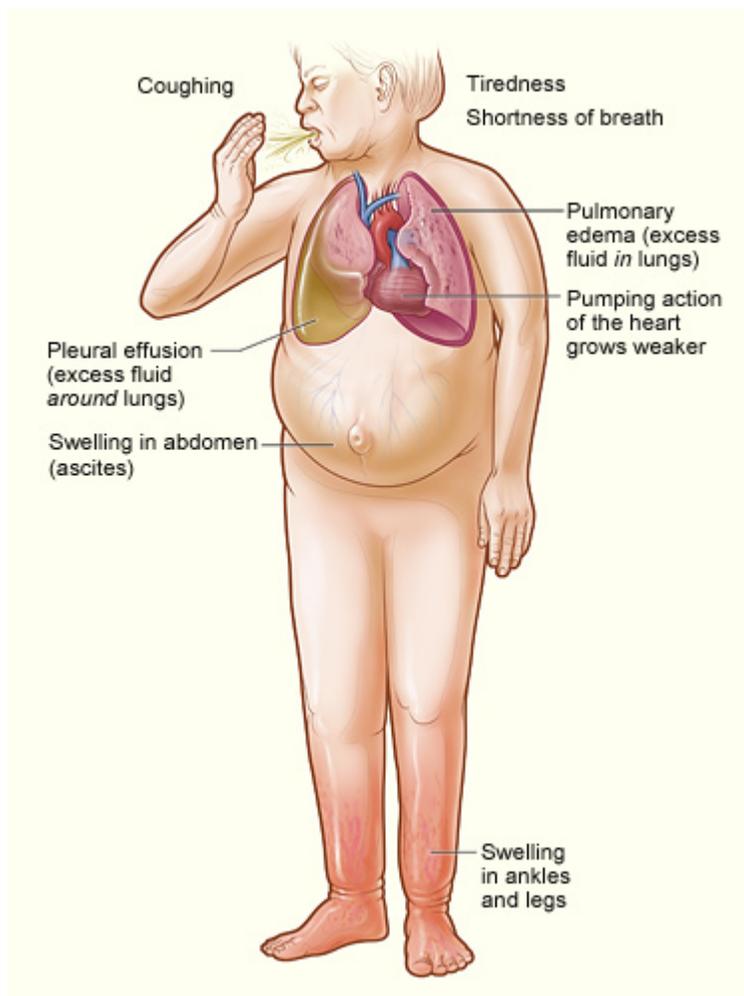

Scheme of oxygenation set connected to “defoamer” container

- a. oxygen source (cylinder with oxygen)
 - b. tube with numerous holes sunk into container with defoamer
 - c. tube for humidified oxygen (its opening should be over the level of fluid);
 - d. patient
- medical treatment: 1% morphine solution (decreases intravascular pressure of pulmonary circuit, inhibits respiration center in medulla oblongata preventive dyspnea progress, sedates patient);
 - solutions of diuretics are used to decrease the circulating blood volume (6-12 ml of 1% furosemid solution, solution of ethacrynic acid), however be careful with them in case of low blood pressure; diuretic effect will last up to 3 hours after i/v infusion, the expected diuresis is 2-3 liters
 - if blood pressure allows you can try to use nitroglycerin to reduce intravascular pressure of pulmonary circuit (1 or 2 tablets with 10 minutes interval)
 - cardiac glycosides for improvement of heart action (0,025% digoxin solution, 0,05% strophanthin solution, 0,06% corglicon solution);
 - in case of high pressure (over 150 mm Hg) use ganglionic blocking agents (1 ml of 5% pentamin solution diluted in 150 ml of saline, give i/v slowly; diluted with

saline 250 mg of trimethaphan solution), because they reduce pressure in pulmonary circuit and lower the amount of blood getting to right half of the heart, however be careful with the dosage and monitor blood pressure level carefully;

- never use osmotic diuretics in case of pulmonary edema – they will increase blood volume and thus heart load!!!

- when everything listed above failed and patient is worsening with every second you should intubate him and start artificial ventilation with positive end expiratory pressure (begin with 4-6 cm H₂O)

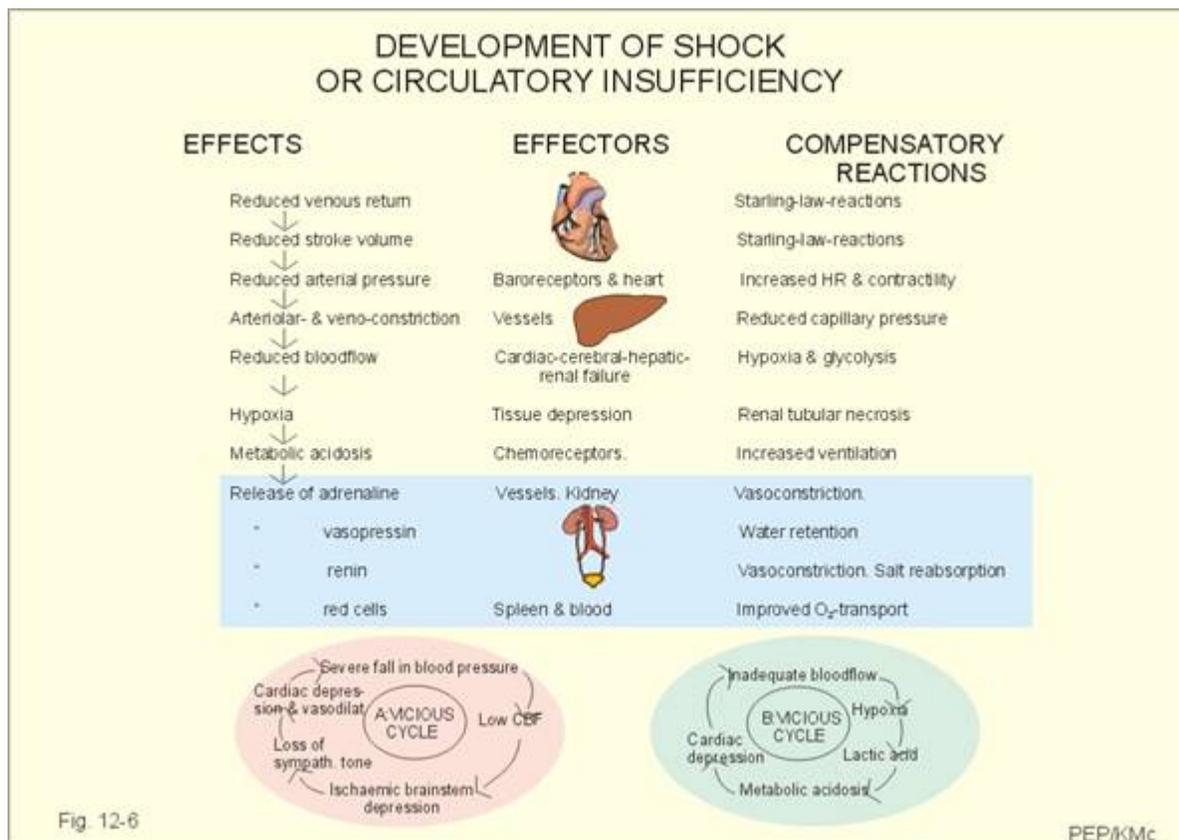

Right-sided heart failure is an inability of right ventricular to pump blood from systemic circuit to the pulmonary circuit due to its weakness or an obstruction to the blood flow.

It occurs in case of pulmonary embolism, right ventricular infarction, excessive infusion therapy (especially including citrated blood) for patients with heart insufficiency, lung diseases (bronchial asthma, emphysema, pneumosclerosis) which cause increase of right ventricular load.

Patients have acrocyanosis, tachycardia, dyspnea, pronounced neck veins, ankle swelling, enlarged liver, ascytis. Central venous pressure is highly increased (up to 20-25 cm H₂O), however pulmonary edema does not appear.

Intensive treatment is mostly pathogenetic:

- limit the infusions (give only life-necessary solutions, check the water balance of the patient and reduce drinking water if necessary);
- in case of citrated blood transfusions use 5-10 ml of 10% calcium gluconate solution per every 500 ml of blood to prevent hypocalcaemia;
- in case of bronchial spasm use bronchial spasmolytics;
- to remove excessive fluid from the body use diuretics (furosemide solution for example);
- metabolic acidosis is corrected with 4% solution of sodium bicarbonate (i/v slowly with acid-base state control);
- in case of pulmonary embolism anticoagulants are used – fraxiparine 0,6 mg subcutaneously; heparin solution – 5000 IU every 4 hours; fibrinolytic drugs (streptokinase, fibrinolysin, urokinase, etc.)

Shock is a pathological state which can be described as a tissue hypoxia caused by hypoperfusion. Pathogenetic basis of shock depends on its reason (trauma, toxins, thermal injury) and at the same time on reactivity of the organism (level of defense

mechanisms mobilization).

Stimulation of sympathetic nervous system - production of catecholamines and other vasoactive substances by hypothalamus and adrenal glands are the universal response of the body to the stress. Those mediators interact with the receptors of peripheral vessels causing their constriction and at the same time they dilate the vascular bed of life-important organs. This is so called “centralization of the flow”: rational decrease of blood flow in less important tissues (skin, organs of abdominal cavity, kidneys) in case of aggressive external influence for protecting life itself (brain, heart, lungs).

However influence of shock agents (pain, hypovolemia, destroyed cells, toxic metabolites), extended microcirculation violations (vascular spasm, microthrombosis and sludge) and caused by them tissue ischemia lead to hypoxic affection and cellular death of the internal organs. Further it can bring multiple organ dysfunction syndrome.

Collapse is a vascular failure. It occurs when body is not able to provide blood flow according to the new level of its needs (either because reaction is not fast enough or because sympathetic activation fails). Vascular bed volume and circulating blood volume are disproportional: too much blood gets to the microcirculation vascular reserve and the amount, which returns to the heart is not enough for the systemic needs (so called “decentralization” of the blood flow). Cardiac output and blood pressure decrease, that causes hypoperfusion of the central nervous system and thus unconsciousness and life-threatening complications.

Collapse definition is a bit nominal, because if such reaction extends in time the state of shock develops. Shock itself can equally run as a vascular failure or as a sudden clinical death.

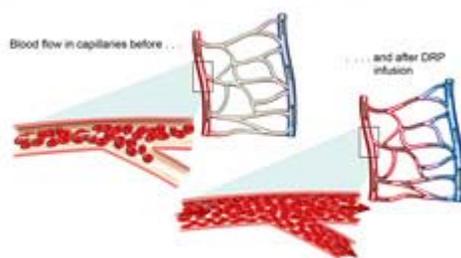

Pathogenetic classification of shock (according to P. Marino, 1998):

- hypovolemic
- cardiogenic
- distributive
- mixed (two and more factors).

Clinical classification of shock:

- traumatic shock;
- haemorrhagic shock;

- dehydration shock;
- burn shock;
- septic shock;
- anaphylactic shock;
- cardiogenic shock;
- exotoxic shock.

Traumatic and haemorrhagic shocks.

Traumatic and haemorrhagic shocks appear in case of sudden severe injuries of the body. Clinical symptoms greatly depend on the initial reason, extent of the tissue damage, blood loss volume, pain intensity, duration of pathological state and type of the body-reaction.

At the beginning patients with trauma are agitated, restless, their complaints (mostly they suffer from pain in the injured area) are numerous and intense. Further, while shock is progressing, you can observe inhibition of the central nervous system up to sopor and coma development. Breathing is rapid and deep, additional muscles participate respiratory acts. When condition of the central nervous system worsens respiration becomes shallow and weak. Comatose patients (if not helped on time) usually suffer from obstructive airways problems (fall of the tongue and soft palate, accumulation of sputum, blood, gastric contents). Skin becomes cyanotic and later mottled (especially noticeable those changes are under the knees and on hips).

In case of great blood loss (over 30% of CBV) skin is pale and clammy. Microcirculation disorders decrease the temperature of the peripheral tissues and difference between rectal and skin temperature is over 3 degrees Celsius. Another important symptom to check is capillary refill: if its over 2 seconds tissue microcirculation is violated (press with your fingertip the nail of the patient for 5 seconds and then check how long this white spot will remain).

Blood loss and tissue fluid loss decrease the subcutaneous turgor, eyeballs tone, blood filling of the subcutaneous veins. Peripheral pulse is weak, rapid and thready; blood pressure and central venous pressure are low. Hypotension and compensatory spasm of renal arteries decreases urine output through reduction of the renal blood flow. This brings state of oliguria-condition in which urine output is less than 0,5 ml per kilogram of body weight per hour.

Classification of blood loss (according to P. Marino, 1998, USA).

Class	Clinical symptoms	Blood loss volume (% of CBV)
I	Orthostatic tachycardia	15
II	Orthostatic hypotension	15-30
III	Low blood pressure in supine position, oliguria	30-40
IV	Consciousness disorders, coma	over 40

In case of traumatic shock erectile and torpid phases are described. Erectile phase is not obligatory: it begins during pre-hospital stage and doesn't last long (minutes). This phase is characterized with agitation, restlessness and stimulation of all vital systems. Torpid phase is much more dangerous, because patients suffer from CNS disorders and their lifesaving systems are as close to breakdown as possible.

To calculate the actual blood loss and thus to know class of shock you can use Allgower index (shock index).

It is a correlation between heart rate and systolic blood pressure:

$$AI = HR / P_{syst.}$$

Normally its value is 0,5-0,7 (for example in case of HR 60 and P_{syst} 120 mm Hg it will be 0,5). Shock conditions causes lowering of blood pressure which is compensated through tachycardia and thus increase of shock index.

Evaluation of blood loss according to shock index.

Shock index	Blood loss volume (% of CBV)	Stage of shock
>1	less than 20	1
1,1-1,7	20-40	2
<1,8	over 40	3

This method of blood loss evaluation is simple and allows quick evaluation of blood loss and its immediate adequate concentration of circulating blood volume. Perhaps you will better understand those calculations using this example:

patient weights 80 kilograms, his blood pressure is 80/50 mm Hg, HR 120 per minute. His perfect circulating blood volume is 70 ml per kilogram: $70 \times 80 = 5600$ ml.

$$SI = 120/80 = 1,5.$$

According to the table above he has 2 stage of shock and he lost nearly 30% (2 stage means from 20% to 40%, lets take 30%) from his CBV. So you will have to compensate 30% from 5 600 ml or: $5600 \times 0,3 = 1680$ ml of blood.

Until shock is not liquidated, even if the bleeding is stopped, lowering of CBL continues (so called relative blood loss, caused by stagnation, aggregation and sequestration of red blood cells in the microcirculation vessels).

	<u>Class I</u>	<u>Class II</u>	<u>Class III</u>	<u>Class IV</u>
Blood Loss	< 750	750-1500	1500-2000	> 2000
% Blood Vol.	< 15%	15 – 30%	30 – 40%	> 40%
Pulse	< 100	> 100	> 120	> 140
Blood Pressure	Normal	Normal	Decreased	Decreased
Pulse Pressure	Normal	Decreased	Decreased	Decreased
Resp. Rate	14 – 20	20 – 30	30 – 40	> 40
UOP	> 30	20 – 30	5 – 15	negligible
Mental Status	sl. Anxious	mildly anx	confused	lethargic
Fluid	crystalloid	crystalloid	blood	blood

During shock compensatory mechanisms of the organism try to fill the vascular bed with whatever fluid they can; this includes water from intercellular space, which causes so

called “blood dilution”. The last one is detected in laboratory tests, which show decrease of blood concentration: subnormal indexes of hematocrit, hemoglobin, red blood cells and protein. This mechanism begins within first few minutes after the injury. However final evaluation of blood concentration indexes is possible only 12-24 hours after the initial trauma.

Profuse acute bleeding (over 30% of CBV during 1 hour) is life threatening. In case of chronic anemia organism is used to hemoglobin deficiency and hemorrhagic lack of even 70% of red blood cells and 30% of plasma might be acceptable (of course it does not mean, that you should not treat the bleeding or blood loss).

CHART 37-3

BEST PRACTICE for
The Client in Hypovolemic Shock

- Ensure a patent airway.
- Start an IV catheter or maintain an established catheter.
- Administer oxygen.
- Elevate the client's feet, keeping his or her head flat or elevated to a 30-degree angle.
- Examine the client for overt bleeding.
- If overt bleeding is present, apply direct pressure to the site.
- Take the client's vital signs every 5 minutes until stable.
- Administer medications as ordered.
- Increase the rate of IV fluid delivery.
- Do not leave the client.

Immediate aid.

First hour of shock is called “golden” because of its prognostic value and great therapeutic possibilities so don't waste even minute of it!

- first of all stop arterial bleeding (press artery to the bone, use special devices like tourniquets or tamponade the wound); be careful with the time of compression, because prolonged total block of blood flow will cause necrosis;
- constantly evaluate patient's condition (pulse over peripheral and central arteries, consciousness, airways patency, effectiveness of external breathing);
- if patient is unconscious and you can't control his airways all the time use the recovery position (three-quarters prone position); be careful with the neck of the patient if you suspect backbone injuries – those patients should be placed in supine position on the firm surface with immobilized neck; patients with pelvic fractures should lay on back with flexed knees;
- immobilize injured limbs with standard splints or improvised material;
- put on the wounds aseptic dressings; bandage is all you need to stop

capillary and venous bleeding; in case of pneumothorax use special Asherman seal or just a three-sided airtight dressing;

- use pain killers: either narcotic analgesics (1% promedol solution) or non-steroidal anti-inflammatory drugs like 50% analgin solution (depends on the pain intensity); patients with shock are unstable, so after giving of analgesics be very attentive to the changes in patient's condition, because pain was sympathetic system stimulator and without it blood pressure will probably lower and respiratory center might be inhibited; if you can't control the state of the patient (too many victims, dangerous environment, transportation) try to use ketamine (2-3 ml of 5% solution, i/m) instead of narcotic drugs: it has analgesic properties, however it will not influence blood pressure or breathing (but to avoid hallucinations use it with 1-2 ml of 5% diazepam solution); local anesthetic infiltration of tissues around the fracture also can be used to reduce pain (10-20 ml of 0,5% Novocain solution);

General principles of intensive trauma treatment

Constantly check the condition of main vital systems, using additional technical and laboratory possibilities. In order to implement such control you should remember about the rule of "4 catheters" for the patients with severe injuries: endotracheal tube (to provide optimal respiration and airways patency control), central venous catheter (for CVP monitoring and infusions), stomach probe (to evacuate its contents), urinary catheter (to control urine output).

Transfusion scheme for patients with blood loss (according to P. Brusov, 1997).

Level of blood compensation	Blood loss (% of CBV)	Total transfusion volume (in % of blood loss volume)	Infusion components
I	less than 10	200-300	Crystalloids
II	less than 20	200	Colloids and crystalloids
III	21-40	180	Packed red blood cells, albumin solution, colloids, crystalloids (0,3+0,1+0,3+0,3)

Patient in critical condition with an urgent need of surgical treatment should be taken to the operating room immediately: in their case intensive therapy of shock will be conducted directly on the operating table during surgery (of course general anesthesia is necessary).

In case of every open wound take care about tetanus prevention (antitetanic immunization according to the scheme).

Shock caused by dehydration

It is a type of hypovolemic shock, which occurs during excessive body fluid loss (not blood, because hemorrhagic shock is another shock type).

Its reasons vary greatly:

- gastrointestinal diseases (profuse vomiting, diarrhea, loss of intestinal fluid through fistula);
- polyuria (uncontrolled diuretic treatment, diabetes mellitus and insipidus, diuretic phase of acute renal failure);
- fluid loss through skin and wound surface (burns, high fever);
- inadequate infusion treatment of postoperative or comatose patients;
- hyperventilation (rapid breathing, Kussmaul breathing, inadequate artificial ventilation parameters in case of apparatus without air humidification).

However not only the complete fluid loss can be the reason of shock, but also it's pathological distribution into the extracellular space (intestinal cavity in case of intestinal paralysis, abdominal cavity in case of ascites, pleural cavity in case of pleurisy). This way will can also act prolonged heavy tissue inflammations (peritonitis) or massive injuries (crush-syndrome).

In cases described above electrolytes are also lost (cations of sodium, potassium, calcium, magnesium; anions of chlorine, hydrocarbonate). It causes complex osmolar, acid-base and electrolytic disorders.

Stage of dehydration shock is evaluated according to the actual fluid loss:

less than 5% of body weight – mild dehydration

5-10% of body weight – moderate dehydration

over 10% of body weight – severe dehydration

Water deficiency brings lowering of cardiac output, blood pressure and central venous pressure (through decrease of blood volume returning to the heart, which leads to compensatory adrenergic vasoconstriction).

Dehydration causes body weight loss, skin and mucosa dryness, decrease of subcutaneous turgor and eyeballs tone, hypothermia, tachycardia, oliguria, thirst. While dehydration progresses compensatory mechanisms weaken and central nervous system suffers: patients become sluggish, confused; hallucinations, cramps and unconsciousness are also possible. Laboratory tests show blood concentration.

One of the most important things in treatment of dehydrated patients is daily balance of fluid: check it carefully through measuring of daily received and lost fluids (food, infusions, stool and urine output). In case of fever or tachypnea make necessary corrections. Balance should be calculated every 12-24 hours (special paper forms make this easier).

Daily fluid balance is calculated by adding all the received fluids (both enteral and parenteral ways) and deducting urine output, stool, perspiration and breathing water loss.

You should remember, that perspiration depends on body temperature: in case of normal temperature (36,6°C) patient loses 0,5 ml/kg of water during every hour; 1 degree of temperature elevation adds 0,25 ml/kg to normal value of 0,5 ml/kg.

According to the fluid balance infusion therapy is divided into positive (for dehydrated patients), negative (for overhydrated patients) and “zero” (for patients without balance disorders).

Water deficiency is calculated according to the formula:

$$W_{\text{def}} = (Ht_p - Ht_n) * 0,2 \text{ BW} / Ht_n,$$

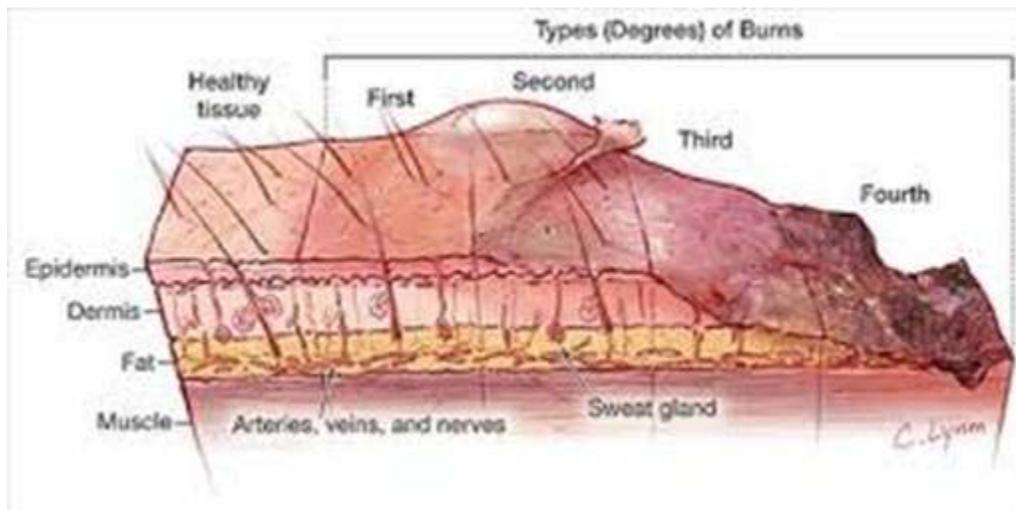

W_{def} – water deficiency, l;

Ht_p – hematocrit of the patient, l/l;

Ht_n - normal hematocrit, l/l;

BW – body weight, kg.

Use crystalloids to treat water deficiency: saline solution, Ringer’s solution, Ringer-lactate solution, electrolytic solutions, 5%, 10, 20% glucose solution. To control potassium concentration (during dehydration this cation is widely lost) prescribe polarizing GIK mixture (pic.9.4), but don’t you ever infuse concentrated potassium solutions quickly – it can cause cardiac arrest (not more than 400 of GIK solution ml per hour).

Burn shock.

Burn shock is a type of hypovolemic shock, caused by thermal or chemical agents.

It appears in adults in case if burns cover over 10-15% of the body surface. Huge plasma loss and pain stimulation of sympathetic nervous system bring hypovolemia, blood flow centralization and low cardiac output syndrome.

At the beginning patients complain of pain, nausea, vomiting, and thirst. Erectile phase of shock changes into torpid, central nervous system after stimulation becomes inhibited (stage depends on burn surface). Breathing and heart rate are increased, blood pressure is decreased. Undamaged skin is cold and mottled. If burning area covers airways asphyxia is highly possible.

Laboratory tests show concentration of the blood.

Immediate aid.

As soon as possible eliminate thermal or chemical agent (cover the fire with wet tissue, wash off chemicals with cold water). Generally use cold water (snow if you don't have an alternative) as cooling agent (not oils, not other organic substances). Take off smoldering clothes, cut them if necessary (don't try to take off something what is "soldered" with the skin by fire). Put a sterile bandage on burn areas. You should use general principles of shock treatment, including rule of 4 "catheters": central venous catheter, urinary catheter, stomach probe and endotracheal tube or nasal catheter for oxygenation – depending on condition of the patient. Take care about the proper pain relieving: prescribe narcotic analgesics (2 ml of 2% promedol solution), neuroleptics (2-3 ml of 0,25% droperidol solution). Infusion therapy is provided with crystalloids, colloids and glucose solutions (in the ratio 1:1:1 in case of mild shock, 2:1:1 in case of severe shock). Constantly monitor condition of the patient: monitor heart rate, blood pressure, central venous pressure and diuresis (make sure its not lower than 0,5 ml/kg per hour). When you suspect a thermal airways injury always intubate the patient: you will not have much time in case if edema will bring asphyxia.

Patients should be treated in special burn centers.

Anaphylactic Shock

Signs and symptoms of Anaphylaxis

Causes:

- Food
- Medication (antibiotics)
- Venom from animals (bugs, snakes, etc.)
- Allergic reactions

Treatment:

- EpiPen (Epinephrine)
- Histamine (pharmaceutical drug)
- 911

How to Prevent it:
The most common cause of this kind of shock are allergic reactions. To counteract the severity of the reaction in the future, immunotherapy is the way to go. The person is gradually vaccinated with progressively larger doses of the allergen, small enough so that the body's immune system can counteract it on its own, conditioning the body.

Glogster by Nick Termini and Zack Assenmacher

Anaphylactic shock

Anaphylactic shock is a type of distributive shock, caused by allergen induced immediate hypersensitivity reaction.

Various factors can cause anaphylactic reaction: serums, antibiotics, blood preparations, local anesthetics (Novocain), hypnotics (Sodium thiopental, Diazepam), radiocontrast agents, etc. Among non-medical allergens most common are: alimentary substances, chemical cleaning agents, cosmetics, insect poisons, fur, etc.

The main condition of anaphylactic reaction is presence of antibodies in previously sensitized organism. Antigen-antibody reaction reveals bioactive substances, such as histamine, bradykinin, slow-reacting substance of anaphylaxis. Those mediators cause vasodilatation and leakage of fluid from vessels into the tissues. The amount of blood returning to the heart decreases greatly, cardiac output reduces and thus blood pressure is lowering until the cardiac arrest appears (usually PEA).

Form of the shock depends on the time of reaction:

- fulminant form – develops within 10 minutes;
- immediate form – pre-shock phase continues 30-40 minutes;

- slow- shock appears within few hours;

Fulminant form can pass without warning signs or with them: the most common are felling of sudden hit, generalized hives and itching, pulsing headache, fear and unconsciousness.

Immediate and slow forms always have precursors (initial warning symptoms) and can develop in different types:

- skin type: itching, generalized hives, flushing;
- cerebral type: intensive headache, nausea, blindness, unconsciousness, cramps;
- asthmatic type: stridor (secondary to swelling of the throat, larynx and trachea), wheezes (caused by spasms of bronchial muscles);
- coronary type: chest pain, hypotension;
- abdominal type: crampy abdominal pain, nausea, vomiting, bloating.

Shock itself is characterized by hypotension (collapse), unconsciousness and breathing disorders. To prevent anaphylaxis you should always remember about importance of detailed allergic history of the patient and proper drug administration (local allergy tests of serums and antibiotics, Bezredko's scheme for serum injections).

In every department of any hospital should be prepared first aid kit for patients with anaphylaxis.

This kit should include:

1. 0,1% adrenaline solution (3-4 ampoules).
2. Infusion set (2) and 2, 5,10 ml syringes (2-4 items of each).
3. Saline solution 40 ml (2 bottles).
4. Polyglucin or refortan (1-2 bottles).
5. 0,5% dopamine solution 5 ml (4-6 ampoules).
6. 3% prednisolone solution (3-5 ampoules).
7. 10% calcium chloride solution (2 ampoules).
8. 2,4% ephyllin solution – 10 ml (2 ampoules).
9. Ambu bag.
10. Venous tourniquet.

11. Antihistamine solutions: 1 ml of 1% dimedrol solution (3-4 ampoules), 2 ml of 2,5% pipolfen solution (2-3 ampoules).

First aid algorithm in case of anaphylactic shock.

Evaluate patient's condition: check pulse, warning signs (precursors).

Immediately liquidate the source of the allergen, which caused anaphylaxis. Lay patient into supine position (head down, legs up). Don't you ever try to take out i/v catheter even if you know for sure, that substance in the infusion set caused anaphylaxis. Separate the set and the catheter, take some blood from the vein and than wash the catheter again, but don't remove it (at least until you don't have the new one). Time is not on your side and you might not be lucky enough to find another vein for infusions. If there was no i/v access – get one.

Give intravenously 0,5-1 ml of adrenaline solution diluted in 10 ml of saline. Check again patient's condition: consciousness, blood pressure, heart rate, and breathing. Start colloid and crystalloid infusions mixed with dopamine (refortan or stabizol with 20 ml of 0,5% dopamine solution). Give bolus of 60-90 mgprednisolone solution (2-3 ml of 3% solution). To improve airway patency you can use euphyllin (10 ml of 2,4% solution). If you notice breathing difficulties (problems with airways or respiration itself) act like in general standards – clean oral cavity and provide airway patency by opening the mouth, titling the head back and thrusting the jaw forward. Use Ambu bag if necessary and respiratory apparatus if available. Cardiac arrest requires immediate CPR.

In case of fulminant anaphylactic reaction only your calm and quick actions will save the patient: call for help, but not leave the patient alone (ask witnesses to help). Stop antigen admission (stop infusion without taking out the catheter). Start colloid and crystalloid infusions, give adrenaline and steroids. Be careful with antihistamine drugs (suprastine, dimedrol, pipolfen) when blood pressure is not yet stable, as they can deepen the hypotension.

Try to minimize the dose, which already is in the tissues: put a tourniquet over a place of injection, use local adrenaline injections around the place of antigen entrance, however those actions are not your main goal and should be provided after stabilization of the patient. Not the amount of the antigen causes shock, but the intense reaction of the organism.

Septic shock

Septic shock is a type of distributive shock, caused by generalized reaction of the organism to microorganisms and their toxins. Its etiology can be connected with

gram-positive and gram-negative bacteria, rickettsia or fungi and any mucosa can be their entrance (intestine, abdominal cavity, urinary tracts, woundsurface). Sepsis has its terminology:

SIRS – systemic inflammatory response syndrome – is a systemic answer of organism to the intensive stimuli (infection, injury, operation, etc.)

When the toxins get to the blood flow tissue macrophages answer their appearance with production of cytokines. Cytokines are mediators of systemic inflammatory response; they trigger a whole number of immune reactions (both humoral and cellular immune response). This bring to circulation and microcirculation disorders and thus to tissue hypoperfusion and tissue anoxemia. Lethality in this type of shock is 60-80%.

Disorders of circulation can be both hyperdynamic and hypodynamic. Hyperdynamic syndrome is characterized with high cardiac output and uninterrupted microcirculation. Hypodynamic reaction appears in case of low cardiac output connected with high vascular resistance; during terminal phase of shock vascular resistance drops drastically and hypotension becomes incurable.

Sepsis has its own terminology. We diagnose SIRS if two of the symptoms listed below are present:

- fever over 38°C or temperature less than 36°C;
- heart rate over 90 pre minute;
- respiration rate over 20 per minute or PaCO₂ < 32 mm HG;
- leucocytosis over $12 \cdot 10^9$ or less than $4 \cdot 10^9$ or more than 10% of young forms

Sepsis itself we state if SIRS is combined with source of infection. Severe sepsis is a sepsis connected with multiple organ dysfunction of two and more systems (for example oliguria and encephalopathy).

Components of multiple organ failure are: septic encephalopathy, polyneuropathy of terminal stages, acute respiratory distress-syndrome, septic shock, ileus and bacterial translocation, renal failure, acute tubular necrosis, DIC syndrome.

Signs of tissue dysfunction:

- arterial hypoxemia (PaO₂ / FiO₂ <300);
- acute oliguria (diuresis less than 0,5 ml/kg per hour);
- creatinine concentration over 0,5 mg/dl;
- activated partial thromboplastin time over 60 seconds;

- enteroparesis;
- thrombocytopenia (less than $100 \cdot 10^9$);
- hyperbilirubinemia (general bilirubin over 4 mg/dl or 70 $\mu\text{mol/l}$).

In those terms septic shock is defined as a condition of tissue and organ hypoperfusion caused by arterial hypotension, which can't be cured with infusions without catecholamines.

Principles of septic shock intensive treatment.

During first 6 hours your main goal is to stabilize the patient:

- central venous pressure should be 8-12 mm Hg (in case of patients with artificial ventilation: 12-15 mm Hg);
- mean arterial pressure > 65 mm Hg;
- diuresis $> 0,5$ ml/kg/hour;
- $\text{SvO}_2 > 70\%$.

1. Provide adequate infusion therapy. Volume of the infusion should be calculated according to the fluid balance and vital indexes (blood pressure, central venous pressure, heart rate). If you state hypotension give 500-1000 ml of crystalloids or 300-500 ml of colloids in 30 minutes; if necessary – repeat with the same volumes (until blood pressure is normal or you notice signs of hyperhydration). There is no evidence that colloids are more useful in this situation.

2. Vasopressors are used if hypotension is resistant to infusion therapy:

- dopamine solution 5-20 $\mu\text{g/kg/min}$
- norepinephrine 0,2-1,0 $\mu\text{g/kg/min}$
- hypophamine 0,01-0,04 U/min in case if dopamine and norepinephrine are ineffective.

3. Empirical antibiotic therapy should be started within first hour of treatment (actually from the moment you diagnosed severe sepsis or septic shock). But before you start it don't forget to take 2 blood samples (20-30 ml of 2 different peripheral veins) and send them to bacteriologist in order to receive type of microorganism and antibiotic sensitivity. The most simple scheme of empiric therapy will be single usage of meropenem or imipenem. If you suspect MRSA (Methicillin resistant Staphylococcus aureus) combine meropenem with vancomycin or linezolid.

4. Steroids are recommended for all patients, who need hemodynamic support (hydrocortisone solution i/v 200-300 mg/day).

5. Respiratory support is a part of ARDS treatment. Indications for artificial ventilation:

- $pO_{2a} < 60$ mm Hg,
- $pCO_{2a} > 50$ mm Hg or < 25 mm Hg,
- $SpO_2 < 85\%$
- respiration rate over 40 per minute.

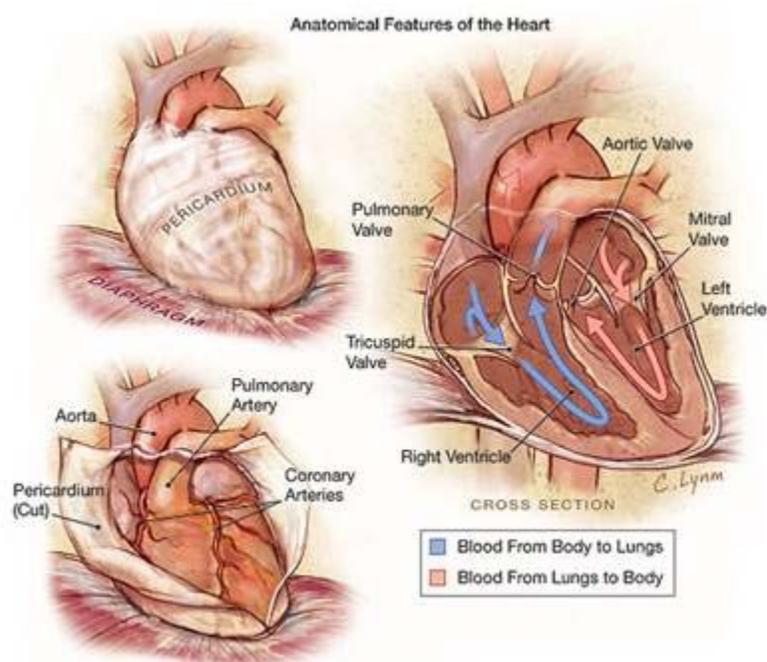

Choosing parameters of ventilation you should remember, that: tidal volume should be 6 ml/kg. P_{plato} – less than 30 cm H₂O, PEEP 5-7 cm H₂O.

6. Surgical treatment of the infection source should be done.

7. Early enteral nutrition improves treatment results and normalizes intestinal functioning. Don't forget about ulcer-prevention (omeprazole 40 mg twice a day, i/v) and peristalsis control (metoclopramide if necessary).

8. Continue syndromic treatment of renal failure, DIC, liver failure, encephalopathy; if it is possible use external methods of detoxification (hemosorbition, plasmapheresis, etc.).

Cardiogenic shock.

Cardiogenic shock is a state of acute heart failure, caused by primary “heart” affection. Usually it happens due to myocardial infarction: necrosis or heart rhythm violations influence negatively pump function of the heart and low cardiac output syndrome appears. This situation

is characterized with high central venous pressure, low blood pressure and compensatory peripheral vascular spasm.

Myocardial infarction according to modern classification is a part of wider category of acute coronary syndrome (together with unstable angina). It is divided into ST elevation MI and non-ST elevation MI (with or without elevation of ST segment on ECG). Those clinical syndromes are different forms of one pathological process: rupture of vulnerable atherosclerotic plaque in coronary artery. Ruptured plaque is filled with blood and this way it blocks blood flow in the artery (additionally affected vessel constricts and blood clot is formed in the place of rupture).

Clinical picture.

Angina pectoris is a burning chest pain or a discomfort feeling, caused by myocardial ischemia. There is also a possibility of referred pain in the jaw, one or both shoulders (usually left), back, neck area or epigastrium. Some of the patients actually never complain of chest pain, but give other pain and discomfort localizations. Unstable angina is suspected when pain pattern changes into more severe, it occurs in rest or minimal exertion and lasts over 10 minutes.

Non-ST-myocardial infarction is suspected when: pain lasts over 20-30 minutes; ST segment is not elevated on ECG, however negative T-wave and depressed ST are possible; troponin tests are positive (directly show myocardial affection). Those clinical features and “coronary” anamnesis state Non-ST-myocardial infarction. Usually those patients do not suffer of sudden occlusion of coronary arteries.

Non-ST-myocardial infarction and unstable angina together are classified as acute coronary syndrome without ST elevation and their treatment is identical.

ST-myocardial infarction is characterised with lasting angina, positive troponin tests, elevated ST segment and Q-waves on 12-leads ECG.

Diagnostics of ACS begins with detailed anamnesis. Physically you can rather differentiate different chest pain reasons than prove infarction (objective symptoms of infarction are really poor: cardiac murmur is possible; asymmetric pulse over upper limbs arteries indicates aorta dissection). ECG shows T-wave changes (sharp or negative T-wave), elevation or depression of ST segment, left bundle branch block (not chronic), heart rhythm violations. Blood tests show moderate leukocytosis $10-15 \cdot 10^9/l$, with young forms of neutrophils, rised erythrocyte sedimentation rate. There are also many MI-marker tests: troponins T and I rise in 3-4 hours after infarction onset and stay high for within 5-7 days (normal values: T_T 0-0,01 ng/l, T_i 0-0,5 ng/l); myoglobin (rises in 2-3 hours, stays within 6-10

hours; normal values 22-66 mkg/l), MB fraction of creatine phosphokinase (rises during first 3-4 hours, maximal level within first 24-36 hours; normal value 0-24 IU/l), lactate dehydrogenase-1 (rises during first 8-10 hours, stays 8-10 days; normal value 240-480 IU/l, LDH-1 is 15-25% of general LDH). There are different express-tests for infarction markers, in many countries they are available even for ambulance service. Additional information can give coagulogram, echocardiography (decrease of ejection fraction, hypokinetic and akinetic areas). Chronography is very important for further treatment tactic; it performed within first hours in case of ST-MI and 24 hours after non-ST-MI onset.

Intensive treatment.

In all cases of acute coronary syndrome are required:

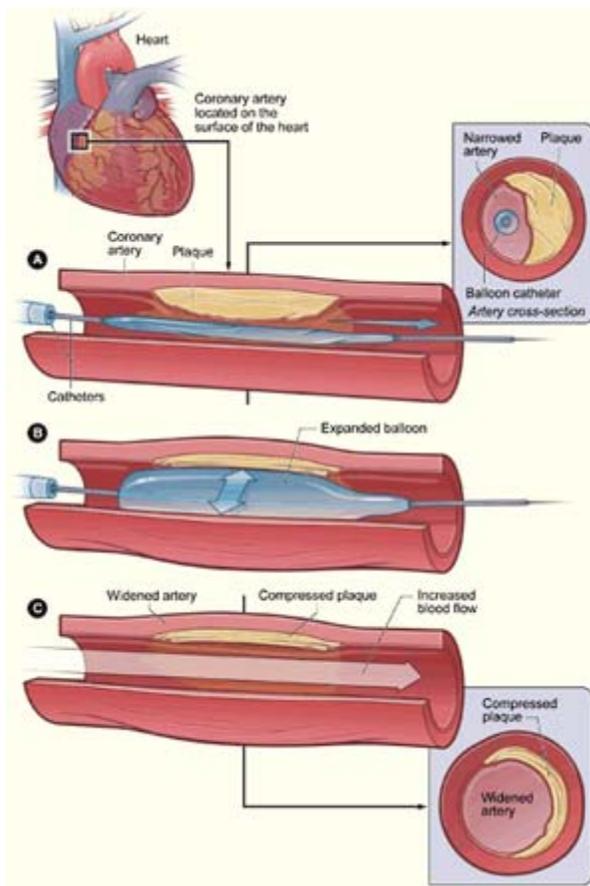

morphine (1 ml , i/v, but don't forget to dilute it with saline and give it very slowly),

oxygen (can be provided through the mask, 6-8 l/min),

nitroglycerin (tablets or 1% solution i/v with blood pressure control),

aspirin (300 mg per os as soon as possible).

The main point of therapy during the first stage of infarction (the most acute) is re-perfusion. After first 12 hours from the moment of pain onset risk of re-perfusion is overwhelming its benefits. Thrombolytics do not provide reperfusion in all patients, however they are dangerous because of haemorrhagic complications. So the choice we actually have during first hours is percutaneous coronary intervention (in case if it is not slowing re-perfusion).

Schemes of thrombolysis

- streptokinase 250 000 U, diluted in 20 ml of saline, given during 30 minutes; then 100 000 U are given i/v during 24-48 hours;
- actilyse 15 mg in bolus, then 0,75 mg/kg during 30 minutes, later 0,5 mg/kg during 60 minutes;
- urokinase 4400 U/kg during 10 minutes, then 4400 U/kg/hour during 12-24 hours.

Relative contraindications to thrombolytic therapy are: early postoperative period, recent injury or gastrointestinal bleeding, vascular cerebral pathology, hypertension with systolic blood pressure over 180 mm Hg or diastolic pressure over 110 mm Hg, high probability of left atrium clot (mitral stenosis with atrialfibrillation), acute pericarditis, subacute bacterial endocarditis, functional disorder of coagulation system, hepatic failure, pregnancy, diabetic hemorrhagic retinopathy, septic thrombophlebitis, patients, who take warfarin constantly.

Absolute contraindications: previous usage of streptokinase (within 4 years); streptococcus infection, active internal bleeding, state after cerebrovascularaccident, recent cerebral or spinal operation, intracerebral aneurism.

Treatment of patients with unstable angina.

The goal of immediate treatment is to prevent further clot formation. You can achieve this by usage of low molecular weight heparin in therapeutic doses. Another way to lower clot-risk is application of β -blockers (or diltiazem) to lower the myocardial oxygen consumption and angiotensin-converting-enzyme inhibitors to avoid left ventricle contractibility disorders or circulation failure.

Further treatment should include heparin (with coagulation control tests – aPTT every 4-6 hours). At the beginning unfractionated heparin is used in the dose of 120-160 U/kilogram, the maintenance dose is 20 U/kg/hour. The duration of such treatment is 4-5 days (if aPTT is less than 45 seconds speed of the infusion is increased by 10%; if aPTT is over 75 seconds the dose is decreased by 10 %). As an alternative you can use low molecular weight heparin (enoxaparin 1 mg/kg every 12 hours; nadroparin 86 U/kg every 12 hours).

β -blockers should be given in all cases except for those with heart rate is 50 and less, systolic blood pressure is lower than 100 mm Hg, AV blocks II-III degrees, concomitant bronchial asthma, obstructive bronchitis. Usually metoprolol is used (25-100 mg per day) intravenously during first hours, but you should control its effects when you change i/v forms into oral forms (heart rate, blood pressure).

You can also use: ACE inhibitors (captopril 6,25-50 mg/day, enalapril 2-20 mg/day, ramipril 2,5-5 mg/day); metabolic medicines (preductal 20 mg twice a day; corvitin 500 mg i/v 3 times a day during first day, twice a day on 2 and 3 day, 250 mg once a day on 4 and 5 day).

Cardiac shock itself has several forms (according to M. Chazov).

1. Reflex shock appears as a reaction to severe pain and is characterized with decrease of vascular tone and blood pressure. It is relatively easy for treatment form for shock.
2. True cardiac shock (already described).
3. Arrhythmogenic shock gives a clinical picture of serious heart rhythm violation, which worsens coronary perfusion and extends necrosis zone.
4. Inert shock is the most severe cardiac shock, hardly cured with conservative methods.

Immediate aid.

1. Place patient into semi-sitting position.
2. Free the chest (unzip shirt if it has tight collar), provide fresh air supply.

3. Check the pulse, blood pressure, consciousness.

4. If you notice pulmonary edema signs treat it appropriately (recommendations written for immediate aid of pulmonary edema you can find in chapter 3).

Intensive treatment.

1. Provide oxygen supply (flow 6-8 liters/minute). Earlier nitrous oxide narcosis was used in case of resistant pain.

2. Use pain killers as described above (1 ml of 1% morphine solution, neuroleptanalgesia: 2 ml of 0,005% fentanyl solution and 1-2 ml of 2,5%droperidol solution; if you don't have narcotic medicines or you don't have possibility to observe patients condition (respiration rate) – use 2 ml of 50%metamizol (analgin) solution intravenously).

3. In order to reduce venous hypertension use diuretics (furosemide solution 20-40 mg intravenously), venous dilators (nitroglycerin and sodiumnitroprusside, 100 mg of each diluted in 200 ml of saline, 5-10 drops per minute), however be very careful with them and control blood pressure all the time while using them.

4. Cardiac output can be regulated in a pharmaceutical way. Your choice of medicine depends on blood pressure:

a. systolic blood pressure less than 70 mm Hg - use norepinephrine (1-30 mcg/min) or dopamine (5-20 mcg/kg/min);

b. systolic blood pressure between 70-100 mm Hg - use dopamine solution (2,5-10 mcg/kg/min);

c. systolic blood pressure over 100 mm Hg – use dobutamine (2-20 mcg/kg /min);

d. in case of diastolic blood pressure is over 100 mm Hg use peripheral vasodilators (nitroglycerin, sodium nitroprusside).

For heart rhythm disorders prescribe antiarrhythmic agents. In case of bradycardia you can choose 1 ml of 0,1 % atropine solution (as adjuncts for haemodynamics control also dopamine, adrenaline in the most severe stages). Tachycardia with heart rate over 130 demands ECG topical diagnostics: atrial fibrillation and atrial flutter are treated with cardiac glycosides, β -blockers, anticoagulants; paroxysmal supraventricular tachycardia –needs vagal tests and adenosine; ventricular tachycardia is treated with lidocaine infusions (1-1,5 mg/kg every 5-10 minutes) and if its not enough – use procaine (20-30 mg/min) or cardioversion.

Exotoxic shock is a type of mixed shock and described in the chapter 8.

Medical operations and manipulations.

Peripheral intravenous access.

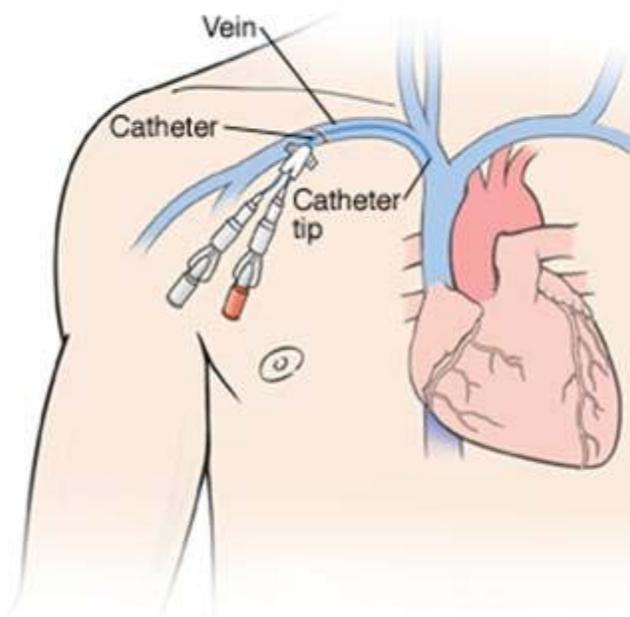

Indications: necessity of infusions.

Required equipment: i/v catheter, giving set (filled with saline), tourniquet, sterile gloves, gauze with antiseptic solution (alcohol swab); i/v dressing.

Procedure: usually i/v lines are inserted in the forearm (lower third,) or hand (try to avoid cubital veins initial catheterization, because you can use them if other possibilities will fail). Apply a tourniquet above the insertion place and disinfect the skin with antiseptic (alcohol swab, special gauze - whatever). Put on the gloves (you can put them at the beginning, but by the moment of taking catheter from the package use antiseptic to disinfect them again) and with your free hand (not the one holding catheter) tract the skin below the vein in order to stabilize its position. Now you have two possibility: direct insertion of the needle into the vein or piercing of the skin aside the vein with further movement of the needle tip over the vein and vein puncture. When blood appears in the chamber, withdraw the needle and

advance the cannula. When you are sure that the catheter is in the vein, release the tourniquet and flush the line with saline (connect the giving set with the cannula). Cover the insertion area with special dressing or simply with the plaster. Make sure everything is working properly (no extravasation signs, no blood in the giving set, quick infusion is possible) and access can't be easily removed. If you notice that growing oedema near the insertion place probably you will have to make another i/v access, because this catheter should be removed and its place should be bandaged in order to prevent further extravasation, i/v insertion of cardiac electrodes.

Central vein catheterization (subclavian vein)

Indications: necessity of permanent infusions, nutrition support, CVP and cardiac output measuring, infusion of drugs which will probably cause phlebitis if used through peripheral veins (hypertonic solutions, chemotherapy, etc).

Required equipment: central venous catheterization set (8-10 cm needle, catheter, wire guide and dilators), giving set, syringes (10 ml, 5 ml), saline (400 ml), 4 ml of 1-2% lidocaine solution, plaster or special dressing, roll (length 40-60*10-15 cm).

Procedure: first of all be aware of the fact that correct patient's position is the key to the successive central vein catheterization. Patient is lying in a supine position with a roll between blades. The arm on the side of puncture is adducted to the trunk and also supine, hand is turned into opposite direction (although some specialists consider this position wrong, because according to their observations it decreases the vein lumen). Usually we are using right subclavian vein, because the risk of complications (pneumothorax for example) is lower from this side (left lung is "higher" due to heart localization, so you can more easily to "catch" it during puncture).

Ask the nurse or assistant to disinfect the puncture area (swab with antiseptic solution 3 times). Wash your hands and put on sterile gloves according to general standards of aseptic. Take the necessary equipment from the kit and position it on a sterile surface in a way you find handy. Find the place of puncture: palpate with the fingers of your right hand point between the middle and medial third of the clavicle, 1-1,5 cm below it. Fill the 5 ml syringe with local anesthetic and infiltrate the tissues around this point. Then take the needle from the set and connect it to the syringe filled with saline. Fix the collar bone over the point of puncture with the fingers of your left hand and perforate the skin, holding the hub firmly. Move forward between collar bone and first rib, until you will feel the increase of resistance (fascia is lying few centimeters deep). After this moment move forward the needle in the direction of sternocostal articulation with continuous aspiration. When you will see the blood in the barrel disconnect the syringe from the needle (close the lumen with the fingertip of your left thumb to prevent air embolism) and insert carefully wire guide until the last of its marks. Holding the wire withdraw the needle. Try not to make unnecessary movements, because needle disconnection and wire insertion are the most “uncertain” steps of central vein cannulation (accidentally you can “loose” the vein). If it is needed use dilators: thread them over the wire and enlarge the entry site (use twisting movements pushing the dilator forward). When you will find the entry wide enough to let the catheter through without much resistance thread the catheter over the wire until the wire will exit the distal lumen of catheter (grasp it there with your left hand). Continue moving the catheter forward (simultaneously pool the wire out) until it will be at the mark your desire. Take out the wire completely and check the placement of catheter by aspiration with the syringe. If you receive venous blood you can flash the catheter with saline and connect giving set (or take blood samples, measure CVP or infuse medicines). Don't forget to fix the external part of the catheter with the special dressing or suture. After all this is done check the catheter placement with an X-ray (it should not end in the right atrium).

Pic. 4.1 Central vein access

- a. Patient's position. Place and direction of puncture.

- b. Needle is in the vein, wire is being inserted.

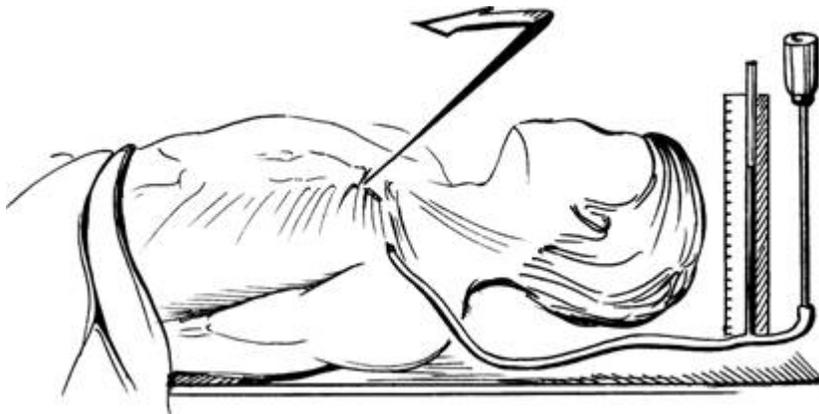

- c. Insertion of the catheter with the help of wire (rotary motion).
 d. Removal of the wire.

Measurement of central venous pressure.

Indications: haemodynamics control (circulating blood volume, vascular tone, heart activity) in case of circulatory diseases, shocks, collapse, prolonged infusion therapy.

Required equipment: central venous line, giving set filled with saline, ruler (you have the most simple method, there are also other ways, which require manometer or transducer).

Procedure: find the middle axillary line and mark it (patient is lying supine) – this is a “zero” level for all the measurements you are going to make (level of right atrium). Connect the giving set to the central venous catheter and place the tubing of the set at the “zero level”. Disconnect the bottle of the infusion and the giving set needle (thus you will connect the fluid in the tubing with atmospheric pressure). The level of the fluid will fall until the moment hydrostatic pressure of the fluid column and pressure of the blood in the catheter (we take it as pressure of the right atrium) will be equal. The height of the fluid column in the tubing is actually patient’s central venous pressure. Measure the fluid column with the ruler and you will get the numerical equivalent of this index.

Measurement of central venous pressure

Control tests.

1. Choose the wrong statement:

- A. venous vessels contain 5 times blood more than arterial
- B. central venous pressure is normally 60-120 mm of water column
- C. arterioles tone influences blood pressure
- D. serotonin constricts vessels
- E. in case of pulmonary edema, due to blood accumulation, central venous pressure lowers.

2. If blood pressure is 80/40 mm of Mercury and the heart rate is 120 per minute, what will be the shock index?

- A. could not be calculated, as we don't know the blood loss
- B. $(80+40)/120=1$
- C. $120/80=1,5$
- D. $80/120=0,67$
- E. $120/40=3$

3. Which statement is wrong in case of traumatic shock?

- A. shock index is very low
- B. low cardiac output occurs
- C. centralization of the circulation develops
- D. central venous pressure lowers
- E. erythrocytes begin to stick together

4. Choose the best treatment of fulminant anaphylactic shock:

- A. dimedrol, prednisolone, cordiamin - intravenously
- B. atropine, pipolfen, prednisolone - ointravenously
- C. poliglukin, calcium chloride, hydrocortisone - intravenously
- D. adrenalin, polyglucin, prednisolone - intravenously
- E. local usage of adrenalin in the place of injection, antihistamine medications intravenously

5. In case of cardiogenic shock you will not observe:

- A. lowering of central venous pressure
 - B. blood stagnation in the lungs
 - C. arrhythmias
 - D. lowering of blood pressure
 - E. decrease of urine output
6. Dehydration shock is characterized with:

- A. blood dilatation
- B. dilatation of the vessels
- C. hypoglycemia
- D. increasing of central venous pressure
- E. weight loss

7. To treat pulmonary edema of cardiac origin you should give:

- A. euphillin
- B. mannitol
- C. morphine
- D. verospiron
- E. calcium chloride

8. Choose the wrong statement:

- A. only in case of cardiac shock central venous pressure increases
- B. to increase blood pressure in case of traumatic shock you should use first of all adrenaline
- C. all shock states reduce cardiac output
- D. each shock lasting long enough can cause renal insufficiency
- E. in case of dehydration shock transfusion of blood is not indicated

Task 1.

Patience, the patient of 44 years, has the central venous pressure 100 mm of water column. What are probable reasons of such value? Describe the therapy.

Task 2.

During the class students of group N were checking blood volume. Results were lost. Calculate blood volume according to the parameters below:

- A. Man of 40, height 170 cm, weight 96 kg
- B. Man of 66, height 150 cm, body weight 66 kg
- C. Man of 14, height 148 cm, weight 41
- D. Man of 59, height 154 cm, weight 88 kg
- E. Man of 28, height 169 cm, body weight 61 kg.

Task 3.

After the train departure station workers found a 44 year old citizen Kane, the patient, who was lying aside the rails and suffering from a severe pain. Patience is holding with both hands his bleeding remains of the right leg (limb is amputated at middle of the thigh). The rest of the leg is lying in the pool of blood on the rails.

- A. Nurse Annie, who came immediately
- B. The “Dream team” – ambulance workers, who arrived in 10 minutes.

Task 4.

Patience, the patient of 44 with a body weight 78 kilograms, is in a shock condition due to trauma. He is sluggish. His skin is cyanotic, his breathing is rapid (24 per minute). Blood pressure is 90/40 mm Hg., heart rate – 128/minute. Central venous pressure is 0. Urinary output per hour is 20 ml. Calculate AI and evaluate the level of traumatic shock compensation.

Task 5.

Patience, the patient of 54, suddenly felt chest pain in 3 o'clock in the morning. He took one nitroglycerin tablet – it didn't help. The “Dream team” – ambulance workers who arrived later found next symptoms: gray clammy skin, shortness of breath, moist rales in lower lobes of the lungs. Heart sounds are weak, blood pressure is 100/60 mm Hg, heart rate – 100/minute. Pulse is weak and arrhythmic.

Describe the algorithm of the “Dream team”.

Task 6.

Your neighbor, granny Annie, suddenly felt ill. She is suffering from hypertonic disease for many years. During the last day her condition worsened – antihypertensive medicines are not effective any more. She has a shortness of breath, noisy breathing, cough with pink phlegm. What are your actions before the arrival of the ambulance?

Task 7.

Nurse Annie was measuring central venous pressure in the intensive care unit. Diagnoses of her patients are: a. myocardial infarction; b. traumatic shock; c. condition

after gastric resection; d. anaphylaxis. The CVP results were: 70 mm Hg, 30 mm Hg, 160 mm Hg, 0 mm Hg. Connect each disease with its probable central venous pressure.

Violations of homeostasis and their correction.

The importance of the water to the organism.

Life on earth was born in the water environment. Water is a universal solvent for all the biochemical processes of the organism. Only in case of stable quantitative and qualitative composition of both intracellular and extra cellular fluids homeostasis is remained.

The body of an adult human contains 60% of water. Intracellular water makes 40% of the body weight, the water of intercellular space makes 15% of body weight and 5% of body weight are made by the water in the vessels. It is considered that due to unlimited diffusion of water between vessels and extra vascular space the volume of extracellular fluid is 20% of body weight (15%+5%).

Physiologically insignificant amounts of water are distributed beyond the tissues in the body cavities: gastrointestinal tract, cerebral ventricles, joint capsules (nearly 1% of the body weight). However during different pathologic conditions this “third space” can cumulate large amounts of fluid: for example in case of ascites caused by chronic cardiac insufficiency or cirrhosis abdominal cavity contains up to 10 liters of fluid. Peritonitis and intestinal obstructions remove the fluid part of blood from the vessels into the intestinal cavity.

Severe dehydration is extremely dangerous for the patient. Water gets to the body with food and drinks, being absorbed by the mucous membranes of gastro-intestinal tract in total amount of 2-3 liters per day. Additionally in different metabolic transformations of lipids, carbohydrates and proteins nearly 300 of endogenous water are created. Water is evacuated from the body with urine (1,5-2 liters), stool (300 ml), perspiration and breathing (those two reasons are combined as “perspiration loss” and make from 300 to 1000 ml per day).

Water balance is regulated through complicated, but reliable mechanisms. Control over water and electrolytes excretion is realized by osmotic receptors of posterior hypothalamus, volume receptors of the atrial walls, baroreceptors of carotid sinus, juxtaglomerular apparatus of the kidneys and adrenal cortical cells.

When there is a water deficiency or electrolytes excess (sodium, chlorine) thirst appears and this makes us drink water. At the same time posterior pituitary produces antidiuretic hormone, which decreases urine output. Adrenals reveal into the blood flow aldosterone, which stimulates reabsorption of sodium ions in the tubules and thus also decreases diuresis (due to osmosis laws water will move to the more concentrated solution).

This way organism can keep precious water.

On the contrary, in case of water excess endocrine activity of glands is inhibited and water is actively removed from the body through the kidneys.

Importance of osmolarity for homoeostasis.

Water sections of the organism (intracellular and extracellular) are divided with semipermeable membrane – cell wall. Water easily penetrates through it according to the laws of osmosis. Osmosis is a movement of water through a partially permeable membrane from the solution with lower concentration to a solution with higher concentration.

Osmotic concentration (osmolarity) is the concentration of active parts in one liter of solution (water). It is defined as a number of miliosmoles per liter (mOsm/l). Normally osmotic concentration of plasma, intracellular and extracellular fluids is equal and varies between 285mOsm/l. This value is one of the most important constants of the organism, because if it changes in one sector the whole fluid of the body will be redistributed (water will move to the environment with higher concentration). Over hydration of one sector will bring dehydration of another. For example, when there is a tissue damage concentration of active osmotic parts increases and water diffuses to this compartment, causing oedema. On the contrary plasma osmolarity decreases, when there is a loss of electrolytes and osmotic concentration of the cellular fluid stays on the previous level. This brings cellular oedema, because water moves through the intracellular space to the cells due to their higher osmotic concentration.

Cerebral oedema appears when the plasma osmolarity is lower than 270 mOsm/l. Activity of central nervous system is violated and hyposmolar coma occurs. Hyperosmolar coma appears when the plasma osmolarity is over 320 mOsm/l: water leaves the cells and fills the vascular bed and this leads to cellular dehydration. The sensitive to cellular dehydration are the cells of the brain.

Plasma osmolarity is measured with osmometer. The principle of measurement is based on difference in freezing temperature between distilled water and plasma. The higher is the osmolarity (quantity of molecules) the lower is freezing temperature.

Plasma osmotic concentration can be calculated according to the formula:

$$\text{Osmotic concentration} = 1,86 * \text{Na} + \text{glucose} + \text{urea} + 10,$$

Plasma osmolarity (osmotic concentration) – mOsm/l

Na- sodium concentration of plasma, mmol/l

Glucose- glucose concentration of the plasma, mmol/l

Urea- urea concentration of the plasma, mmol/l

According to this formula sodium concentration is the main factor influencing plasma osmolarity. Normally sodium concentration is 136-144 mmol/l. Water and electrolytes balance can be violated with external fluid and electrolytes loss, their excessive inflow or wrong distribution.

9.3 Fluid imbalance and principles of its intensive treatment.

Water imbalance is divided into dehydration and overhydration.

Dehydration is caused by:

- excessive perspiration in conditions of high temperature;
- rapid breathing (dyspnea, tachypnea) or artificial ventilation without humidification of the air;
- vomiting, diarrhoea, fistulas;
- blood loss, burns;
- diuretics overdose;
- excessive urine output;
- inadequate enteral and parenteral nutrition or infusion therapy (comatose patients, postoperative care);
- pathological water distribution (“third space” in case of inflammation or injury).

Dehydration signs: weight loss, decrease of skin turgor and eyeballs tone, dry skin and mucous membranes; low central venous pressure, cardiac output and blood pressure (collapse is possible); decreased urine output and peripheral veins tone; capillary refill over 2 seconds (microcirculation disorders) and low skin temperature; intracellular dehydration is characterized with thirst and consciousness disorders. Laboratory tests show blood concentration: hematocrit, hemoglobinconcentration, protein level and red blood cells concentration increase.

Overhydration appears in case of:

- excessive water consumption, inadequate infusion therapy;

- acute and chronic renal failure, hepatic and cardiac insufficiency;
- disorders of fluid balance regulation;
- low protein edema.

Clinical findings in case of overhydration are: weight gain, peripheral oedema, transudation of the plasma into the body cavities (pleural, abdominal), high blood pressure and central venous pressure. In case of intracellular overhydration appear additional symptoms: nausea, vomiting, signs of cerebral edema (spoor, coma). Laboratory tests prove hemodilution.

According to the osmotic concentration of plasma dehydration and overhydration are divided into hypotonic, isotonic and hypertonic.

Isotonic dehydration is caused by equal loss of electrolytes and fluid from the extracellular space (without cellular disorders). Blood tests show hemoconcentration; sodium level and osmotic concentration are normal.

To treat this type of water imbalance use normal saline solution, Ringer solution, glucose-saline solutions, etc.. The volumes of infusions can be calculated according to the formula:

$$V_{H_2O} = 0,2 * BW * (H_{tp} - 0,4) / 0,4 ,$$

V_{H_2O} – volume of infusion, l

H_{tp} – patient's hematocrit, l/l,

BW – body weight, $0,2 * BW$ – volume of extracellular fluid,

0,4- normal hematocrit, l/l,

Hypertonic dehydration is caused by mostly water loss: first it appears in the vascular bed, than in the cells. Laboratory tests show hemoconcentration: elevated levels of proteins, red blood cells, hematocrit. Plasma sodium is over 155 mmol/l and osmotic concentration increases over 310 mOsm/l.

Intensive treatment: if there is no vomiting allow patients to drink. Intravenously give 0,45% saline solution and 2,5 % glucose solution, mixed with insulin. The volume of infusions is calculated according to the formula:

$$V_{H_2O} = 0,6 * BW (Na_p - 140) / 140,$$

V_{H_2O} – water deficiency, l

Na_p – plasma sodium, mmol/l

BW – body weight, 0,6*BW volume of general body fluid

140 – physiological plasma sodium concentration

Hypotonic dehydration is characterized with clinical features of extracellular dehydration. Laboratory tests show decrease of sodium and chlorine ions. Those changes cause intracellular movement of the water (intracellular overhydration). Hemoglobin, hematocrit and protein levels are increased. Sodium is lower than 136mmol/l, osmolarity is lower than 280 mOsm/l.

To treat this type of water imbalance use normal or hypertonic saline and sodium bicarbonate solution (depends on blood pH). Do not use glucose solutions!

The deficiency of electrolytes is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

Na_d – sodium deficiency, mmol

Na_p – plasma sodium, mmol/l

BW – body weight, 0,2 BW – volume of extracellular fluid

Isotonic overhydration is caused by excess of the water in the vascular bed and extracellular space; however intracellular homeostasis is not violated. Hemoglobin is less than 120 g/l, protein level is less than 60 g/l, plasma sodium is 136-144 mmol/l, osmotic concentration is 285-310 mOsm/l.

Treat the reason of imbalance: cardiac failure, liver insufficiency, etc. Prescribe cardiac glycosides, limit salt and water consumption. Give osmotic diuretics (mannitol solution 1,5 g/kg), saluretics (furosemide solution 2 mg/kg), aldosterone antagonists (triamterene – 200 mg), steroids (prednisolone solution 1-2 mg/kg) albumin solution if necessary (0,2-0,3 g/kg).

Hypertonic overhydration is a state of extracellular electrolytes and water excess combined with intracellular dehydration. Blood tests show decrease of hemoglobin, hematocrit, protein level, however sodium concentration is increased over 144 mmol/l, osmotic concentration is over 310 mOsm/l.

To treat this condition use solutions without electrolytes: glucose with insulin, albumin solutions and prescribe saluretics (furosemide solution), aldosterone antagonists (spironolactone). If it is necessary perform dialysis and peritoneal dialysis. Do not use crystalloids!

Hypotonic overhydration is a state of extracellular and intracellular water excess. Blood tests show decrease of haemoglobin, hematocrit, proteins, sodium and osmotic concentration. Intensive therapy of this condition includes osmotic diuretics (200-400 ml of 20% mannitol solution), hypertonic solutions (50 ml of 10% saline intravenously), steroids. When it is required use ultrafiltration to remove water excess.

Electrolytes disorders and their treatment

Potassium is a main intracellular cation. Its normal plasma concentration is 3,8-5,1 mmol/l. Daily required amount of potassium is 1 mmol/kg of body weight.

Potassium level less than 3,8 mmol/l is known as kaliopenia. Potassium deficiency is calculated according to the formula:

$$K_d = (4,5 - K_p) * 0,6 \text{ BW}$$

K - potassium deficiency, mmol;

K_p – potassium level of the patient mmol/l;

$0,6 * \text{BW}$ – total body water, l.

To treat this state use 7,5% solution of potassium chloride (1ml of this solution contains 1 mmol of potassium). Give it intravenously slowly with glucose and insulin (20-25 ml/hour). You can also prescribe magnesium preparations. Standard solution for kaliopenia treatment is:

10% glucose solution 400 ml

7,5% potassium chloride solution 20 ml

25% magnesium sulphate solution 3 ml

insulin 12 units

Give it intravenously slowly, during one hour. Forced bolus infusion of potassium solutions (10-15 ml) can bring cardiac arrest.

Potassium level over 5,2 mmol/l is a state called hyperkalemia. To treat this condition use calcium gluconate or calcium chloride solutions (10 ml of 10% solution intravenously), glucose and insulin solution, saluretics, steroids, sodium bicarbonate solution. Hyperkalemia over 7 mmol/l is an absolute indication for dialysis.

Sodium is the main extracellular cation. Its normal plasma concentration is 135-155 mmol/l. Daily required amount of potassium is 2 mmol/kg of body weight.

Sodium concentration which is lower than 135 mmol/l is known as hyponatraemia. This condition is caused by sodium deficiency or water excess. Sodium deficiency is calculated according to the formula:

$$Na_d = (140 - Na_p) * 0,2 BW,$$

Na- sodium deficiency, mmol;

Na_p – sodium concentration of the patient mmol/l;

0,2*BW – extracellular fluid volume, l.

To treat it use normal saline (1000 ml contains 154 Na mmol) or 5,8% solution of sodium chloride – your choice will depend on osmotic concentration.

Sodium concentration over 155 mmol/l is a state called hypernatremia. This condition usually appears in case of hypertonic dehydration or hypertonicoverhydration. Treatment was described in the text above.

Chlorine is the main extracellular anion. Its normal plasma concentration is 98-107 mmol/l. Daily requirement of chlorine is 215 mmol.

Hypochloremia is a condition of decreased plasma chlorine concentration (less than 98 mmol/l).

Chlorine deficiency is calculated according to the formula:

$$Cl_d = (100 - Cl_p) * 0,2 BW,$$

Cl_d- chlorine deficiency, mmol

Cl_p – plasma chlorine concentration of the patient, mmol/l

0,2*BW – extracellular fluid volume, l.

To treat hypochloremia use normal saline (1000 ml contains 154 mmol of chlorine) or 5,8% sodium chloride solution (1 ml contains 1 mmol of chlorine). The choice of solution depends on the osmotic concentration of the plasma.

Hyperchloremia is a condition of increased chlorine concentration (over 107 mmol/l). Intensive therapy of this state includes treatment of the disease, which caused it (decompensated heart failure, hyperchloremic diabetes insipidus, glomerulonephritis). You can also use glucose, albumin solutions and dialysis.

Magnesium is mostly an intracellular cation. Its plasma concentration is

0,8-1,5 mmol/l. Daily requirement of magnesium is 0,3 mmol/kg.

Hypomagnesemia is a state of decreased magnesium concentration: less than 0,8 mmol/l. Magnesium deficiency is calculated according to the formula:

$$Mg_d = (1,0 - Mg_p) * 0,6BW,$$

Mg_d - magnesium deficiency, mmol

Mg_p – plasma magnesium concentration of the patient, mmol/l

0,6*BW – extracellular fluid volume, l.

Use 25% magnesium sulphate solution to treat this state (1 ml of it contains 0,5 mmol of magnesium).

Hypermagnesemia is a state of increased magnesium concentration (more than 1,5 mmol/l). This condition appears usually in case of hyperkalemia and you should treat it as you treat hyperkalemia.

Calcium is one of the extracellular cations. Its normal concentration is 2,35-2,75 mmol/l. Daily requirement of calcium is 0,5 mmol/kg.

Calcium concentration less than 2,35 mmol/l is called hypocalcemia. Calcium deficiency is calculated according to the formula:

$$Ca_d = (2,5 - Ca_p) * 0,2 BW,$$

Ca_d – calcium deficiency, mmol

Ca_p – plasma calcium concentration of the patient, mmol/l

0,2*BW – extracellular fluid volume, l.

To treat this state use 10% calcium chloride (1 ml of the solution contains 1,1 mmol of calcium), ergocalciferol; in case of convulsions prescribe sedative medicines.

Hypercalcemia is a condition with increased calcium concentration (over 2,75 mmol/l). Treat the disease, which caused it: primary hyperparathyroidism, malignant bone tumors, etc. Additionally use infusion therapy (solutions of glucose with insulin), steroids, dialysis and hemosorbtion.

Acid-base imbalance and its treatment.

There are 2 main types of acid-base imbalance: acidosis and alkalosis.

pH is a decimal logarithm of the reciprocal of the hydrogen ion activity. It shows

acid-base state of the blood.

Normal pH of arterial blood is 7,36-7,44. Acid based imbalance is divided according to the pH level into:

pH 7,35-7,21 – subcompensated acidosis

pH < 7,2 – decompensated acidosis

pH 7,45-7,55 – subcompensated alkalosis

pH > 7,56 – decompensated alkalosis

Respiratory part of the acid-base imbalance is characterized with pCO₂. Normally pCO₂ of arterial blood is 36-44 mm Hg. Hypercapnia (pCO₂ increased over 45 mm Hg) is a sign of respiratory acidosis. Hypocapnia (pCO₂ less than 35 mm Hg) is a symptom of respiratory alkalosis.

Basis excess index is also a characteristic of metabolic processes. Normally H⁺ ions produced during metabolic reactions are neutralized with buffer system. BE of arterial blood is 0±1,5. Positive value of BE (with +) is a sign of base excess or plasma acid deficiency (metabolic alkalosis). Negative value of BE (with -) is a symptom of bases deficiency, which is caused by acid neutralization in case of metabolic acidosis.

Respiratory acidosis (hypercapnia) is a condition caused by insufficient elimination of CO₂ from the body during hypoventilation. Laboratory tests show:

pH < 7,35,

pCO_{2a} > 46 mm Hg

BE - normal values

However when the respiratory acidosis progresses renal compensation fails to maintain normal values and BE gradually increases. In order to improve this condition you should treat acute and chronic respiratory violations. When pCO₂ is over 60 mm Hg begin artificial lung ventilation (through the mask or tube; when the necessity of ventilation lasts longer than 3 days – perform tracheostomy).

Respiratory alkalosis (hypocapnia) is usually an effect of hyperventilation, caused by excessive stimulation of respiratory centre (injuries, metabolic acidosis, hyperactive metabolism, etc.) or wrong parameters of mechanical ventilation. Gasometry shows:

pH > 7,45,

pCO_{2a} < 33 mm Hg

BE < +1,5 mmol/l.

However prolong alkalosis brings decrease of BE due to compensatory retain of H⁺ ions. To improve this imbalance treat its reason: normalize ventilation parameters; if patients breathing has rate over 40 per minute – sedate the patient, perform the intubation and begin artificial ventilation with normal parameters.

Metabolic acidosis is characterized with absolute and relative increase of H⁺ ions concentration due to acid accumulation (metabolic disorders, block of acid elimination, excessive acid consumption in case of poisonings, etc.). Laboratory tests show:

pH < 7,35,

pCO_{2a} < 35 mm Hg

BE (-3) mmol/l.

Treat the main reason of acid-base disorder: diabetic ketoacidosis, renal insufficiency, poisoning, hyponatremia or hyperchloremia, etc. Normalize pH with 4% sodium bicarbonate solution. Its dose is calculated according to the formula:

$$V = 0,3 * BE * BW$$

V- volume of sodium bicarbonate solution, ml

BE – bases excess with “-”, mmol/l

BW – body weight, kg

Metabolic alkalosis is a condition of absolute and relative decrease of H⁺ ions concentration. Blood tests show:

pH > 7,45,

pCO_{2a} normal or insignificantly increased (compensatory reaction)

BE 3,0 mmol/l.

To treat this condition use “acid” solutions, which contain chlorides (saline, potassium chloride). In case of kaliopenia give potassium solutions.

Respiratory and metabolic imbalances can mix in case of severe decompensated diseases due to failure of compensatory mechanisms. Correct interpretation of these violations is possible only in case of regular and iterative gasometry blood tests.

Control tasks.

Task 1.

Calculate the total body water volume and its extracellular and intracellular volumes of the Patient, the patient of 48 years and body weight 88 kg.

Task 2.

Patient, the patient of 23 with body weight 70 kg has sodium level 152 mmol/l and hematocrit 0,49 l/l. Name the type of water balance disorder.

Task 3.

Patient, the patient of 54 with body weight 76 kg has sodium level 128 mmol/l. Calculate the volume of saline and 7,5% sodium chloride solution necessary for the treatment of this condition.

Task 4.

Patient, the patient of 60 with body weight 60 kg has sodium level 140 mmol/l and hematocrit 0,55 l/l. Name the type of disorder and prescribe infusion therapy.

Task 5.

Patient, the patient of 42 with body weight 80 kg has potassium level 2,6 mmol/l. Calculate the volume of 4% potassium chloride solution necessary for treatment of this condition.

Task 6.

Patient, the patient of 33 with body weight 67 kg and diagnosis “gastric ulcer, complicated with pylorostenosis” has potassium concentration 3 mmol/l, chlorine concentration 88 mmol/l. pH 7,49, pCO_{2a} 42 mm Hg, BE + 10 mmol/l. Name the type of disorder.

Task 7.

Patient, the patient of 50 with body weight 75 kg, was transported to the admission unit of the hospital with: unconsciousness, cyanotic skin, low blood pressure, shallow breathing. Blood tests show: pH 7,18, pCO_{2a} 78 mm Hg, pO_{2A} – 57 mm Hg, BE -4,2 mmol/l. Name the type of acid-base disorder and prescribe treatment.

Task 8.

Patient, the patient with body weight 62 kg and renal insufficiency has: potassium concentration 5,2 mmol/l, sodium concentration 130 mmol/l, calcium concentration 1,5 mmol/l, pH 7,22, pCO_{2a} 34 mm Hg, BE -9,2 mmol/l. Name the type of disorder.

Systemic inflammatory response syndrome in surgical patients. Pathogenesis, its importance in the clinical course of various diseases and traumas. Treatment tactic.

In medicine, systemic inflammatory response syndrome (SIRS) is an inflammatory state affecting the whole body, frequently in response of the immune system to infection, but not necessarily so. It is related to sepsis, a condition in which individuals both meet criteria for SIRS and have a known or highly suspected infection.

The latest finding shows that SIRS in trauma patients may be caused by immune reaction to mitochondria massively released into bloodstream from dying cells at the site of injury. [1]Contents [hide]

[edit]

Classification

SIRS is a serious condition related to systemic inflammation, organ dysfunction, and organ failure. It is a subset of cytokine storm, in which there is abnormal regulation of various cytokines.[citation needed] SIRS is also closely related to sepsis, in which patients satisfy criteria for SIRS and have a suspected or proven infection.[2][3][4]

[edit]

Definition

SIRS was first described by Dr. Nelson, of the University of Toronto, at the Nordic Micro Circulation meeting in Geilo, Norway in February of 1983. The intent of creating an encompassing definition was to bring together the multiple etiologies of post episode organ dysfunction (fibrin deposition, platelet aggregation, coagulopathies, leukocyte lysosomal release) into a family of negatively synergistic responses to injury and/or infection which can collectively lead to micro circulatory dysfunction. The implication of such a definition

suggested that recognition of the activation of one of the above noted humoral pathways suggests that additional processes are also active. The aggregate of such pathophysiology would lead to clinical conditions such as renal failure and/or pulmonary edema.

Criteria for SIRS were established in 1992 as part of the American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference.[2] The conference concluded that the manifestations of SIRS include, but are not limited to:

Body temperature less than 36°C or greater than 38°C

Heart rate greater than 90 beats per minute

Tachypnea (high respiratory rate), with greater than 20 breaths per minute; or, an arterial partial pressure of carbon dioxide less than 4.3 kPa (32 mmHg)

White blood cell count less than 4000 cells/mm³ (4 x 10⁹ cells/L) or greater than 12,000 cells/mm³ (12 x 10⁹ cells/L); or the presence of greater than 10% immature neutrophils (band forms)

SIRS can be diagnosed when two or more of these criteria are present.[3][4][5][6]

The International Pediatric Sepsis Consensus has proposed some changes to adapt these criteria to the pediatric population.

Fever and leukocytosis are features of the acute-phase reaction, while tachycardia is often the initial sign of hemodynamic compromise. Tachypnea may be related to the increased metabolic stress due to infection and inflammation, but may also be an ominous sign of inadequate perfusion resulting in the onset of anaerobic cellular metabolism.

In children, the SIRS criteria are modified in the following fashion:

Heart rate > 2 standard deviations above normal for age in the absence of stimuli such as pain and drug administration, OR unexplained persistent elevation for greater than 30 minutes to 4 hours. In infants, also includes Heart rate < 10th percentile for age in the absence of vagal stimuli, beta-blockers, or congenital heart disease OR unexplained persistent depression for greater than 30 minutes.

Body temperature obtained orally, rectally, from Foley catheter probe, or from central venous catheter probe < 36 °C or > 38.5 °C. Temperature must be abnormal to qualify as SIRS in pediatric patients.

Respiratory rate > 2 standard deviations above normal for age OR the requirement for mechanical ventilation not related to neuromuscular disease or the administration of anesthesia.

White blood cell count elevated or depressed for age not related to chemotherapy, or greater than 10% bands + other immature forms.

Note that SIRS criteria are very non-specific, and must be interpreted carefully within the clinical context. These criteria exist primarily for the purpose of more objectively classifying critically-ill patients so that future clinical studies may be more rigorous and more easily reproducible.

As an alternative, when two or more of the systemic inflammatory response syndrome criteria are met without evidence of infection, patients may be diagnosed simply with "SIRS." Patients with SIRS and acute organ dysfunction may be termed "severe SIRS."

[edit]

Complications

SIRS is frequently complicated by failure of one or more organs or organ systems.[2][3][4] The complications of SIRS include:

- Acute lung injury
- Acute kidney injury
- Shock
- Multiple organ dysfunction syndrome

[edit]

Causes

The causes of SIRS are broadly classified as infectious or noninfectious. As above, when SIRS is due to an infection, it is considered sepsis. Noninfectious causes of SIRS include trauma, burns, pancreatitis, ischemia, and hemorrhage.[2][3][4]

Other causes include:[citation needed]

- Complications of surgery
- Adrenal insufficiency
- Pulmonary embolism
- Complicated aortic aneurysm
- Cardiac tamponade
- Anaphylaxis
- Drug overdose

[edit]

Treatment

Generally, the treatment for SIRS is directed towards the underlying problem or inciting cause (i.e. adequate fluid replacement for hypovolemia, IVF/NPO for pancreatitis, epinephrine/steroids/benadryl for anaphylaxis).[1] Selenium, glutamine, and eicosapentaenoic acid have shown effectiveness in improving

symptoms in clinical trials.[10] Other antioxidants such as vitamin E may be helpful as well.[11]

SEPSIS and It's Disease spectrum

- Various stages of disease
 - Bacteremia
 - SIRS
 - Sepsis syndrome
 - Sepsis shock : early and refractory

Definition

- **Infection**
 - Presence of microorganisms in a normally sterile site.
- **Bacteremia**
 - Cultivable bacteria in the blood stream.
- **Sepsis**
 - The systemic response to infection. If associated with proven or clinically suspected infection, SIRS is called "sepsis".

American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference Committee. *Crit Care Med.* 1992;20:864-874.

SIRS

(Systemic Inflammatory Response Syndrome)

- The systemic response to a wide range of stresses.
 - Temperature $>38^{\circ}\text{C}$ (100.4°) or $<36^{\circ}\text{C}$ (96.8°F).
 - Heart rate >90 beats/min.
 - Respiratory rate >20 breaths/min or $\text{PaCO}_2 <32$ mmHg.
 - White blood cells $> 12,000$ cells/ml or $< 4,000$ cells/ml or $>10\%$ immature (band) forms.
- Note
 - Two or more of the following must be present.
 - These changes should be represent acute alterations from baseline in the absence of other known cause for the abnormalities.

American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference Committee. *Crit Care Med.* 1992;20:864-874.

Severe Sepsis

- Sepsis with organ hypoperfusion
one of the followings :
 - $\text{SBP} < 90$ mmHg
 - Acute mental status change
 - $\text{PaO}_2 < 60$ mmHg on RA ($\text{PaO}_2 / \text{FiO}_2 < 250$)
 - Increased lactic acid/acidosis
 - Oliguria
 - DIC or Platelet $< 80,000 /\text{mm}^3$
 - Liver enzymes > 2 x normal

American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference Committee. *Crit Care Med.* 1992;20:864-874.

MODS (Multiple Organ Dysfunction Syndrome)

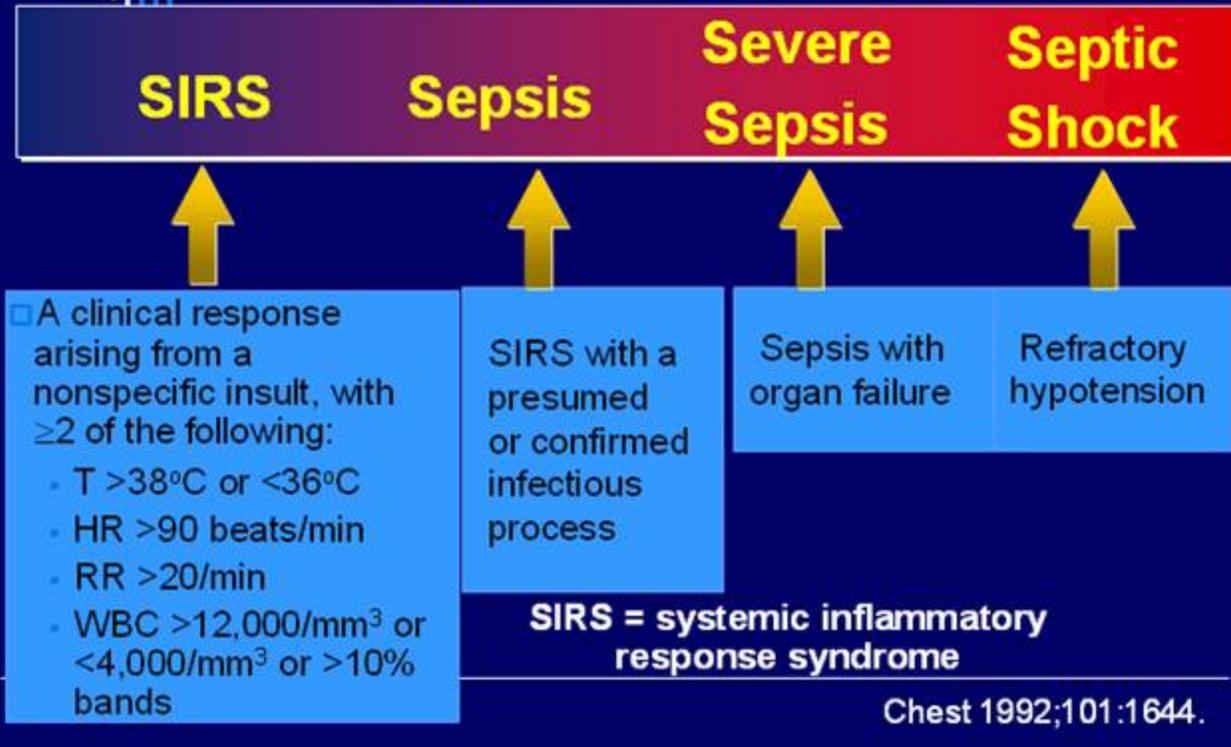

□ Sepsis with multiorgan hypoperfusion

Two or more of the followings:

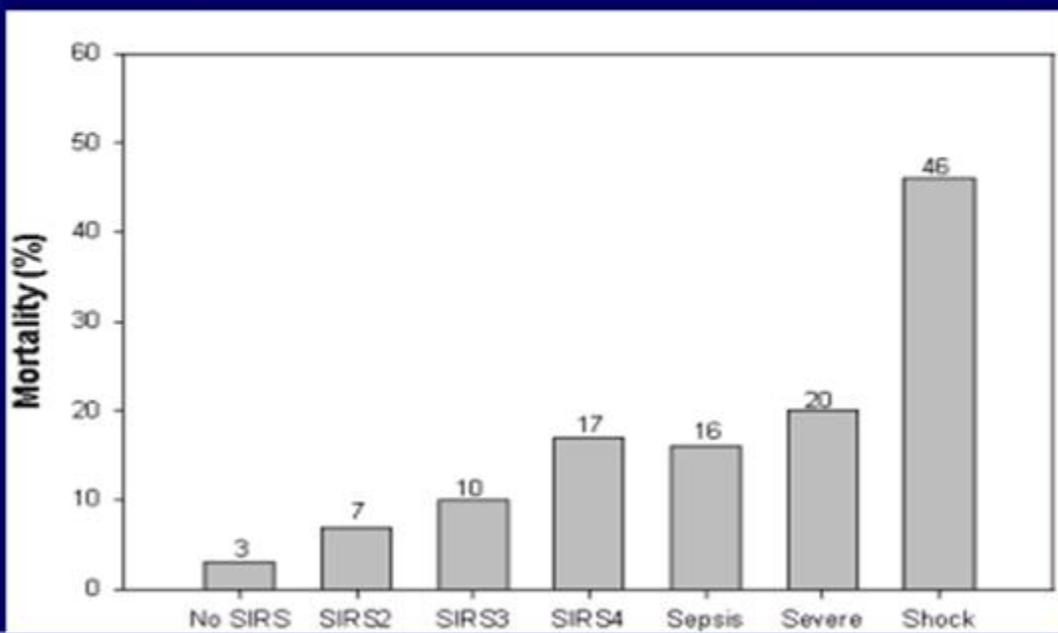

- SBP < 90 mmHg
- Acute mental status change
- PaO₂ < 60 mmHg on RA (PaO₂/FiO₂ < 250)
- Increased lactic acid/acidosis
- Oliguria
- DIC or Platelet < 80,000 /mm³
- Liver enzymes > 2 x normal

The Response to Pathogens "Cross-Talk"

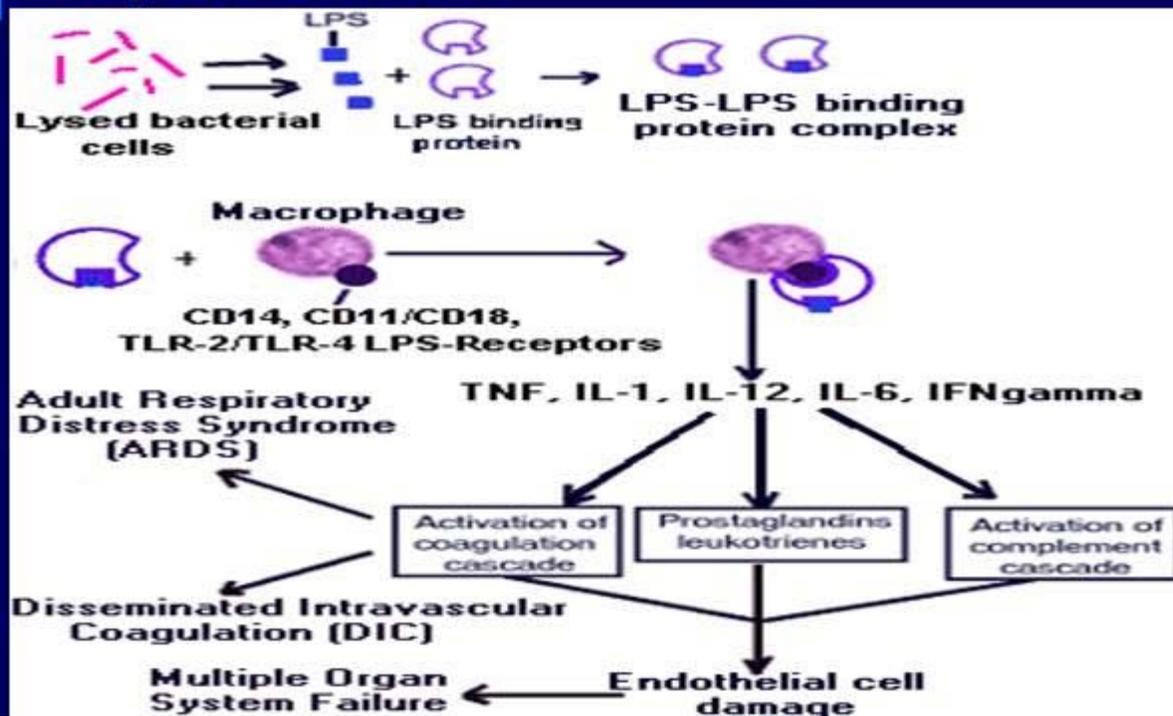

Inflammatory Response to Sepsis

Procoagulant Response in Sepsis

Pathogenesis of sepsis and septic shock

Normal Systemic Response to Infection and Injury (1)

- Leukocytosis Mobilizes neutrophils into the circulation
- Tachycardia Increases cardiac output, blood flow to injured tissue
- Fever Raises core temperature; peripheral vasoconstriction shunts blood flow to injured tissue. Occurs much more often when infection is the trigger for systemic responses

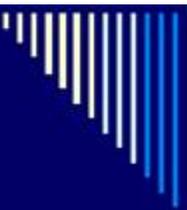

Normal Systemic Response to Infection and Injury (2)

□ Acute-Phase Responses

■ Anti-infective

- Increases synthesis of complement factors, microbe pattern-recognition molecules (mannose-binding lectin, LBP, CRP, CD14, Others)
- Sequesters iron (lactoferrin) and zinc (metallothionein)

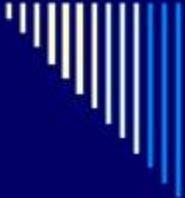

Normal Systemic Response to Infection and Injury (3)

□ Anti-inflammatory

- Releases anti-inflammatory neuroendocrine hormones (cortisol, ACTH, epinephrine, α -MSH)
 - Increases synthesis of proteins that help prevent inflammation within the systemic compartment
 - Cytokine antagonists (IL-1Ra, sTNF-Rs)
 - Anti-inflammatory mediators (e.g., IL-4, IL-6, IL-6R, IL-10, IL-13, TGF- β)
 - Protease inhibitors (e.g., α 1-antiprotease)
 - Antioxidants (haptoglobin)
- Reprograms circulating leukocytes (epinephrine, cortisol, PGE₂, ?other)

Mandell et al. Principles and Practice of Infectious Diseases 6th ed; 906:906-926.

Normal Systemic Response to Infection and Injury (3)

□ Anti-inflammatory

- Releases anti-inflammatory neuroendocrine hormones (cortisol, ACTH, epinephrine, α -MSH)
 - Increases synthesis of proteins that help prevent inflammation within the systemic compartment
 - Cytokine antagonists (IL-1Ra, sTNF-Rs)
 - Anti-inflammatory mediators (e.g., IL-4, IL-6, IL-6R, IL-10, IL-13, TGF- β)
 - Protease inhibitors (e.g., α 1-antiprotease)
 - Antioxidants (haptoglobin)
- Reprograms circulating leukocytes (epinephrine, cortisol, PGE₂, ?other)

Mandell et al. Principals and Practice of Infectious Diseases 6th ed; 906:906-926.

Normal Systemic Response to Infection and Injury (3)

□ Anti-inflammatory

- Releases anti-inflammatory neuroendocrine hormones (cortisol, ACTH, epinephrine, α -MSH)
 - Increases synthesis of proteins that help prevent inflammation within the systemic compartment
 - Cytokine antagonists (IL-1Ra, sTNF-Rs)
 - Anti-inflammatory mediators (e.g., IL-4, IL-6, IL-6R, IL-10, IL-13, TGF- β)
 - Protease inhibitors (e.g., α 1-antiprotease)
 - Antioxidants (haptoglobin)
- Reprograms circulating leukocytes (epinephrine, cortisol, PGE₂, ?other)

Mandell et al. Principals and Practice of Infectious Diseases 6th ed; 906:906-926.

Normal Systemic Response to Infection and Injury (4)

- **Procoagulant**
 - Walls off infection, prevents systemic spread
- Increases synthesis or release of fibrinogen, PAI-1, C4b
- Decreases synthesis of protein C, anti-thrombin III
- **Metabolic**
 - Preserves euglycemia, mobilizes fatty acids, amino acids
 - Epinephrine, cortisol, glucagon, cytokines
- **Thermoregulatory**
 - Inhibits microbial growth
 - Fever

Risk factors of sepsis

- aggressive oncological chemotherapy and radiation therapy
- use of corticosteroid and immunosuppressive therapies for organ transplants and inflammatory diseases
- longer lives of patients predisposed to sepsis, the elderly, diabetics, cancer patients, patients with major organ failure, and with granulocytopenia.
- Neonates are more likely to develop sepsis (ex. group B Streptococcal infections).
- increased use of invasive devices such as surgical prostheses, inhalation equipment, and intravenous and urinary catheters.
- indiscriminate use of antimicrobial drugs that create conditions of overgrowth, colonization, and subsequent infection by aggressive, antimicrobial-resistant organisms.

Angus DC, et al. Crit Care Med 2001, 29:1303-1310.

Source (usually an endogenous source of infection)

- intestinal tract
- oropharynx
- instrumentation sites
- contaminated inhalation therapy equipment
- IV fluids.
- **Most frequent sites of infection: Lungs, abdomen, and urinary tract.**
- Other sources include the skin/soft tissue and the CNS.

Angus DC, et al. Crit Care Med 2001, 29:1303-1310.

Diagnosis

- **History**
 - community or nosocomially acquired infection
 - immunocompromised patient
 - exposure to animals, travel, tick bites, occupational hazards, alcohol use, seizures, loss of consciousness, medications
 - underlying diseases ; specific infectious agents
 - Some clues to a septic event include
 - Fever or unexplained signs with malignancy or instrumentation
 - Hypotension
 - Oliguria or anuria
 - Tachypnea or hyperpnea
 - Hypothermia without obvious cause
 - Bleeding

Angus DC, et al. Crit Care Med 2001, 29:1303-1310.

Specific Infectious agents

- Splenectomy (traumatic or functional)
 - *S pneumoniae*, *H influenzae*, *N meningitidis*
- Neutropenia (<500 neutrophil/ml)
 - Gram-negative, including *P aeruginosa*, gram-positives, including *S aureus*
 - Fungi, especially *Candida* species
- Hypogammaglobulinemia (e.g. CLL)
 - *S pneumoniae*, *E coli*
- Burns
 - MRSA, *P aeruginosa*, resistant gram-negatives

MacArthur RD, et al. *Mosby*, 2001:3-10.
Wheeler AP, et al. *NEJM* 1999;340:207-214.
Chaoagul W, et al. *J Infect Dis* 1989;159:890-899.

Specific Infectious agents

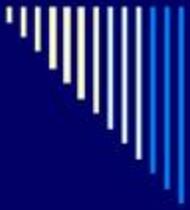

- Aids
 - *P. aeruginosa* (if neutropenic), *S. aureus*, PCP pneumonia
- Intravascular devices
 - *S. aureus*, *S. epidermidis*
- Nosocomial infections
 - MRSA, Enterococcus species, resistant gram-negative, Candida species
- Septic patients in NE of Thailand
 - *Burkholderia pseudomallei*

Diagnosis

- Physical Examination
 - essential
 - In all neutropenic patients and in patients with as suspected pelvic infection the physical exam should include rectal, pelvic, and genital examinations
 - perirectal, and/or perineal abscesses
 - pelvic inflammatory disease and/or abscesses, or prostatitis

Angus DC, et al. Crit Care Med 2001, 29:1303-1310.

Signs and Symptoms

- Nonspecific symptoms of sepsis : not pathognomonic
 - fever
 - chills
 - constitutional symptoms of fatigue, malaise
 - anxiety or confusion
- absent symptoms in serious infections, especially in elderly individuals

Angus DC, et al. Crit Care Med 2001, 29:1303-1310.

Complications

- Adult respiratory distress syndrome (ARDS)
- Disseminated Intravascular Coagulation (DIC)
- Acute Renal failure (ARF)
- Intestinal bleeding
- Liver failure
- Central Nervous System dysfunction
- Heart failure
- Death

Angus DC, et al. Crit Care Med 2001, 29:1303-1310.

Diagnosis

- Before the initiation of antimicrobial therapy, at least two blood cultures should be obtained
 - At least one drawn percutaneously
 - At least one drawn through each vascular access device if inserted longer than 48 hours
- Other cultures such as urine, cerebrospinal fluid, wounds, respiratory secretions or other body fluids should be obtained as the clinical situation dictates
- Other diagnostic studies such as imaging and sampling should be performed promptly to determine the source and causative organism of the infection
 - may be limited by patient stability

Sepsis management bundle

- Fluid resuscitation
- Appropriate cultures prior to antibiotic administration
- Early targeted antibiotics and source control
- Use of vasopressors/inotropes when fluid resuscitation optimized

Surviving Sepsis Campaign Management Guidelines Committee. *Crit Care Med* 2004; 32:858-873.

Sepsis management bundle

- ❑ Evaluation for adrenal insufficiency
- ❑ Stress dose corticosteroid administration
- ❑ Recombinant human activated protein C (xigris) for severe sepsis
- ❑ Low tidal volume mechanical ventilation for ARDS
- ❑ Tight glucose control

Surviving Sepsis Campaign Management Guidelines Committee. Crit Care Med 2004; 32:858-873.

Infection Control

- ❑ Appropriate cultures prior to antibiotic administration
- ❑ Early targeted antibiotics and source control

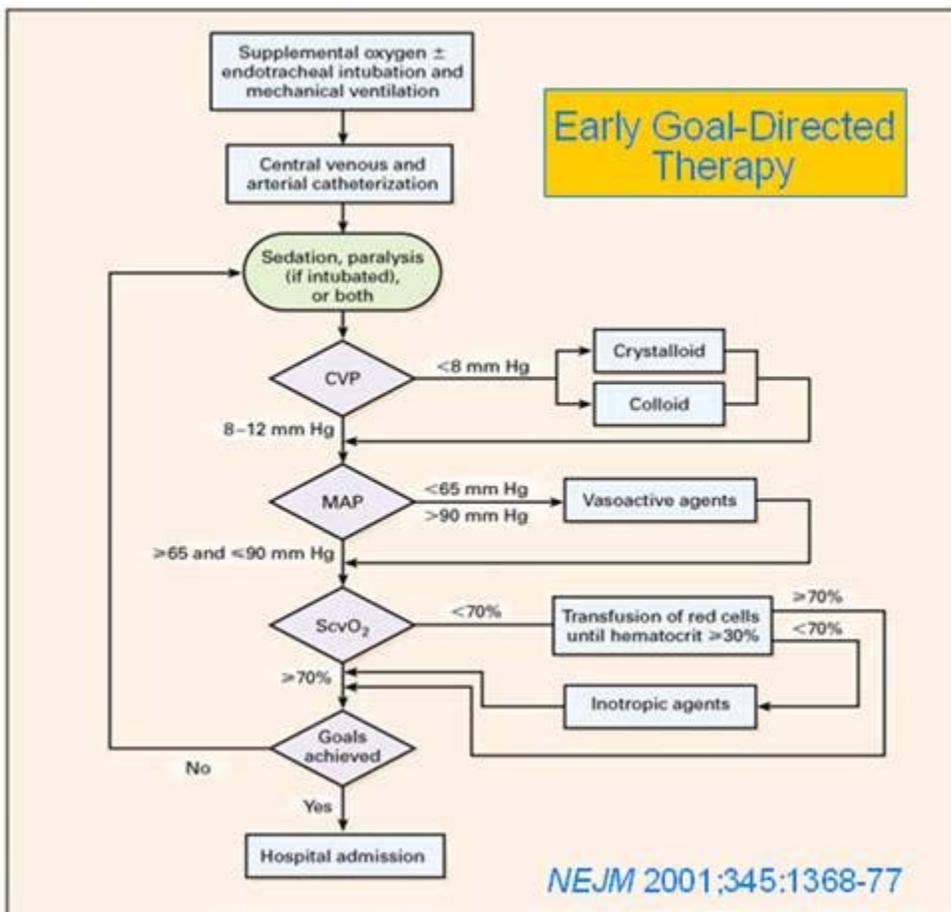

Surviving Sepsis Campaign Management Guidelines Committee. Crit Care Med 2004; 32:858-873.

CVP : central venous pressure

MAP : mean arterial pressure

ScvO₂ : central venous oxygen saturation

Antibiotic use in Sepsis (1)

- The drugs used depends on the source of the sepsis
- Community acquired pneumonia
 - third (ceftriaxone) or fourth (cefepime) generation cephalosporin is given with an aminoglycoside (usually gentamicin)
- Nosocomial pneumonia
 - Cefipime or Imipenem-cilastatin and an aminoglycoside
- Abdominal infection
 - Imipenem-cilastatin or Piperacillin-tazobactam and aminoglycoside

Angus DC, et al. Crit Care Med 2001, 29:1303-1310.

The Septic Patient

The term SIRS is used to describe the widely disseminated inflammatory reaction which can complicate a wide range of disorders eg, pancreatitis, trauma, ischaemia.

The term SEPSIS is used in those patients in whom SIRS is associated with proven infection

Systemic inflammatory response syndrome (SIRS)

- Cytokine mediators of SIRS: TNF, IL-1, IL-6, IL- 8
- Secondary inflammation mediators:
 - Arachidonic acid metabolites
 - Nitric oxide
 - Oxygen radicals
 - Platelet activating factor

Systemic inflammatory response syndrome (SIRS)

Systemic changes

- Loss of microvascular integrity
- Increased vascular permeability
- Systemic vasodilatation
- Depressed myocardial contractility
- Poor oxygen delivery
- Increased microvascular clotting

Early features of sepsis

- Fever or hypothermia
- Leucocytosis or leucopenia
- Tachycardia
- Tachypnoea
- Organ dysfunction: Brain - altered mental state
Lungs - hypoxia
Kidneys - oliguria

Nosocomial Infections (Hospital acquired infections)

(Gk: nosokomeion)

Gk: nosos- of disease; komeo – to nurse

- The patient in the ITU who has some degree of organ dysfunction is vulnerable to nosocomial infections.
- Good principles of infection control and avoidance of cross-infection by staff
- Bacteria in the GI tract of the patient is the commonest source
- Nosocomial pneumonia occurs from spillage from the upper GI tract into the lungs
- H₂ receptor antagonists encourages nosocomial infections
- Sucralfate used as stress ulcer prophylaxis is also bacteriostatic and thus reduces the incidence

Intra-abdominal sepsis Sub-phrenic abscess Management

- Resuscitation
- Confirmation of diagnosis
- Definitive treatment

Sub-phrenic abscess

“Pus somewhere, pus nowhere, pus under the diaphragm.”

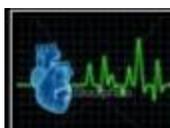

Investigations for confirmation

- Blood: Culture, FBC, CRP
- CXR
- Ultrasound
- ?CT

The Septic Patient Management

- Supportive measures:
 - Oxygenation
 - Ventilation if necessary
 - IV fluids
 - Inotropic support
 - Nutritional support
- Specific measures
 - Antibiotics
 - Drainage

Respiratory failure

Respiratory failure is defined as an arterial oxygen tension (PaO_2) at sea level of less than 8 kPa, i.e. hypoxia due inadequate gas exchange within the lung.

Emergency

- Multiple trauma (including burns)
- Leaking AAA
- Severe acute pancreatitis
- Post-operative complications:
 - Surgical
 - Cardiac
 - Respiratory
 - Renal
- Severe sepsis

Elective

- Major vascular eg, AAA
- Oesophagectomy
- Cardiac operations
- Major procedures
 - Whipple's
 - Patients in ASA 2 category or more

Indications for ICU transfer

- Potential incipient or actual organ failure in a remediable condition
- Advanced monitoring of organ function
- Treatment of organ failure:
 - Heart – use of inotropes
 - Lungs – ventilation
 - Kidneys – renal replacement therapy
- A need for 1:1 nursing

Respiratory

- **Pulse oximetry**
 - O₂ saturation of arterial blood
- **Capnography**
 - CO₂ tension in expired gas

Cardiovascular

- **Arterial lines**
- **CVP**
- **Pulmonary artery flotation catheter (PAFC)**
- **Cardiac output measurement**

Pulse oximetry

- **95% - 100% = normal**
- **93% = Warning! PaO₂ around 8.5 kPa**
- **< 90% = patient is in severe trouble**

ETCC Manual: RCSEd

Pulse oximetry

- Gives estimate of percentage saturation of oxygen binding sites
- Related to PaO_2 by oxygen dissociation curve

ETCC Manual: RCSEd

Capnography

- Infra-red absorption through gas stream
- Relies on rapid equilibration of CO_2 between alveolus and pulmonary capillary
- Useful guide to $PaCO_2$ but beware of lung disease
- Continuous measurement

Arterial line

Indications

- Continuous BP measurement
- Access for serial arterial blood gas analysis

Complications

- Bleeding
- Thrombosis
- Infection
- Pseudoaneurysm
- Accidental drug injection

Central venous catheterisation

Complications

- Inadvertent - arterial puncture
 - thoracic duct puncture
 - lung puncture
- Air embolus
- Catheter-related sepsis
- Clot formation
- Malposition and rupture of vein

ETCC Manual: RCSEd

Pulmonary artery wedge pressure (PWAP)

It is an accurate representation of the left atrial pressure which closely parallels the left ventricular end-diastolic pressure thus helping to guide fluid therapy.

ETCC Manual: RCSEd

Pulmonary artery wedge pressure

Introduced in 1970s by two cardiologists, Drs Swan and Ganz. Used to measure:

- Pressure within the pulmonary artery
- Pulmonary artery wedge pressure
- Cardiac output by thermodilution or dye dilution method
- Sampling of mixed venous blood

ETCC Manual: RCSEd

Pulmonary artery wedge pressure

Complications

- Valvular damage
- Ventricular rupture
- Pulmonary artery rupture
- Aneurysm or infarction
- Those of central venous catheterisation

Standard values

- Central venous pressure (CVP): 0-6 mm Hg
- Right ventricular pressure: 25 / 0-6mm Hg
- Pulmonary artery pressure (PAP): 25 / 6-12 mm Hg
- Wedge pressure (PAWP): 6-12 mm Hg
- Cardiac index (CI): $>2.8-3.6 \text{ L / min / m}^2$
- Systemic vascular resistance(SVR): $770-1500 \text{ dynes / sec / cm}^5$
- Oxygen delivery: $600 \text{ ml / min / m}^2$
- Oxygen consumption: $150 \text{ mls / min / m}^2$

ETCC Manual, 2005d

Critical states in surgical patients: acute respiratory distress syndrome, abdominal cavity syndrome, collapse.

Acute respiratory distress syndrome (ARDS), also known as respiratory distress syndrome (RDS) or adult respiratory distress syndrome (in contrast with IRDS) is a serious reaction to various forms of injuries to the lung.

ARDS is a severe lung disease caused by a variety of direct and indirect issues. It is characterized by inflammation of the lung parenchyma leading to impaired gas exchange with concomitant systemic release of inflammatory mediators causing inflammation, hypoxemia and frequently resulting in multiple organ failure. This condition is often fatal, usually requiring mechanical ventilation and admission to an intensive care unit. A less severe form is called acute lung injury (ALI).

ACUTE RESPIRATORY DISTRESS SYNDROME

Historical Perspective and Definitions

The first description of acute respiratory distress syndrome appeared in 1967, when Ashbaugh and colleagues described 12 patients with acute respiratory distress, cyanosis refractory to oxygen therapy, decreased lung compliance, and diffuse infiltrates evident on the chest radiograph. Initially called the adult respiratory distress syndrome, this entity is now termed the acute respiratory distress syndrome, since it does occur in children. Because the initial definition lacks specific criteria that could be used to identify patients systematically, there was controversy over the incidence and natural history of the syndrome and the mortality associated with it. In 1988, an expanded definition was proposed that quantified the physiologic respiratory impairment through the use of a four-point lung-injury scoring system that was based on the level of positive end-expiratory pressure, the ratio of the partial pressure of arterial oxygen to the fraction of inspired oxygen, the static lung compliance, and the degree of infiltration evident on chest radiographs. Other factors included in the assessment were the inciting clinical disorder and the presence or absence of nonpulmonary organ dysfunction

Although the lung-injury scoring system has been widely used to quantify the severity of lung injury in both clinical research and clinical trials, it cannot be used to predict the outcome during the first 24 to 72 hours after the onset of the acute respiratory distress syndrome and thus has limited clinical usefulness. When the scoring system is used four to seven days after the onset of the syndrome, scores of 2.5 or higher may be predictive of a complicated course with the need for prolonged mechanical ventilation.

In 1994, a new definition was recommended by the American–European Consensus Conference Committee. The consensus definition has two advantages. First, it recognizes that the severity of clinical lung injury varies: patients with less severe hypoxemia (as defined by a ratio of the partial pressure of arterial oxygen to the fraction of inspired oxygen of 300 or less) are considered to have acute lung injury, and those with more severe hypoxemia (as defined by a ratio of 200 or less) are considered to have the acute respiratory distress syndrome. The recognition of patients with acute lung injury may facilitate earlier enrollment of affected patients in clinical trials. Second, the definition is simple to apply in the clinical setting. However, this simplicity is also a disadvantage, since factors that influence the outcome, such as the underlying cause and whether other organ systems are affected, do not need to be assessed. In addition, the criterion for the presence of bilateral infiltrates on chest radiography consistent with the presence of pulmonary edema is not sufficiently specific to be applied consistently by experienced clinicians. Nevertheless, the widespread acceptance of both the 1994 consensus definition and the 1988 lung-injury scoring system has improved the standardization of clinical research and trials. We recommend that clinicians routinely use the 1994 consensus definition to allow comparison of their patients with patients enrolled in clinical trials.

Epidemiology

Incidence

An accurate estimation of the incidence of acute lung injury and the acute respiratory distress syndrome has been hindered by the lack of a uniform definition and the heterogeneity of the causes and clinical manifestations. An early estimate by the National Institutes of Health (NIH) suggested that the annual incidence in the United States was 75 per 100,000 population. More recent studies reported lower incidences of 1.5 to 8.3 per 100,000. However, the first epidemiologic study to use the 1994 consensus definition reported considerably higher annual

incidences in Scandinavia: 17.9 per 100,000 for acute lung injury and 13.5 per 100,000 for the acute respiratory distress syndrome. On the basis of the results of screening of large numbers of patients by the NIH Acute Respiratory Distress Syndrome Network over the past three years, some investigators believe that the original estimate of 75 per 100,000 per year may be accurate. To settle this issue, a prospective epidemiologic study that is using the 1994 consensus definition is under way in Seattle.

ARDS Causes

•Direct Lung Injury:

- a) PNA and aspiration of gastric contents
or other causes of chemical pneumonitis
- b) pulmonary contusion, penetrating lung injury
- c) fat emboli
- d) near drowning
- e) inhalation injury
- f) reperfusion pulm edema after lung transplant

•Indirect lung injury

- a) sepsis
- b) severe trauma w/ shock hypoperfusion
- c) drug over dose
- d) cardiopulmonary bypass
- e) acute pancreatitis
- f) transfusion of multp blood products

ARDS was defined as the ratio of arterial partial oxygen tension (PaO₂) as fraction of inspired oxygen (FiO₂) below 200 mmHg in the presence of bilateral alveolar infiltrates on the chest x-ray. These infiltrates may appear similar to those of left ventricular failure, but the cardiac silhouette appears normal in ARDS. Also, the pulmonary capillary wedge pressure is normal (less than 18 mmHg) in ARDS, but raised in left ventricular failure.

A PaO₂/FiO₂ ratio less than 300 mmHg with bilateral infiltrates indicates acute lung injury (ALI). Although formally considered different from ARDS, ALI is usually just a precursor to ARDS. (Consensus after 1967 and 1994)

ARDS is characterized by

Acute onset

Bilateral infiltrates on chest radiograph sparing costophrenic angles

Pulmonary artery wedge pressure < 18 mmHg (obtained by pulmonary artery catheterization), if this information is available; if unavailable, then lack of clinical evidence of left ventricular failure suffices:

if PaO₂:FiO₂ < 300 mmHg (40 kPa) acute lung injury (ALI) is considered to be present

if PaO₂:FiO₂ < 200 mmHg (26.7 kPa) acute respiratory distress syndrome (ARDS) is considered to be present

To summarize and simplify, ARDS is an acute (rapid onset) syndrome (collection of symptoms) that affects the lungs widely and results in a severe oxygenation defect, but is not heart failure.

ARDS Symptoms

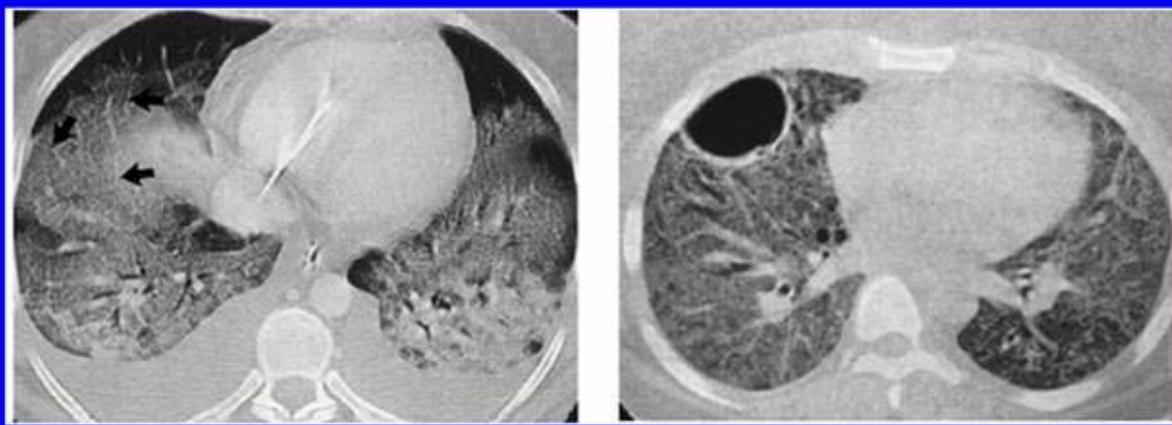

- Severe difficulty in breathing
- [Anxiety](#)
- Agitation
- [Fever](#)

Clinical, Pathological, and Radiographic Features

The definitions discussed above identify patients early in the course of acute lung injury and

the acute respiratory distress syndrome. However, the syndrome is often progressive, characterized by distinct stages with different clinical, histopathological, and radiographic manifestations. The acute, or exudative, phase is manifested by the rapid onset of respiratory failure in a patient with a risk factor for the condition. Arterial hypoxemia that is refractory to treatment with supplemental oxygen is a characteristic feature.

ARDS exudative and fibrotic phases

An arterial blood gas analysis and chest X-ray allow formal diagnosis by the aforementioned criteria. Although severe hypoxemia is generally included, the appropriate threshold defining abnormal PaO₂ has never been systematically studied. Note though, that a severe oxygenation defect is not synonymous with ventilatory support. Any PaO₂ below 100 (generally saturation less than 100%) on a supplemental oxygen fraction of 50% meets criteria for ARDS. This can easily be achieved by high flow oxygen supplementation without ventilatory support.

Any cardiogenic cause of pulmonary edema should be excluded. This can be done by placing a pulmonary artery catheter for measuring the pulmonary artery wedge pressure. However, this is not necessary and is now rarely done as abundant evidence has emerged demonstrating that the use of pulmonary artery catheters does not lead to improved patient outcomes in critical illness including ARDS.

Plain Chest X-rays are sufficient to document bilateral alveolar infiltrates in the majority of

cases. While CT scanning leads to more accurate images of the pulmonary parenchyma in ARDS, it has little utility in the clinical management of patients with ARDS, and remains largely a research tool.

Radiographically, the findings are indistinguishable from those of cardiogenic pulmonary edema. Bilateral infiltrates may be patchy or asymmetric and may include pleural effusions. Computed tomographic scanning has demonstrated that alveolar filling, consolidation, and atelectasis occur predominantly in dependent lung zones, whereas other areas may be relatively spared. However, bronchoalveolar-lavage studies indicate that even radiographically spared, nondependent areas may have substantial inflammation. Pathological findings include diffuse alveolar damage, with neutrophils, macrophages, erythrocytes, hyaline membranes, and protein-rich edema fluid in the alveolar spaces, capillary injury, and disruption of the alveolar epithelium.

Although acute lung injury and the acute respiratory distress syndrome may resolve completely in some patients after the acute phase, in others it progresses to fibrosing alveolitis with persistent hypoxemia, increased alveolar dead space, and a further decrease in pulmonary compliance. Pulmonary hypertension, owing to obliteration of the pulmonary-capillary bed, may be severe and may lead to right ventricular failure. Chest radiographs show linear opacities, consistent with the presence of evolving fibrosis. Pneumothorax may occur, but the incidence is only 10 to 13 percent and is not clearly related to airway pressures or the level of positive end-expiratory pressure. Computed tomography of the chest shows diffuse interstitial opacities and bullae. Histologically, there is fibrosis along with acute and chronic inflammatory cells and partial resolution of the pulmonary edema

The recovery phase is characterized by the gradual resolution of hypoxemia and improved lung compliance. Typically, the radiographic abnormalities resolve completely. The degree of histologic resolution of fibrosis has not been well characterized, although in many patients pulmonary function returns to normal.

Clinical Disorders and Risk Factors

The ability to identify patients at risk for acute lung injury and the acute respiratory distress syndrome is important if therapies are to be developed to prevent the disorder. The commonly

associated clinical disorders can be divided into those associated with direct injury to the lung and those that cause indirect lung injury in the setting of a systemic process.

Overall, sepsis is associated with the highest risk of progression to acute lung injury or the acute respiratory distress syndrome, approximately 40 percent. The presence of multiple predisposing disorders substantially increases the risk, as does the presence of secondary factors including chronic alcohol abuse, chronic lung disease, and a low serum pH.

Outcomes

Until recently, most studies of acute lung injury and the acute respiratory distress syndrome have reported a mortality rate of 40 to 60 percent. The majority of deaths are attributable to sepsis or multiorgan dysfunction rather than primary respiratory causes, although the recent therapeutic success of ventilation with low tidal volumes indicates that in some cases death is directly related to lung injury. Two reports suggest that mortality from this disease may be decreasing. The first, from a large county hospital in Seattle, found that the mortality rate was 36 percent in 1993 as compared with rates of 53 to 68 percent in the period from 1983 to 1987. The second, from a hospital in the United Kingdom, reported a decline in the mortality rate from 66 percent to 34 percent between 1990 to 1993 and 1994 to 1997. Possible explanations for the decrease include more effective treatments for sepsis, changes in the method of mechanical ventilation, and improvement in the supportive care of critically ill patients. The possibility that mortality is decreasing emphasizes the importance of the use of randomized control subjects rather than historical controls in clinical studies of the disorder.

Factors whose presence can be used to predict the risk of death at the time of diagnosis of acute lung injury and the acute respiratory distress syndrome include chronic liver disease, nonpulmonary organ dysfunction, sepsis, and advanced age. Surprisingly, initial indexes of oxygenation and ventilation, including the ratio of the partial pressure of arterial oxygen to the fraction of inspired oxygen and the lung-injury score, do not predict outcome. In three large studies, the mortality rate among patients with an initial ratio of partial pressure of arterial oxygen to fraction of inspired oxygen of 300 or less was similar to that among patients with a ratio of 200 or less. However, the failure of pulmonary function to improve during the first week of treatment is a negative prognostic factor.

In most patients who survive, pulmonary function returns nearly to normal within 6 to 12 months, despite the severe injury to the lung. Residual impairment of pulmonary mechanics

may include mild restriction, obstruction, impairment of the diffusing capacity for carbon monoxide, or gas-exchange abnormalities with exercise, but these abnormalities are usually asymptomatic. Severe disease and prolonged mechanical ventilation identify patients at highest risk for persistent abnormalities of pulmonary function. Those who survive the illness have a reduced health-related quality of life as well as pulmonary-disease-specific health-related quality of life.

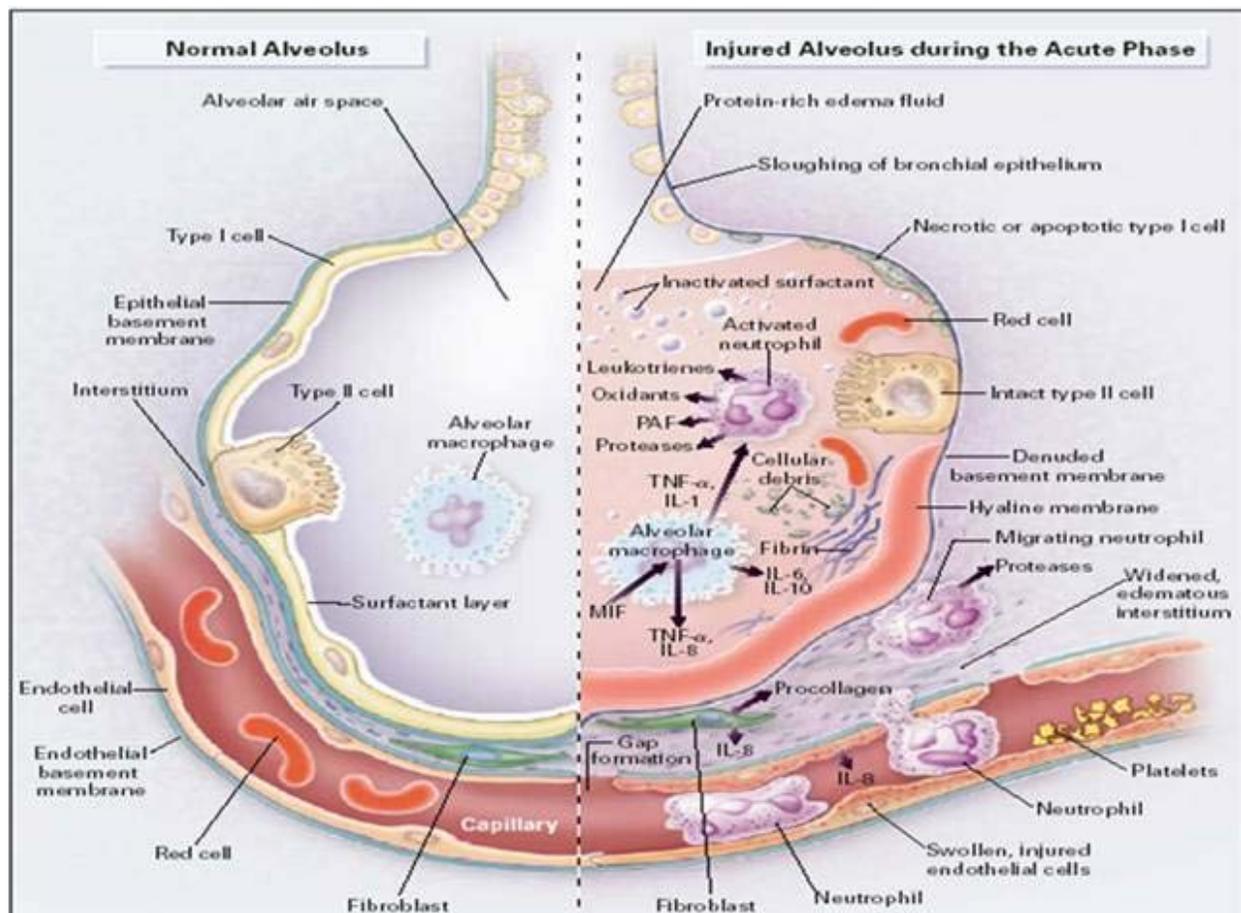

Pathogenesis

Stages of ARDS

1. Exudative (acute) phase - 0- 4 days
2. Proliferative phase - 4- 8 days
3. Fibrotic phase - >8 days
4. Recovery

Endothelial and Epithelial Injury

Two separate barriers form the alveolar–capillary barrier, the microvascular endothelium and the alveolar epithelium. The acute phase of acute lung injury and the acute respiratory distress syndrome is characterized by the influx of protein-rich edema fluid into the air spaces as a consequence of increased permeability of the alveolar–capillary barrier. The importance of endothelial injury and increased vascular permeability to the formation of pulmonary edema in this disorder has been well established.

The critical importance of epithelial injury to both the development of and recovery from the disorder has become better recognized. The degree of alveolar epithelial injury is an important predictor of the outcome. The normal alveolar epithelium is composed of two types of cells. Flat type I cells make up 90 percent of the alveolar surface area and are easily injured. Cuboidal type II cells make up the remaining 10 percent of the alveolar surface area and are more resistant to injury; their functions include surfactant production, ion transport, and proliferation and differentiation to type I cells after injury.

The loss of epithelial integrity in acute lung injury and the acute respiratory distress syndrome has a number of consequences. First, under normal conditions, the epithelial barrier is much less permeable than the endothelial barrier. Thus, epithelial injury can contribute to alveolar flooding. Second, the loss of epithelial integrity and injury to type II cells disrupt normal epithelial fluid transport, impairing the removal of edema fluid from the alveolar space. Third, injury to type II cells reduces the production and turnover of surfactant, contributing to the characteristic surfactant abnormalities. Fourth, loss of the epithelial barrier can lead to septic shock in patients with bacterial pneumonia. Finally, if injury to the alveolar epithelium is severe, disorganized or insufficient epithelial repair may lead to fibrosis.

Neutrophil-Dependent Lung Injury

Clinical and experimental studies have provided circumstantial evidence of the occurrence of neutrophil-mediated injury in acute lung injury and the acute respiratory distress syndrome. Histologic studies of lung specimens obtained early in the course of the disorder show a marked accumulation of neutrophils. Neutrophils predominate in the pulmonary edema fluid and bronchoalveolar-lavage fluid obtained from affected patients, and many animal models of acute lung injury are neutrophil-dependent. Some of the mechanisms of the sequestration and activation of neutrophils and of neutrophil-mediated lung injury are summarized in.

New evidence raises the question of whether neutrophilic inflammation is the cause or the result of lung injury. Acute lung injury and the acute respiratory distress syndrome may develop in patients with profound neutropenia, and some animal models of acute lung injury are neutrophil-independent. In clinical trials in which patients with severe pneumonia received granulocyte colony-stimulating factor in order to increase the number of circulating neutrophils, the incidence or severity of lung injury did not increase. The neutrophil has a critical role in host defense in this disorder, a factor that may explain, in part, why antiinflammatory strategies have largely been unsuccessful.

Other Proinflammatory Mechanisms

Inflammation

Inflammation alone, as in sepsis, causes endothelial dysfunction, fluid extravasation from the capillaries and impaired drainage of fluid from the lungs. Dysfunction of type II pulmonary epithelial cells may also be present, with a concomitant reduction in surfactant production. Elevated inspired oxygen concentration often becomes necessary at this stage, and they may facilitate a 'respiratory burst' in immune cells.

In a secondary phase, endothelial dysfunction causes cells and inflammatory exudate to enter the alveoli. This pulmonary edema increases the thickness of the alveolo-capillary space, increasing the distance the oxygen must diffuse to reach blood. This impairs gas exchange leading to hypoxia, increases the work of breathing, eventually induces fibrosis of the airspace.

Moreover, edema and decreased surfactant production by type II pneumocytes may cause whole alveoli to collapse, or to completely flood. This loss of aeration contributes further to the right-

to-left shunt in ARDS. As the alveoli contain progressively less gas, more blood flows through them without being oxygenated resulting in massive intrapulmonary shunting.

Collapsed alveoli (and small bronchi) do not allow gas exchange. It is not uncommon to see patients with a PaO₂ of 60 mmHg (8.0 kPa) despite mechanical ventilation with 100% inspired oxygen.

The loss of aeration may follow different patterns according to the nature of the underlying disease, and other factors. In pneumonia-induced ARDS, for example, large, more commonly causes relatively compact areas of alveolar infiltrates. These are usually distributed to the lower lobes, in their posterior segments, and they roughly correspond to the initial infected area.

In sepsis or trauma-induced ARDS, infiltrates are usually more patchy and diffuse. The posterior and basal segments are always more affected, but the distribution is even less homogeneous.

Loss of aeration also causes important changes in lung mechanical properties. These alterations are fundamental in the process of inflammation amplification and progression to ARDS in mechanically ventilated patients.

Cytokines

A complex network of cytokines and other proinflammatory compounds initiate and amplify the inflammatory response in acute lung injury and the acute respiratory distress syndrome. Proinflammatory cytokines may be produced locally in the lung by inflammatory cells, lung epithelial cells, or fibroblasts. The regulation of cytokine production by extrapulmonary factors has also been described. Macrophage inhibitory factor is a regulatory cytokine produced by the anterior pituitary that is found in high concentrations in the bronchoalveolar-lavage fluid of patients with the syndrome. This cytokine increases production of the proinflammatory cytokines interleukin-8 and tumor necrosis factor α and can override glucocorticoid-mediated inhibition of cytokine secretion.

New evidence indicates that it is not only the production of proinflammatory cytokines that is important, but also the balance between proinflammatory and antiinflammatory mediators. Several endogenous inhibitors of proinflammatory cytokines have been described, including

interleukin-1–receptor antagonist, soluble tumor necrosis factor receptor, autoantibodies against interleukin-8, and antiinflammatory cytokines such as interleukin-10 and 11. Better understanding of the role of cytokines in acute lung injury and the acute respiratory distress syndrome will be gained through studies of the biologic activity of specific cytokines, rather than by an assessment of static levels by immunologic methods.

Ventilator-Induced Lung Injury

Mechanical ventilation is an essential part of the treatment of ARDS. As loss of aeration (and the underlying disease) progress, the work of breathing (WOB) eventually grows to a level incompatible with life. Thus, mechanical ventilation is initiated to relieve respiratory muscles of their work, and to protect the usually obtunded patient's airways.

Older studies focused on the potential toxic effects of high fractions of inspired oxygen, but experimental evidence indicates that mechanical ventilation at high volumes and pressures can injure the lung, causing increased permeability pulmonary edema in the uninjured lung and enhanced edema in the injured lung. Initial theories formulated to explain these deleterious effects focused on capillary stress failure due to alveolar overdistention. More recently, cyclic opening and closing of atelectatic alveoli during mechanical ventilation have been shown to cause lung injury independently of alveolar overdistention. Alveolar overdistention coupled with the repeated collapse and reopening of alveoli can initiate a cascade of proinflammatory cytokines.

However, mechanical ventilation may constitute a risk factor for the development, or the worsening, of ARDS.

Aside from the infectious complications arising from invasive ventilation with tracheal intubation, positive-pressure ventilation directly alters lung mechanics during ARDS. The result is higher mortality, i.e. through baro-trauma, when these techniques are used.

In 1998, Amato et al. published a paper showing substantial improvement in the outcome of patients ventilated with lower tidal volumes (V_t) ($6 \text{ mL}\cdot\text{kg}^{-1}$). This result was confirmed in a 2000 study sponsored by the NIH. Although both these studies were widely criticized for several reasons, and although the authors were not the first to experiment lower-volume ventilation, they shed new light on the relationship between mechanical ventilation and ARDS.

One opinion is that the forces applied to the lung by the ventilator may work as a lever to

induce further damage to lung parenchyma. It appears that shear stress at the interface between collapsed and aerated units may result in the breakdown of aerated units, which inflate asymmetrically due to the 'stickiness' of surrounding flooded alveoli. The fewer such interfaces around an alveolus, the lesser the stress.

Indeed, even relatively low stress forces may induce signal transduction systems at the cellular level, thus inducing the release of inflammatory mediators.

This form of stress is thought to be applied by the transpulmonary pressure (gradient) (PI) generated by the ventilator or, better, its cyclical variations. The better outcome obtained in patients ventilated with lower Vt may be interpreted as a beneficial effect of the lower PI. Transpulmonary pressure, is an indirect function of the Vt setting on the ventilator, and only trial patients with plateau pressures (a surrogate for the actual PI) were less than 32 cmH₂O (3.1 kPa) had improved survival.

The way PI is applied on alveolar surface determines the shear stress to which lung units are exposed. ARDS is characterized by a usually inhomogeneous reduction of the airspace, and thus by a tendency towards higher PI at the same Vt, and towards higher stress on less diseased units.

The inhomogeneity of alveoli at different stages of disease is further increased by the gravitational gradient to which they are exposed, and the different perfusion pressures at which blood flows through them. Finally, abdominal pressure exerts an additional pressure on inferoposterior lung segments, favoring compression and collapse of those units.

The different mechanical properties of alveoli in ARDS may be interpreted as having varying time constants (the product of alveolar compliance × resistance). A long time constant indicates an alveolus which opens slowly during tidal inflation, as a consequence of contrasting pressure around it, or altered water-air interface inside it (loss of surfactant, flooding).

Slow alveoli are said to be 'kept open' using positive end-expiratory pressure, a feature of modern ventilators which maintains a positive airway pressure throughout the whole respiratory cycle. A higher mean pressure cycle-wide slows the collapse of diseased units, but it has to be weighed against the corresponding elevation in PI/plateau pressure. Newer ventilatory approaches attempt to maximize mean airway pressure for its ability to 'recruit' collapsed lung units while minimizing the shear stress caused by frequent openings and closings of aerated

units.

The prone position also reduces the inhomogeneity in alveolar time constants induced by gravity and edema. If clinically appropriate, mobilization of the ventilated patient can assist in achieving the same goal.

In patients with acute lung injury and the acute respiratory distress syndrome, ventilation at traditional tidal volumes (10 to 15 ml per kilogram of predicted body weight) may overdistend uninjured alveoli, perhaps promoting further lung injury, inhibiting resolution of the disorder, and contributing to multiorgan failure. The failure of traditional ventilatory strategies to prevent end-expiratory closure of atelectatic alveoli may also contribute to lung injury. These issues have led to a number of clinical trials of protective ventilatory strategies to reduce alveolar overdistention and increase the recruitment of atelectatic alveoli. Interestingly, a recent study found that a strategy of protective ventilation could reduce both the pulmonary and the systemic cytokine response.

Other Mechanisms of Injury

Like any form of inflammation, acute lung injury and the acute respiratory distress syndrome represent a complex process in which multiple pathways can propagate or inhibit lung injury. For example, abnormalities of the coagulation system often develop, leading to platelet–fibrin thrombi in small vessels and impaired fibrinolysis within the distal air spaces of the injured lung. Also, abnormalities in the production, composition, and function of surfactant probably contribute to alveolar collapse and gas-exchange abnormalities.

Fibrosing Alveolitis

After the acute phase of acute lung injury and the acute respiratory distress syndrome, some patients have an uncomplicated course and rapid resolution of the disorder. Others have progression to fibrotic lung injury, and such injury can be observed histologically as early as five to seven days after the onset of the disorder. The alveolar space becomes filled with mesenchymal cells and their products, along with new blood vessels. The finding of fibrosing alveolitis on histologic analysis correlates with an increased risk of death, and patients who die of the condition have a marked accumulation of collagen and fibronectin in the lung at autopsy.

The process of fibrosing alveolitis apparently begins early in the course of the disorder and may be promoted by early proinflammatory mediators such as interleukin-1. Levels of

procollagen III peptide, a precursor of collagen synthesis, are elevated in the alveolar compartment very early in the course of the illness, even at the time of intubation and the initiation of mechanical ventilation. Furthermore, the early appearance of procollagen III in the alveolar space is associated with an increased risk of death.

Resolution

Strategies that hasten the resolution of the illness may ultimately be as important as those that attenuate early inflammatory lung injury. Alveolar edema is resolved by the active transport of sodium and perhaps chloride from the distal air spaces into the lung interstitium. Water follows passively, probably through transcellular water channels, the aquaporins, located primarily on type I cells. In clinical studies, clearance of alveolar fluid can occur surprisingly early and is often apparent within the first few hours after intubation and the initiation of mechanical ventilation. Maintenance of the ability to remove alveolar fluid is associated with improved oxygenation, a shorter duration of mechanical ventilation, and an increased likelihood of survival.

A considerable quantity of both soluble and insoluble protein must also be removed from the air spaces. The removal of insoluble protein is particularly important, since hyaline membranes provide a framework for the growth of fibrous tissue. Soluble protein appears to be removed primarily by diffusion between alveolar epithelial cells. Insoluble protein may be removed by endocytosis and transcytosis by alveolar epithelial cells and by phagocytosis by macrophages

The alveolar epithelial type II cell is the progenitor for reepithelialization of a denuded alveolar epithelium. Type II cells proliferate to cover the denuded basement membrane and then differentiate into type I cells, restoring the normal alveolar architecture and increasing the fluid-transport capacity of the alveolar epithelium. This proliferation is controlled by epithelial growth factors, including keratinocyte and hepatocyte growth factors.

The mechanisms underlying the resolution of the inflammatory-cell infiltrate and fibrosis are unclear. Apoptosis (programmed cell death) is thought to be a major mechanism for the clearance of neutrophils from sites of inflammation and may be important in the clearance of neutrophils from the injured lung. However, in one study of bronchoalveolar-lavage fluid from patients with acute lung injury and the acute respiratory distress syndrome, the numbers of apoptotic neutrophils were low, perhaps because of the presence of antiapoptotic factors such as granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating

factor. Nevertheless, high concentrations of the markers of apoptosis are present in the pulmonary edema fluid of patients, and exposure in vitro to bronchoalveolar-lavage fluids from these patients can promote epithelial-cell apoptosis. These are potentially important observations, since the mechanisms that alter epithelial integrity need to be identified. The role of proapoptotic and antiapoptotic mechanisms in both the injury and repair of the alveolar epithelium and the lung endothelium is an important area for future research.

Exams and Tests for ARDS

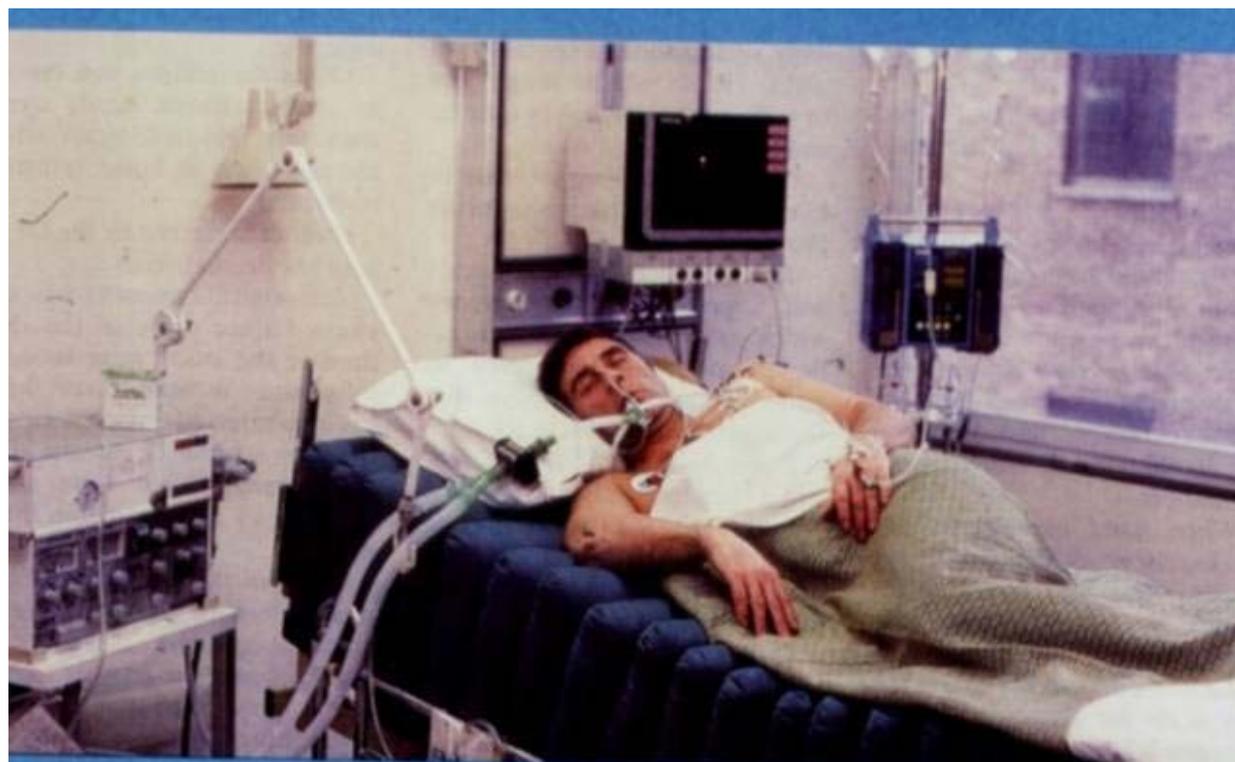

- [Arterial blood gas](#) analysis reveals hypoxemia (reduced levels of oxygen in the blood).
- A [complete blood count](#) may be taken. The number of white blood cells is increased in sepsis.
- [Chest x-ray](#) will show the presence of fluid in the lungs.
- [CT scan](#) of the chest may be required only in some situations (routine chest x-ray is sufficient in most cases).
- Echocardiogram (an [ultrasound](#) of the [heart](#)) may help exclude any heart problems that can cause fluid build-up in the lung.
- Monitoring with a [pulmonary artery catheter](#) may be done to exclude a [cardiac](#) cause for the difficulty in breathing.
- [Bronchoscopy](#) (a procedure used to look inside the [windpipe](#) and large airways of the lung) may be considered to evaluate the possibility of lung infection.

Treatment

Approach to Treatment

Improvement in the supportive care of patients with acute lung injury and the acute respiratory distress syndrome may have contributed to the recent decline in the mortality rate. There should be a careful search for the underlying cause, with particular attention paid to the possibility of

treatable infections such as sepsis or pneumonia. Abdominal infections should be treated promptly with antimicrobial agents or surgery. Prevention or early treatment of nosocomial infections is critical, since patients frequently die of uncontrolled infection. Adequate nutrition through the use of enteral feeding is preferred to parenteral nutrition since this route does not carry the serious risk of catheter-induced sepsis. Prevention of gastrointestinal bleeding and thromboembolism is also important.

An improved understanding of the pathogenesis of acute lung injury and the acute respiratory distress syndrome has led to the assessment of several novel treatment strategies. Although many specific therapies have not proved beneficial, it is encouraging that the quality of clinical trials is improving. An important advance has been the establishment of a network supported by the NIH that includes 10 centers, 24 hospitals, and 75 intensive care units and that provides the infrastructure for well-designed, multicenter, randomized trials of potential new therapies.

General

Acute respiratory distress syndrome is usually treated with mechanical ventilation in the Intensive Care Unit. Ventilation is usually delivered through oro-tracheal intubation, or tracheostomy whenever prolonged ventilation (≥ 2 weeks) is deemed inevitable.

The possibilities of non-invasive ventilation are limited to the very early period of the disease

or, better, to prevention in individuals at risk for the development of the disease (atypical pneumonias, pulmonary contusion, major surgery patients).

Treatment of the underlying cause is imperative, as it tends to maintain the ARDS picture.

Appropriate antibiotic therapy must be administered as soon as microbiological culture results are available. Empirical therapy may be appropriate if local microbiological surveillance is efficient. More than 60% ARDS patients experience a (nosocomial) pulmonary infection either before or after the onset of lung injury.

The origin of infection, when surgically treatable, must be operated on. When sepsis is diagnosed, appropriate local protocols should be enacted.

Commonly used supportive therapy includes particular techniques of mechanical ventilation and pharmacological agents whose effectiveness with respect to the outcome has not yet been proven. It is now debated whether mechanical ventilation is to be considered mere supportive therapy or actual treatment, since it may substantially affect survival.

Mechanical Ventilation

The most appropriate method of mechanical ventilation in the acute respiratory distress syndrome has been controversial since the syndrome was first described. Although the tidal volume in normal persons at rest is 6 to 7 ml per kilogram, historically a volume of 12 to 15 ml per kilogram was recommended in patients with acute lung injury and the acute respiratory distress syndrome. This comparatively high tidal volume may cause further lung injury. Interestingly, the possibility of ventilator-associated lung injury was first considered in the 1970s, leading to a study of extracorporeal membrane oxygenation in which the tidal volume was reduced to 8 to 9 ml per kilogram. However, this strategy, like extracorporeal removal of carbon dioxide in a subsequent study, failed to decrease mortality.

As described in this issue of the *Journal*, the NIH Acute Respiratory Distress Syndrome Network compared a traditional tidal volume (12 ml per kilogram of predicted body weight) with a lower tidal volume (6 ml per kilogram of predicted body weight) in 861 patients. In the group receiving lower tidal volumes, plateau pressure (airway pressure measured after a 0.5-second pause at the end of inspiration) could not exceed 30 cm of water and a detailed

protocol was used to adjust the fraction of inspired oxygen and positive end-expiratory pressure. The in-hospital mortality rate was 39.8 percent in the group treated with traditional tidal volumes and 31.0 percent in the group treated with lower tidal volumes ($P=0.007$). Thus, mortality was reduced by 22 percent in the group treated with lower tidal volumes, a finding of major importance. This large multicenter trial provides convincing evidence that a specific therapy for the acute respiratory distress syndrome can reduce mortality. It also provides evidence of the clinical significance of ventilator-associated lung injury and provides a well-defined protocol for ventilation against which future strategies can be compared.

The positive results of this trial differed from those of two previous studies of low tidal volumes, a Canadian study of 120 patients and a European study of 116 patients. There are several possible explanations for the discrepant results. First, the NIH study had the lowest tidal volume when the tidal volumes were compared with the use of the same calculation of ideal body weight. Thus, the NIH study may have been better able to show a difference between the treatment groups. Second, the study treated respiratory acidosis associated with alveolar hypoventilation and hypercapnia by allowing the respiratory rate to increase to 35 breaths per minute and by the administration of sodium bicarbonate. Conceivably, respiratory acidosis could have had deleterious effects in the groups treated with low tidal volumes in the other two studies. Finally, the other studies had many fewer patients, thus reducing the statistical power to find a treatment effect.

APRV (Airway Pressure Release Ventilation) and ARDS / ALI

No particular ventilator mode is known to improve mortality in ARDS. The landmark ARDSNet trial used a volume controlled mode and showed decrease mortality with smaller volumes. However, other modes of ventilation have not been directly compared to volume controlled ventilation.

Some practitioners favor airway pressure release ventilation (APRV). Advantages to APRV ventilation include: decreased airway pressures, decreased minute ventilation, decreased dead-space ventilation, promotion of spontaneous breathing, almost 24 hour a day alveolar recruitment, decreased use of sedation, near elimination of neuromuscular blockade, optimized arterial blood gas results, mechanical restoration of FRC (functional residual capacity), a positive effect on cardiac output (due to the negative inflection from the elevated baseline with each spontaneous breath), increased organ and tissue perfusion, potential for increased urine

output secondary to increased renal perfusion.

A patient with ARDS on average spends 8 to 11 days on a mechanical ventilator; APRV may reduce this time significantly and conserve valuable resources.

A study is needed to evaluate whether APRV will reduce patient mortality when compared to the ARDSNet protocol. However, there seems to be little political will, within the medical community, to address the need for this study, in spite of the clinical successes seen with APRV.

Positive end-expiratory pressure

There has also been considerable interest in the optimal level of positive end-expiratory pressure in patients with acute lung injury and the acute respiratory distress syndrome. It was noted early on that the use of positive end-expiratory pressure could improve oxygenation in these patients, allowing the fraction of inspired oxygen to be reduced. The best-documented effect of positive end-expiratory pressure on lung function is an increase in functional residual capacity, probably as a result of the recruitment of collapsed alveoli. Although lung injury was prevented in rats by the prophylactic use of positive end-expiratory pressure, the prophylactic use of a positive end-expiratory pressure of 8 cm of water in patients at risk for the acute respiratory distress syndrome was not successful.

Recently, Amato et al. used an “open-lung” approach to mechanical ventilation in patients with acute lung injury and the acute respiratory distress syndrome. In addition to a low tidal volume and pressure-controlled inverse-ratio ventilation, the protocol included raising the level of positive end-expiratory pressure above the lower inflection point on a pressure–volume curve for each patient in an attempt to ensure adequate recruitment of atelectatic lung. With this approach, mortality was reduced. However, the adoption of this approach cannot yet be recommended for several reasons. First, this study was small, involving only 53 patients and only a single center. Second, mortality in the group treated with conventional ventilation was unusually high (71 percent), suggesting that the high tidal volume used may have been especially injurious. Furthermore, the difference in mortality between the two groups was only apparent at 28 days; the rates of survival until hospital discharge were not significantly different between the two groups. Third, a reliable measurement of the lower inflection point of

the pressure–volume curve is technically difficult and usually requires sedation and paralysis of the patient.

Positive end-expiratory pressure (PEEP) is used in mechanically-ventilated patients with ARDS to improve oxygenation. In ARDS, three populations of alveoli can be distinguished. There are normal alveoli which are always inflated and engaging in gas exchange, flooded alveoli which can never, under any ventilatory regime, be used for gas exchange, and atelectatic or partially flooded alveoli that can be "recruited" to participate in gas exchange under certain ventilatory regimes. The recruitable alveoli represent a continuous population, some of which can be recruited with minimal PEEP, and others which can only be recruited with high levels of PEEP. An additional complication is that some or perhaps most alveoli can only be opened with higher airway pressures than are needed to keep them open. Hence the justification for maneuvers where PEEP is increased to very high levels for seconds to minutes before dropping the PEEP to a lower level. Finally, PEEP can be harmful. High PEEP necessarily increases mean airway pressure and alveolar pressure. This in turn can damage normal alveoli by overdistension resulting in DAD.

The 'best PEEP' used to be defined as 'some' cmH₂O above the lower inflection point (LIP) in the sigmoidal pressure-volume relationship curve of the lung. Recent research has shown that the LIP-point pressure is no better than any pressure above it, as recruitment of collapsed alveoli, and more importantly the overdistension of aerated units, occur throughout the whole inflation. Despite the awkwardness of most procedures used to trace the pressure-volume curve, it is still used by some to define the minimum PEEP to be applied to their patients. Some of the newest ventilators have the ability to automatically plot a pressure-volume curve. The possibility of having an 'instantaneous' tracing trigger might produce renewed interest in this analysis.

PEEP may also be set empirically. Some authors suggest performing a 'recruiting maneuver' (i.e., a short time at a very high continuous positive airway pressure, such as 50 cmH₂O (4.9 kPa), to recruit, or open, collapsed units with a high distending pressure) before restoring previous ventilation. The final PEEP level should be the one just before the drop in PaO₂ (or peripheral blood oxygen saturation) during a step-down trial.

Intrinsic PEEP (iPEEP), or auto-PEEP, first described by John Marini of St. Paul Regions

Hospital, is a potentially unrecognized contributor to PEEP in patients. When ventilating at high frequencies, its contribution can be substantial, particularly in patients with obstructive lung disease. iPEEP has been measured in very few formal studies on ventilation in ARDS patients, and its contribution is largely unknown. Its measurement is recommended in the treatment of ARDS patients, especially when using high-frequency (oscillatory/jet) ventilation.

A compromise between the beneficial and adverse effects of PEEP is inevitable.

In spite of these issues, the study by Amato et al. raises the possibility that improved alveolar recruitment with the use of higher levels of positive end-expiratory pressure than were used in the NIH study might further reduce ventilator-associated lung injury. This possibility is currently being tested in a new NIH Acute Respiratory Distress Syndrome Network ventilation trial. A number of alternative approaches to conventional mechanical ventilation have also been proposed, including prone positioning of the patient during ventilation, but have not yet been proved to be beneficial.

Prone position

Distribution of lung infiltrates in acute respiratory distress syndrome is non-uniform. Repositioning into the prone position (face down) might improve oxygenation by relieving atelectasis and improving perfusion. However, although the hypoxemia is overcome there seems to be no effect on overall survival.

Fluid and Hemodynamic Management

The rationale for restricting fluids in patients with acute lung injury and the acute respiratory distress syndrome is to decrease pulmonary edema. Studies in animals with acute lung injury indicated that the degree of edema was reduced if left atrial pressure was lowered. Some clinical studies have supported this hypothesis. Soon, a randomized trial of fluid management designed to compare restricted with liberal fluid management based on monitoring hemodynamics with either a pulmonary-artery catheter or a central venous catheter will be carried out by the NIH Acute Respiratory Distress Syndrome Network. While we await these results, a reasonable objective is to maintain the intravascular volume at the lowest level that is consistent with adequate systemic perfusion, as assessed by metabolic acid–base balance and renal function. If systemic perfusion cannot be maintained after the restoration of intravascular

volume, as is the case in patients with septic shock, treatment with vasopressors is indicated to restore end-organ perfusion and normalize oxygen delivery. However, on the basis of the negative results of clinical trials, the use of supranormal levels of oxygen delivery cannot be recommended.

Surfactant Therapy

Because of the success of surfactant-replacement therapy in infants with the neonatal respiratory distress syndrome, surfactant replacement has been proposed as a treatment for patients with acute lung injury and the acute respiratory distress syndrome. However, in one study, treatment with a synthetic surfactant had no effect on oxygenation, the duration of mechanical ventilation, or survival. There are several possible explanations for the negative results. First, the surfactant was delivered as an aerosol, and less than 5 percent may have reached the distal air spaces. Also, the product used, a protein-free phospholipid preparation, may not be the most effective for patients with acute lung injury and the acute respiratory distress syndrome. Newer preparations of surfactant that contain recombinant surfactant proteins and new approaches to their instillation, including tracheal instillation and bronchoalveolar lavage, are being evaluated in clinical trials.

Inhaled Nitric Oxide and Other Vasodilators

Nitric oxide is a potent vasodilator that can be delivered to the pulmonary vasculature by inhalation without causing systemic vasodilation. Although observational studies suggested that inhaled nitric oxide might be beneficial in patients with acute lung injury and the acute respiratory distress syndrome, the results of randomized, double-blind studies have been discouraging. In a phase 2 study, inhaled nitric oxide did not reduce mortality or reduce the duration of mechanical ventilation. The improvements in oxygenation with this treatment were small and were not sustained, and pulmonary-artery pressure decreased very little, and only on the first day of treatment. Also, a recent phase 3 study of inhaled nitric oxide showed that it had no effect on either mortality or the duration of mechanical ventilation. Thus, inhaled nitric oxide cannot be recommended for the routine treatment of acute lung injury and the acute respiratory distress syndrome, but it may be useful as a rescue therapy in patients with refractory hypoxemia. Treatment with several less selective vasodilators, including sodium nitroprusside, hydralazine, alprostadil (prostaglandin E₁), and epoprostenol (prostacyclin), has also not been shown to be beneficial.

Glucocorticoids and Other Antiinflammatory Agents

Recognition of the inflammatory nature of the lung injury in acute lung injury and the acute respiratory distress syndrome prompted interest in antiinflammatory treatments, particularly glucocorticoids. However, glucocorticoids had no benefit when they were given before the onset of the disease or early in its course. More recently, glucocorticoids have been used to treat the later, fibrosing-alveolitis phase of the disease. Encouraging results were reported in preliminary studies and in a small randomized trial of 24 patients. A larger randomized, multicenter U.S. trial of treatment with high-dose methylprednisolone for at least seven days is under way. Because treatment with high-dose methylprednisolone may increase the incidence of infection, the routine use of this drug in patients with established acute lung injury and the acute respiratory distress syndrome cannot be recommended until results of a large multicenter trial become available.

A short course of high-dose glucocorticoids could be considered as rescue therapy in patients with severe disease that is not resolving. In addition to glucocorticoids, other antiinflammatory agents designed to interrupt the process of acute lung injury have been investigated but have proved unsuccessful. The failure may reflect the complexity and redundancy of the inflammation in acute lung injury or the inability to deliver these agents early enough in the course of the illness.

Acceleration of Resolution

Recognition of the importance of the resolution phase of acute lung injury and the acute respiratory distress syndrome has stimulated interest in strategies to hasten patients' recovery from lung injury. Experimentally, removal of pulmonary edema fluid from the alveolar space can be enhanced by both catecholamine-dependent and catecholamine-independent mechanisms, including those increased by inhaled and systemic beta-agonists. Beta-agonists are appealing candidates because they are already in wide clinical use and have no serious side effects, even in critically ill patients. Treatment with beta-agonists may also increase the secretion of surfactant and perhaps exert an antiinflammatory effect, thus helping to restore vascular permeability of the lung.

Since acute injury to epithelial type I cells causes denudation of the alveolar epithelium, an additional approach to hastening the resolution of acute lung injury and the acute respiratory distress syndrome is to accelerate reepithelialization of the alveolar barrier. The proliferation of

alveolar epithelial type II cells is controlled by a number of epithelial growth factors, including keratinocyte growth factor. Experimentally, administration of keratinocyte growth factor protects against lung injury, probably in part by increasing the proliferation of alveolar type II cells and the clearance rate of alveolar fluid and by inducing antioxidant effects, and perhaps by reducing lung endothelial injury. These findings raise the possibility that an epithelium-specific growth factor could be used to accelerate the resolution of the syndrome. Overall, strategies directed at restoring the function of alveolar epithelium deserve careful evaluation.

Conclusions

In conclusion, substantial progress has been made in the understanding of acute lung injury and the acute respiratory distress syndrome. More information regarding epidemiology and pathogenesis has become available, and the importance of the resolution phase of the illness has been recognized, opening up new avenues for therapeutic intervention. Although progress in specific treatments has lagged behind basic research, the formation of the NIH Acute Respiratory Distress Syndrome Network led to a clinical trial of a ventilation strategy involving low tidal volumes, which reduced mortality by 22 percent. Large, prospective, randomized trials of new ventilatory and pharmacologic strategies may further reduce mortality from this common clinical syndrome.

General Principles of Emergency Care

General Principles of Emergency Care

Splint injured parts in the position they are found Prevent chilling, but do not add excessive heat Do not remove penetrating objects Do not try to give anything by mouth to an unconscious person or one with serious injuries Stay with the injured person until medical care or transportation arrives

Physical Examination :

The first priority: ABCs Airway, breathing, and circulation Watch chest for rhythmic breathing; listen near mouth and nose for air movement Palpate the carotid and peripheral pulses Once respiration and circulation established, assess for uncontrolled bleeding and shock If none, assess systematic head-to-toe

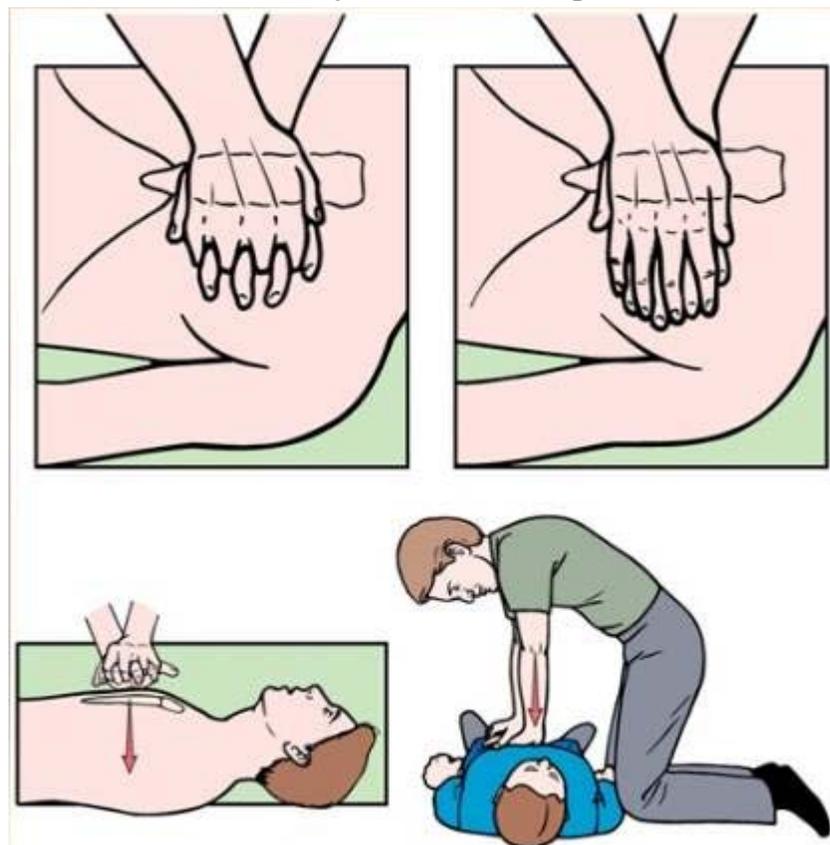

Evaluation of Accident and Emergency Patients :

Primary survey (ABCDE): Airway Breathing Circulation/hemorrhage Disability or

defibrillation Exposure Secondary survey (head-to-toe): Head, face, neck, neurologic status
Chest Abdomen/genitourinary system Limbs Log roll

Systematic Head-to-Toe Assessment

Evaluate comprehension: ask patient to follow simple commands, such as opening and closing the eyes Inspect eyes to assess pupil size, equality, and reaction to light Ask about neck pain or stiffness and the ability to swallow Inspect for chest wall movement symmetry

Systematic Head-to-Toe Assessment :

Systematic Head-to-Toe Assessment Assess breathing, dyspnea, and abnormal sounds associated with respirations Examine contour of abdomen for distention Light palpation to detect pain or tenderness Inspect the extremities for deformity or injury, and evaluate movement Assess peripheral pulses and warmth and sensation in the extremities

Cardiopulmonary Arrest :

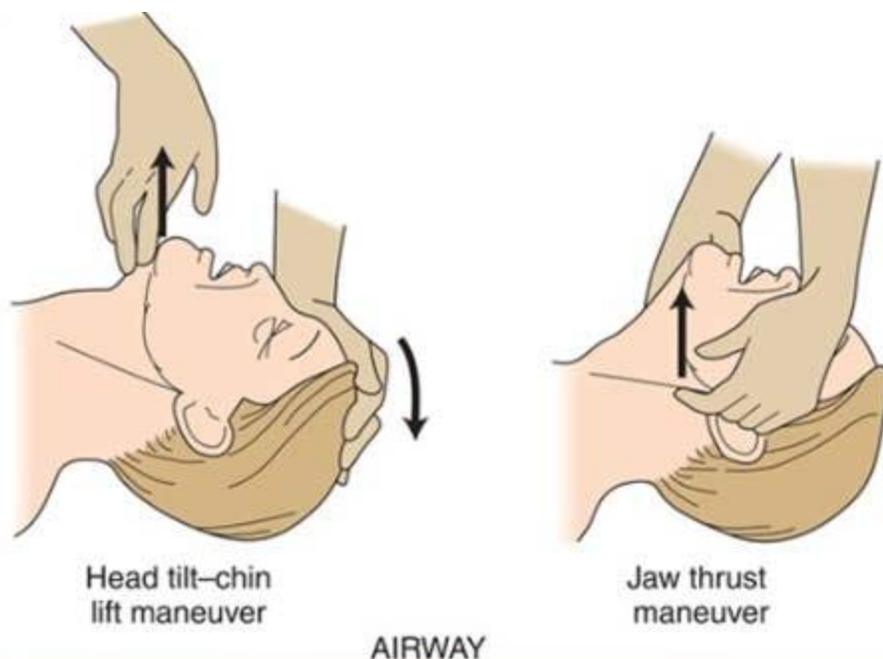

Cardiopulmonary Arrest Absence of a heartbeat and respirations Causes Myocardial infarction, heart failure, electrocution, drowning, drug overdose, anaphylaxis, and asphyxiation Signs and symptoms Collapse and quickly lose consciousness No pulse or respiration

Cardiopulmonary Arrest :

Cardiopulmonary Arrest Interventions Determine responsiveness Open airway Check for

breathing (look, listen, feel) If nonresponsive and not breathing, palpate for a pulse If no pulse in 10 seconds, begin compression:ventilation cycles of 30:2 If a pulse, deliver 10-12 rescue breaths per minute In no advanced airway, continue the 30:2 ratio With advanced airway, compressions of 100 per minute without pausing for ventilations which are done at a rate of 8-10 per minute

Figure: Airway :

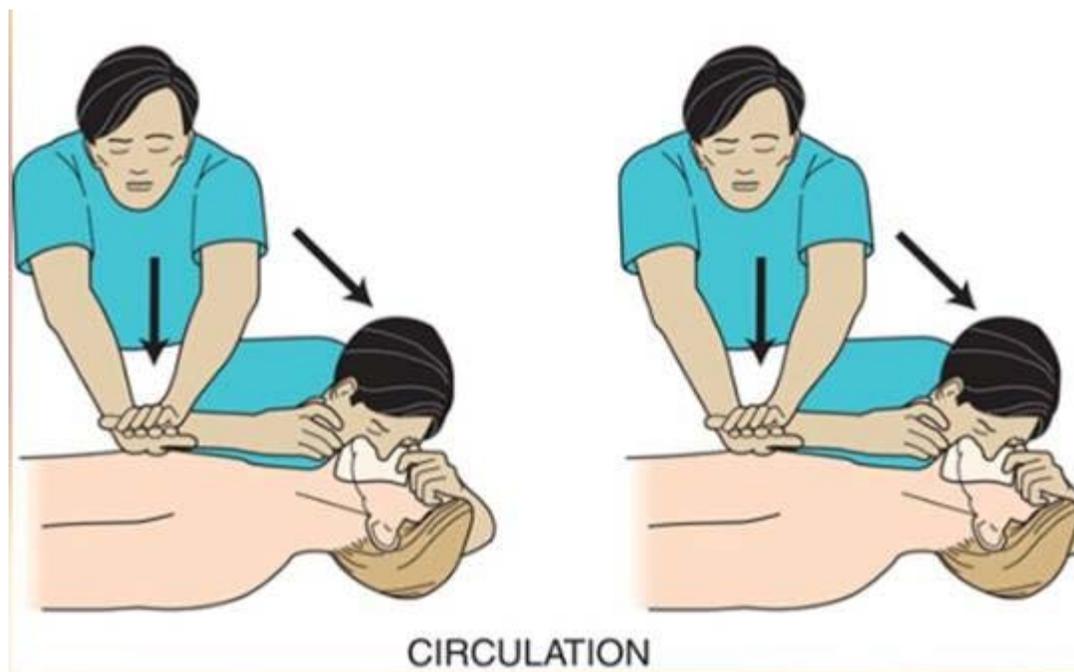

Cardiopulmonary Arrest :

Cardiopulmonary Arrest Two-rescuer CPR One rescuer compresses the chest at a rate of 100 per minute without pausing for ventilations Second rescuer ventilates with 8-10 breaths/minute Swap roles about every 2 minutes to avoid tiring Recovery position Unresponsive victim who is breathing should be log-rolled to one side if no cervical trauma is suspected

Choking or Airway Obstruction :

Choking or Airway Obstruction Assessment Universal sign of choking is grabbing the throat with one or both hands First determine if airway completely blocked If victim is able to speak, breathe, or cough with good air exchange, do nothing If unable to speak, breathe, or cough with good air exchange, act quickly to prevent suffocation

Choking or Airway Obstruction :

Choking or Airway Obstruction Victim is conscious Perform the Heimlich maneuver If effective, air expels foreign body from the airway If not, repeat maneuver until the object is expelled or victim loses consciousness

Choking or Airway Obstruction :

Choking or Airway Obstruction Victim unconscious/loses consciousness Lift the jaw and sweep a finger through the mouth to try to remove the object Tilt the head back, lift the chin, pinch the nostrils, try to ventilate If the airway is still obstructed, attempts at ventilation will fail Reposition the head and attempt once more to ventilate If unsuccessful, proceed to the next step Straddle the victim's thighs, place one hand on top of the other, and deliver up to five abdominal thrusts Repeat these three steps until the airway is clear

A

From Lewis, S.M., Hetherington, W.M., & Ditman, S.R. (Eds.) (2005). Medical-surgical nursing: Assessment

Straddle the victim's thighs, place one hand on top of the other, and deliver up to five abdominal thrusts Repeat these three steps until the airway is clear

B

Shock :

Shock Results from acute circulatory failure caused by inadequate blood volume, heart failure, overwhelming infection, severe allergic reactions, or extreme pain or fright

Hemorrhage :

Hemorrhage The loss of a large amount of blood Loss of more than 1 liter (L) of blood in an adult may lead to hypovolemic shock Death from continued uncontrolled bleeding Bleeding may be external or internal Internal bleeding is suspected if signs of shock but no external bleeding is evident

Exsanguination :

Exsanguination To Bleed Out all the Blood from the body

Hemorrhage :

Hemorrhage Apply direct, continuous pressure Elevate and immobilize the injured part (unless fracture is suspected) After bleeding stops, secure a large dressing, if available, over the wound Reinforce the dressing but do not change it If direct wound pressure and elevation fail to control bleeding, apply indirect pressure to the main artery that supplies the area

Hemorrhage Epistaxis Blood from anterior or posterior portion of the nose Most anterior nosebleeds respond to pressure Instruct the patient to sit down and lean the head forward Pinch the nostrils shut for at least 10 minutes Advise patient not to blow or pick at nose for several hours Continued bleeding or bleeding from the posterior area of the nose requires medical

treatment

Fracture :

Fracture A break in a bone Simple (closed) fracture Does not break the skin Compound (open) fracture Broken bone protrudes through the skin Complete fracture Broken ends are separated Incomplete fracture Bone ends are not separated

Fracture :

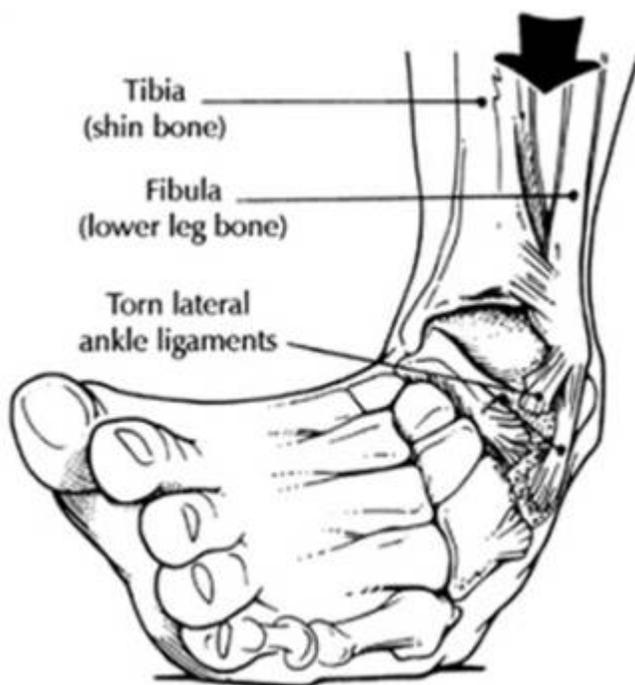

Fracture Assessment Primary symptom is pain Numbness/tingling from nerve injury and blood vessels Signs: deformity, swelling, discoloration, decreased function, and bone fragments protruding through the skin

Strains and Sprains :

Strains and Sprains Strains Injuries to muscles or tendons, or both Sprains Injuries to ligaments These injuries are painful; may be swelling Emergency treatment is: RICE- (rest, ice, compression, elevation) Victim to see physician for further evaluation

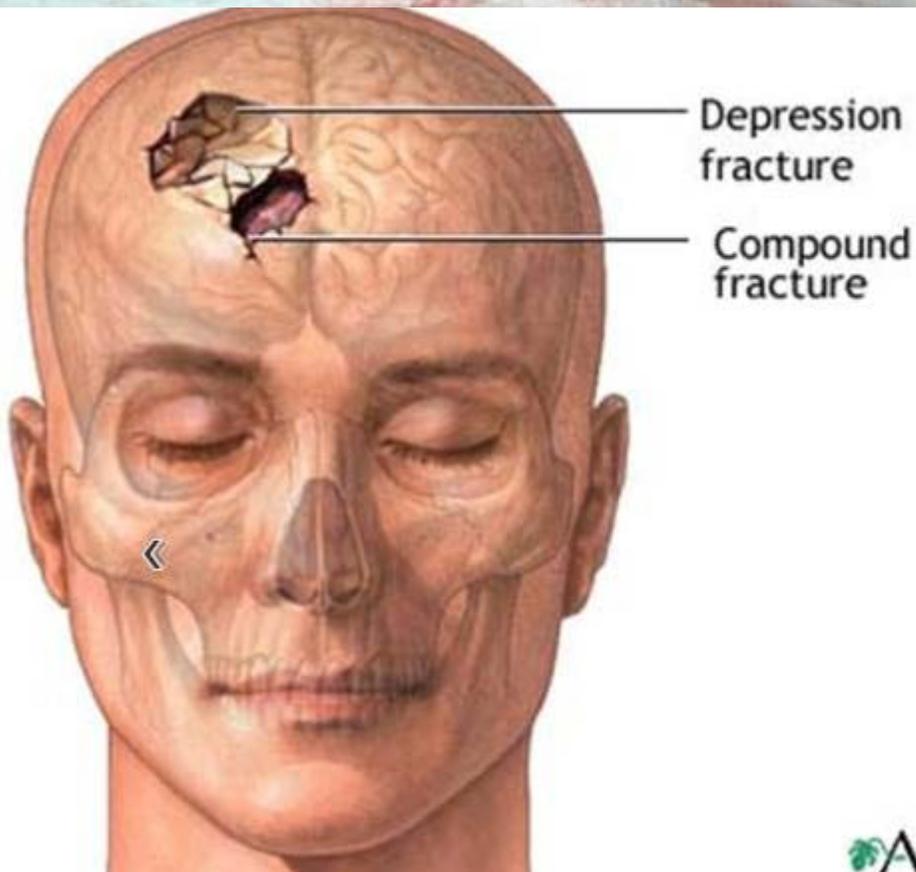

Head Injury :

Head Injury Suspected with any type of blow to the head or any unexplained loss of consciousness
Assessment Inspection and palpation of the head Evaluate for signs and symptoms of increased intracranial pressure Be alert for the leakage of cerebrospinal fluid that occurs with basilar skull fractures

Head Injury :

Head Injury Must be assessed by a physician as soon as possible Immobilize neck and keep victim flat with proper alignment of the neck and head Backboard used for transporting victim

Neck and Spinal Injuries :

Neck and Spinal Injuries Assessment Assess breathing and circulation and then begin resuscitation if needed Remember to use the jaw-thrust method to open the airway! Assess

movement and sensation in all extremities

Neck and Spinal Injuries Immediately summon expert emergency team In remote or life-threatening settings, the victim may have to be moved A rolled towel or article of clothing can be used as a collar to support the neck The victim can then be moved by log-rolling to one side and then rolling back onto a board, keeping the spine as straight as possible Throughout the movement, one rescuer supports the head while two others support the shoulders, hips, and legs

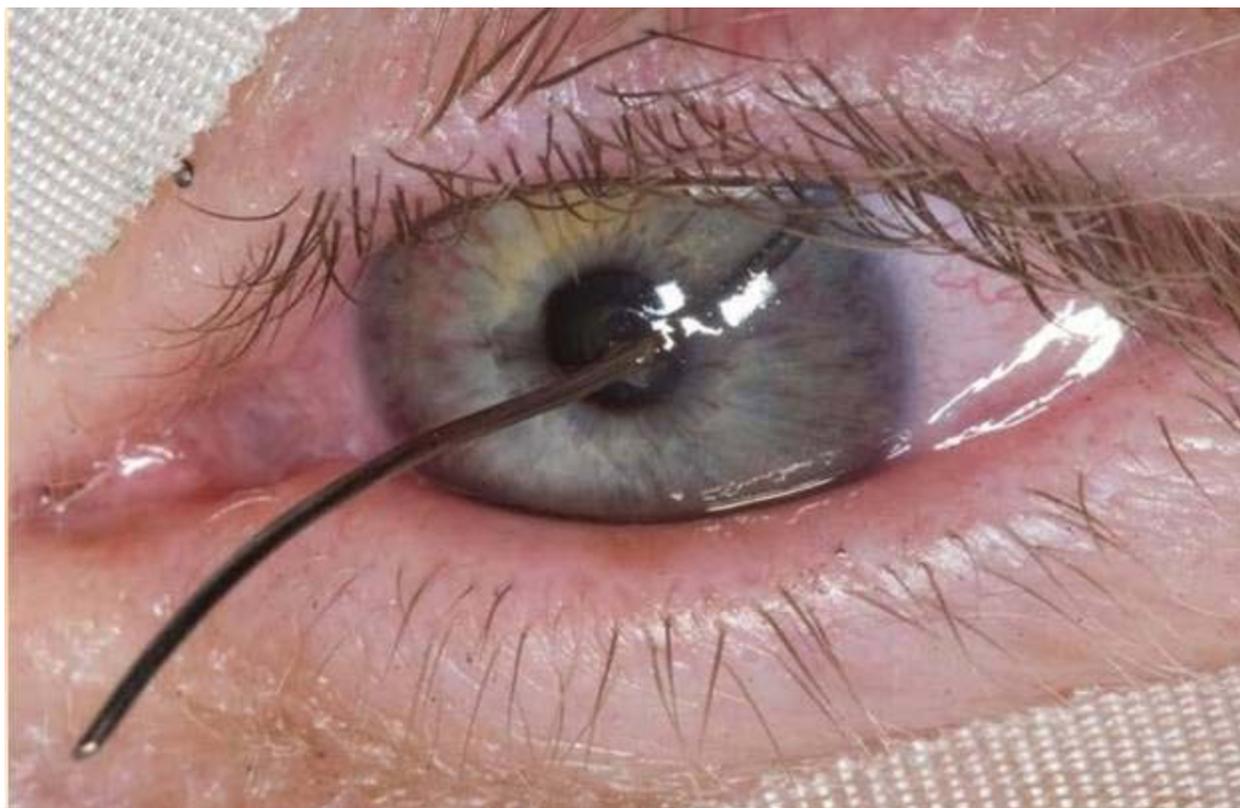

Eye Injury :

Eye Injury Assessment Inspect eyelid for trauma and the eye for redness, foreign bodies, or penetrating objects To inspect for foreign bodies, evert the eyelids

Ear Trauma :

Ear Trauma Assessment Assess extent of injury; note if any tissue is fully separated and severity of bleeding Apply direct pressure to injury to control bleeding

Ear Trauma :

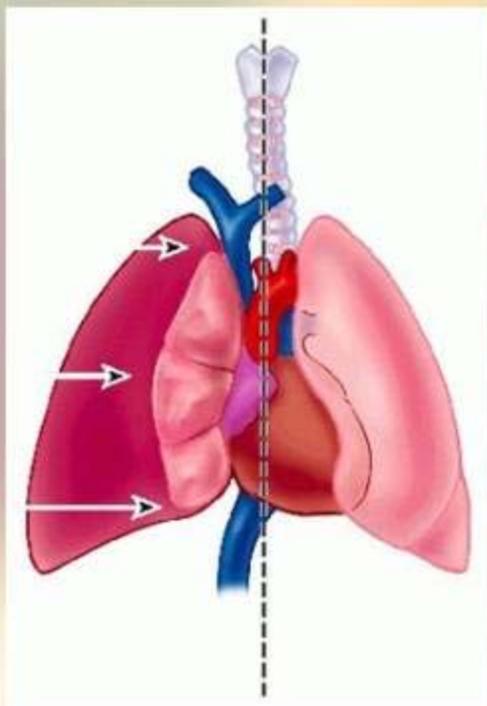

Ear Trauma If injured part is actually separated, reattachment may be possible Retrieve the tissue, wrap it in plastic, keep it cool, and transport it with the victim

Chest Injury :

Chest Injury Critical injuries: open pneumothorax, flail chest, massive hemothorax, and cardiac tamponade

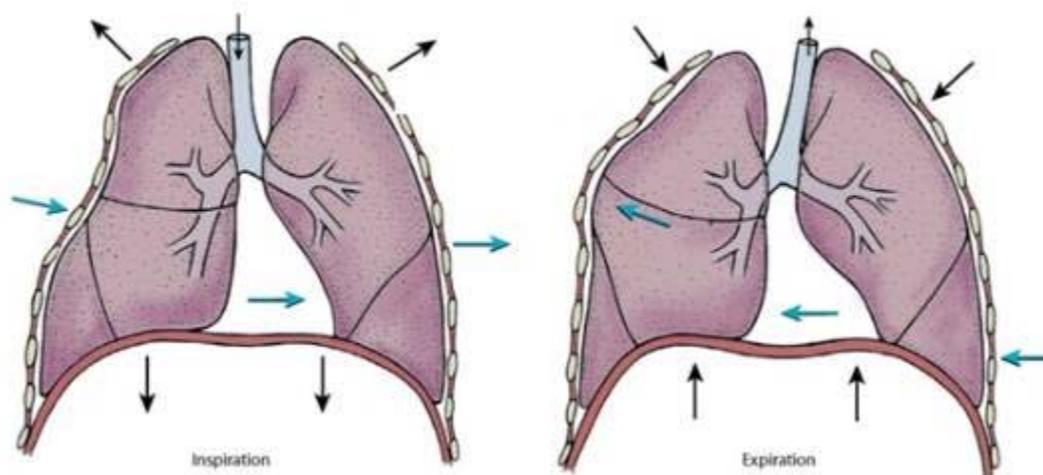

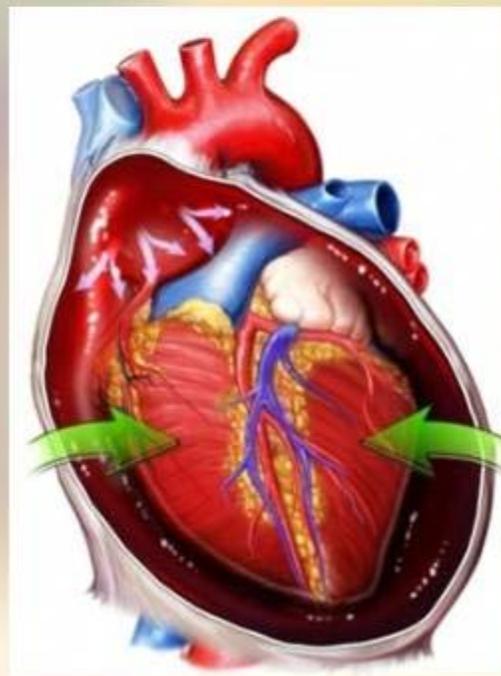

Pneumothorax

Pneumothorax

Cardiac Tamponade

Cardiac Tamponade

From Mosby's F.D. & Saunders, M. (1998). Medical-surgical nursing: Foundations for clinical practice (3rd ed.). Philadelphia: Saunders.

Assessment of Pt with Chest Injuries rate and character of respirations, skin color, pulse rate and rhythm symmetry of the chest wall movement presence of any apparent injuries to the chest
Signs and symptoms of chest injuries
Dyspnea Tachycardia Restlessness Cyanosis asymmetric or other abnormal chest wall movement, abnormal sounds of breathing Note mental state and level of consciousness

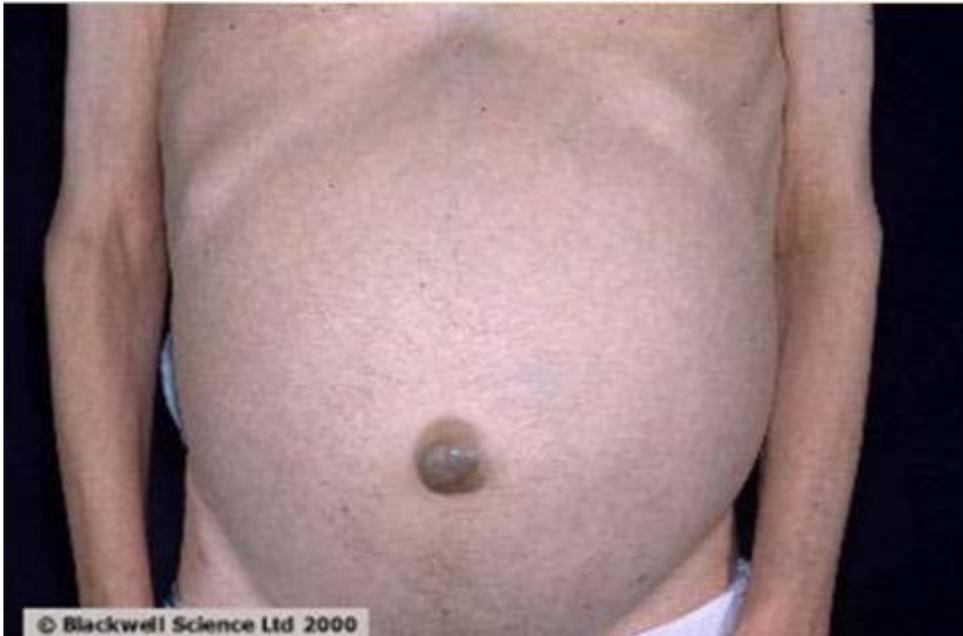

Abdominal

Injury: Assessment :

Abdominal Injury: Assessment Assess abdomen for evidence of injury Nausea/ Vomiting
Inspect Suspect internal abdominal injuries if victim complains of abdominal pain or abdomen
shows evidence of trauma or distention Protrusion of internal organs through a wound is called
evisceration

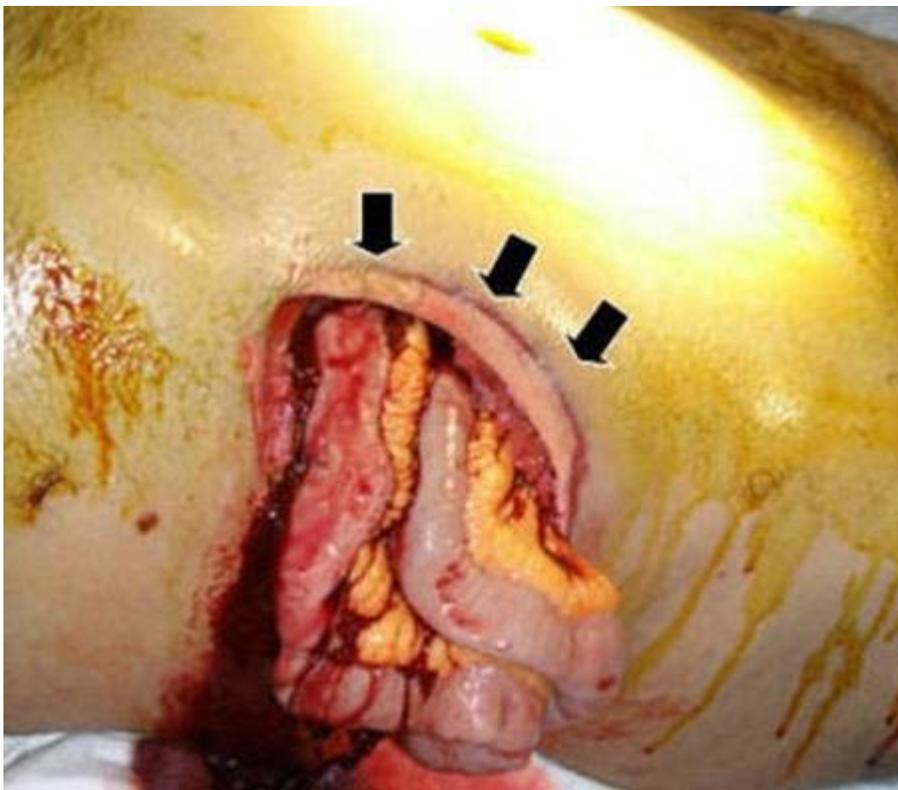

Abdominal Injury :

Abdominal Injury Cullen's Sign- Bluish tinge around umbilicus may indicates abdominal
hemorrhage

Abdominal Injury: Interventions :

Abdominal Injury: Interventions Require medical evaluation Give nothing by mouth in preparing for transport Do not attempt to replace eviscerated organs in the abdomen; this may cause additional harm Cover organs with material, such as plastic wrap or foil, to conserve moisture and warmth A saline-soaked sterile dressing is ideal but is not likely to be available on the scene of an accident Cover wound with clean cloth; transport to hospital

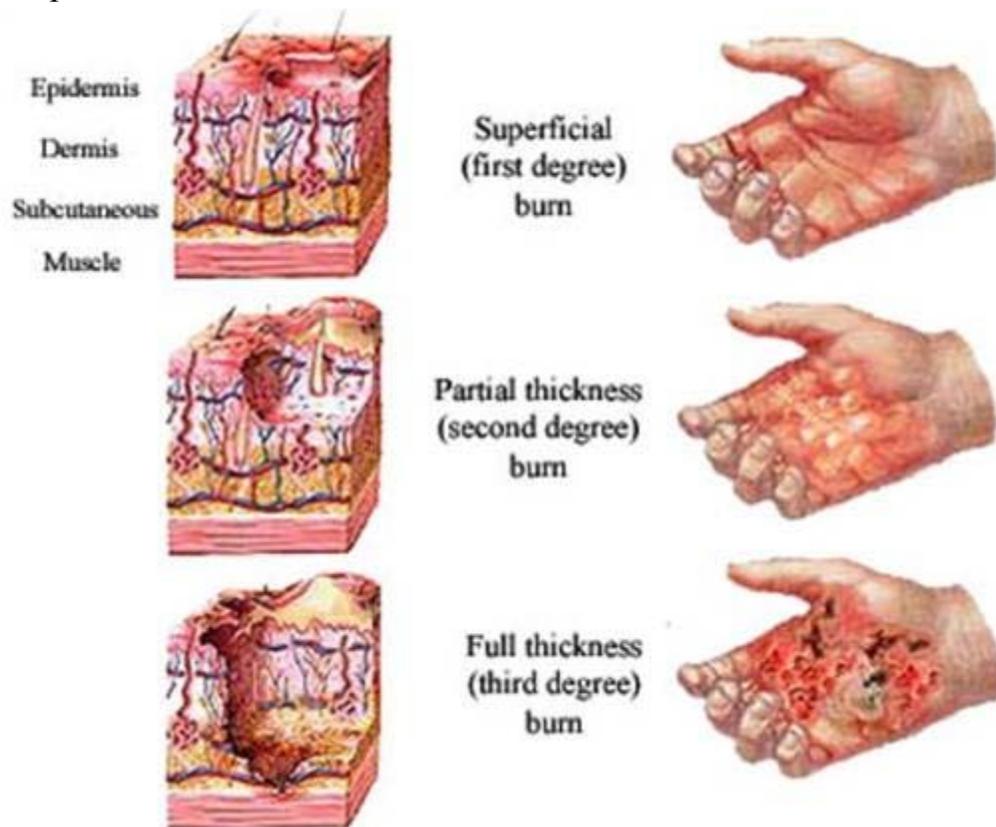

Traumatic Amputation :

Traumatic Amputation If partially/completely detached, reattachment possible Clean the wound surfaces with sterile water or saline and place the tissue in its normal position A body part that is completely detached should ideally be wrapped in sterile gauze moistened with sterile saline, placed in a watertight container such as a resealable plastic bag, and placed in an iced saline bath The tissue should not be frozen or placed in contact with ice Amputated extremities may be healthy enough for reattachment for 4-6 hours; digits as long as 8 hours

Amputated Hand :

Amputated Hand

:
Shark Bite Amputation

Burns: Assessment :

Burns: Assessment Determine the type of burn If patient has a flame burn or was in a closed, smoke-filled area, assess respirations first Determine the extent and depth of the burns Inspect skin for color, blisters, tissue destruction Superficial burns: typically pink or red and painful Deeper burns: red, white, or black; may destroy not only the skin but also the underlying tissues Electrical: difficult to assess; full extent of tissue damage may not be apparent for several days Chemical: immediately remove any remaining chemical

Burns: Interventions :

Burns: Interventions Ensure a patent airway and respirations for burn victims Rescue breathing, if needed

Hyperthermia :

Hyperthermia Body temperature $>37.2^{\circ}\text{C}$ (99°F) Heat edema and heat cramps are mild degrees of hyperthermia Can be treated by moving individual into cool place and providing fluids with electrolytes Heat exhaustion and heat stroke more serious See Table 16-5, p. 236

Hypothermia :

Hypothermia Decrease in body core temperature to $<36^{\circ}\text{C}$ (95°F) Caused by prolonged exposure to cold, extremely cold temperatures, or immersion in cold water Causes depression of vital functions, and if not corrected, death results from cardiac dysrhythmias

Hypothermia :

Hypothermia Mild stage Patient shivers in an effort to generate body heat Blood vessels in the extremities are constricted, and performing complex motor tasks is impaired Moderate hypothermia Appears dazed, poor motor coordination, slurred speech, and violent shivering May behave irrationally Severe hypothermia Waves of shivering, rigid muscles, and pale skin Pulse rate is slow and the pupils are dilated

Hypothermia

Frost Bite and Frost Nip :

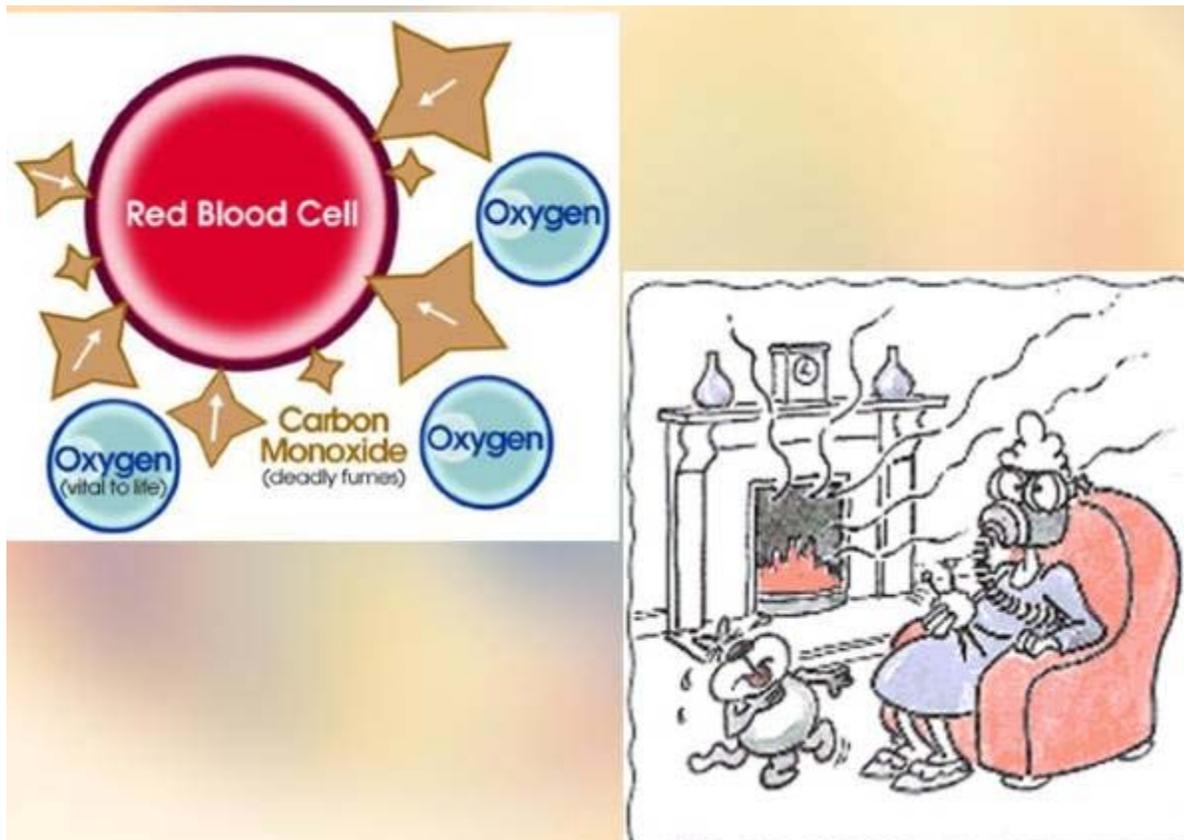

Frost Bite and Frost Nip Frost nip: mild tissue damage caused by cold Frost bite: More serious cold injury Blood vessels constrict when exposed to extreme cold. Blood clots form and circulation is impaired Tissues die as a result Pain is the first sign, followed by tingling, and numbness

Treatment for Frostbite :

Treatment for Frostbite Mild- rapid re-warming More serious- Do not attempt to thaw tissue unless warmth maintained Re-warm in heated 100-105* water-Do not rub or massage area Feet should be defrosted only if the person doesn't need to walk

Carbon Monoxide Poisoning :

Carbon Monoxide Poisoning Assessment Early signs and symptoms: headache and shortness of breath with mild exertion Then dizziness, nausea, vomiting, and mental changes As carbon monoxide in bloodstream rises, victim loses consciousness and develops cardiac and respiratory irregularities Cherry-red skin clear indicator of carbon monoxide poisoning, but skin color often found to be pale or bluish with reddish mucous membranes

Nursing Diagnosis, Goal, and Outcome Criteria :

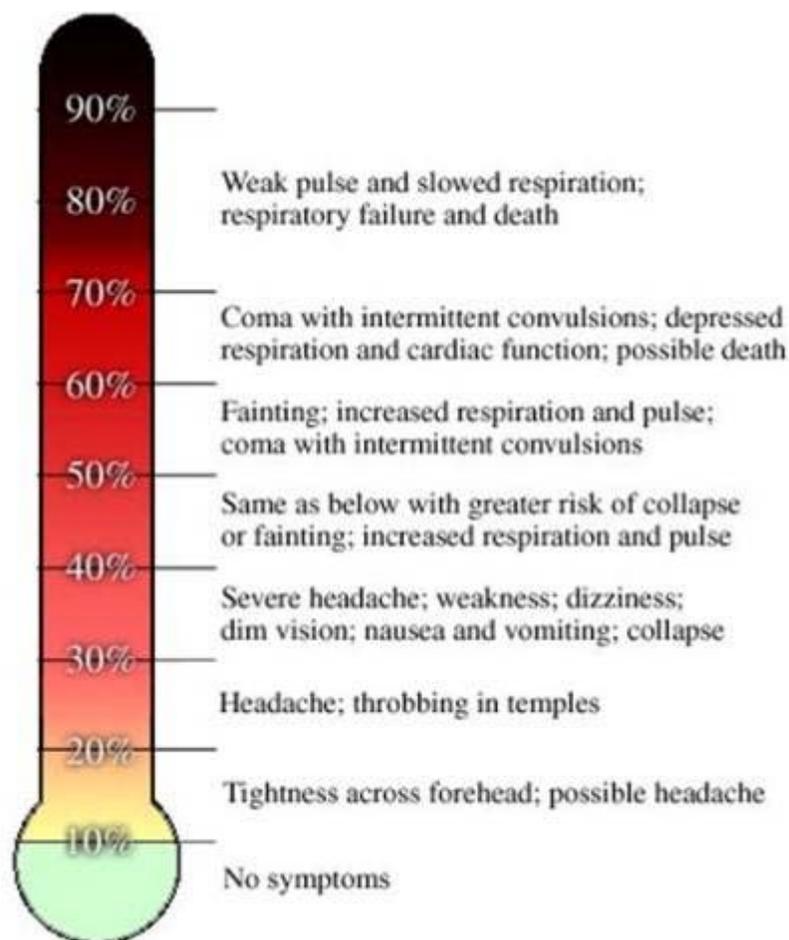

Nursing Diagnosis, Goal, and Outcome Criteria Impaired gas exchange related to carbon monoxide poisoning The goal of nursing care for the emergency treatment of the victim of carbon monoxide poisoning is normal oxygenation

Interventions :

Interventions Immediately move the victim to fresh air If person not breathing, start rescue breathing Seek emergency medical assistance immediately Give oxygen as soon as it is available At the hospital the patient may be placed in a hyperbaric oxygen chamber

Prevention :

Prevention Keep gas furnaces and stoves in proper repair Burners that use gas must be vented to the outside Don't use charcoal or wood-burning devices in closed area Never let automobile engine run in closed garage Install carbon monoxide detector alarm

Drug or Chemical Poisoning :

Drug or Chemical Poisoning Assessment History: data about relevant signs and symptoms

Name of drug or chemical. If the victim cannot provide the information, look for clues and save the container
 Amount consumed
 Length of time since substance was taken
 Last food consumed: amount, time
 Signs and symptoms that may be caused by poisons
 Victim's age and approximate weight
 Other medications, drugs, or alcohol ingested

Drug or Chemical Poisoning :

Drug or Chemical Poisoning Interventions
 Immediately call your poison center
 Some poisonings can be treated at home, others require a physician or a hospital
 Treatment of poisoning in an emergency facility may be with activated charcoal, total bowel lavage, and/or cathartics

Food Poisoning :

Food Poisoning Assessment Symptoms: nausea, vomiting, abdominal cramps, and diarrhea

Botulism caused by *Clostridium botulinum* has neurotoxic effects: difficulty breathing, seeing, and swallowing
 Clue that food poisoning is causing victim's symptoms is that all who consumed a certain food become ill
 To assist in identifying poisons, collect samples of stool or

vomited materials for possible lab analysis

Food Poisoning :

Food Poisoning Ptomaine poisoning Bacterial or chemical Cleanliness, good personal hygiene, and proper preparation and handling of foods Symptoms and treatment (Also refer to Health Promotion Points 44-2.)

Multistate Outbreak of *E. coli* O157:H7 Infections Linked to Eating Raw Refrigerated, Prepackaged Cookie Dough

Multistate Outbreak of *E. coli* O157:H7 Infections Associated with Beef from JBS Swift Beef Company

Multistate Outbreak of *E. coli* O157:H7 Infections Linked to Eating Raw Refrigerated, Prepackaged Cookie Dough Multistate Outbreak of *E. coli* O157:H7 Infections Associated with Beef from JBS Swift Beef Company

Healthy People 2010 Food Safety :

Healthy People 2010 Food Safety Focus area # 10: Food Safety. To reduce food-borne illnesses.

Food Poisoning: Interventions :

Food Poisoning: Interventions Medical care necessary if symptoms are severe or persistent The physician may order antiemetics and antidiarrheals Intravenous fluids may be prescribed with severe vomiting and diarrhea

Bites and Stings :

Bites and Stings Assessment Try to determine the type of bite Inspect bite to identify characteristics of bite site and any changes in surrounding tissue Ask about any symptoms that developed after the bite: pain, edema, numbness, tingling, nausea, fever, dizziness, and dyspnea Interventions: see Table 16-7, p. 239

Animal Bites :

Animal Bites Animal bites and Animal Control Agency: Wash area with warm soapy water for 5-10 minutes Rabies immunization or 5 IM injections given over a period of 3 weeks

Copperhead Snake :

Snakebite: :

Snakebite: Poisonous snakes and venomous snakebite Treatment Wash area Immobilize Apply suction Go to hospital Give antivenin

Insect Bites and Stings :

Remove Stinger

Health Promotion Points : Anaphylaxis Kit Individuals who have known allergies to insect bites or other common environmental allergens should carry an anaphylaxis kit. Family and friends should know how to use the contents in case the individual is unable to treat herself.

Coral Snake

Snakebite: :

Snakebite: Poisonous snakes and venomous snakebite Treatment Wash area Immobilize Apply suction Go to hospital Give antivenin

Rattlesnake

Insect Bites and Stings :

Insect Bites and Stings

Insect Bites and Stings

Remove Stinger

Health Promotion Points : Anaphylaxis Kit :

Health Promotion Points : Anaphylaxis Kit Individuals who have known allergies to insect bites or other common environmental allergens should carry an anaphylaxis kit. Family and friends should know how to use the contents in case the individual is unable to treat herself.

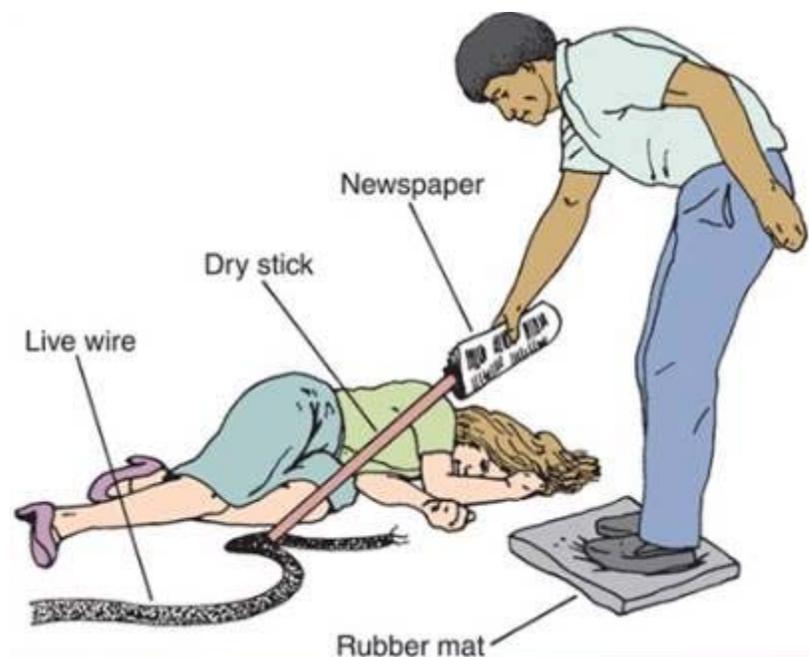

Administering Epi Pen :

Signs and Symptoms of Anaphylaxis :

Signs and Symptoms of Anaphylaxis Hives Swelling Generalized weakness Chest tightness
Abdominal cramps Constriction of throat Loss of consciousness

Safety Alert : Lightning :

Safety Alert : Lightning If outdoors when lightning occurs, avoid water, high ground, open spaces, and metal objects. Do not seek shelter under canopies, small picnic or rain shelters, or trees.

Acts of Bioterrorism Deliberate release of pathogens to kill people Anthrax, botulism, plague, smallpox, tularemia: most common biologic agents in terrorist attack Easily spread; potential to cause many deaths Health care providers must know how to protect themselves and others Staff should know where to obtain personal protective equipment and what types of precautions (i.e., patient isolation) should be taken

Disaster Planning :

Disaster Planning A challenge for the health care system is to be ready for natural disasters that often occur with short warning American Red Cross and the Salvation Army are experienced in handling these situations and quickly move in to help A call for nurse volunteers usually follows Regardless of the area of clinical expertise, there is certain to be a way each nurse can contribute

Psychological Emergencies :

Psychological Emergencies Combative patient Domestic violence/abuse Child abuse Elder abuse Psychological trauma

Legal Aspects of Emergency Care Emergency doctrine In emergencies, person may be unable to consent to care Treatment can be provided under the assumption that the patient would have consented if able Good Samaritan laws Limit liability and provide protection against malpractice claims when health care providers render first aid at the scene of an emergency These laws do not protect the nurse in the event of gross negligence or willful misconduct

Ischemic heart disease: a stable and unstable angina pectoris, MI. Treatment. Differentiation of the chest pain causes.

Background: Angina pectoris is the result of myocardial ischemia caused by an imbalance between myocardial blood supply and oxygen demand. Angina is a common presenting symptom (typically, chest pain) among patients with coronary artery disease. A comprehensive approach to diagnosis and to medical management of angina pectoris is an integral part of the daily responsibilities of physicians.

Pathophysiology: Myocardial ischemia develops when coronary blood flow becomes inadequate to meet myocardial oxygen demand. This causes myocardial cells to switch from aerobic to anaerobic metabolism, with a progressive impairment of metabolic, mechanical, and electrical functions. Angina pectoris is the most common clinical manifestation of myocardial ischemia. It is caused by chemical and mechanical stimulation of sensory afferent nerve endings in the coronary vessels and myocardium. These nerve fibers extend from the first to fourth thoracic spinal nerves, ascending via the spinal cord to the thalamus, and from there to the cerebral cortex.

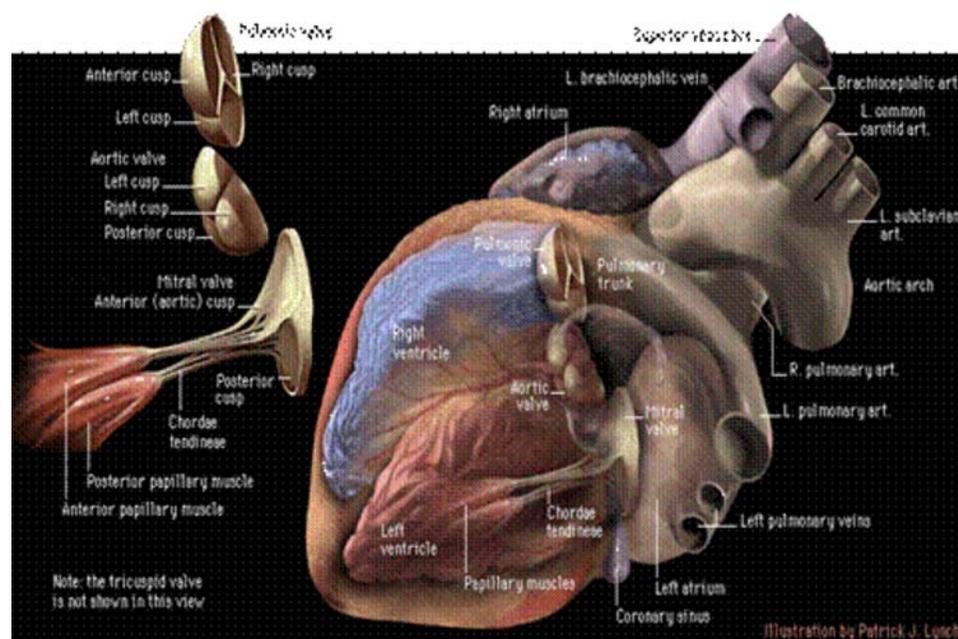

Fig. 1 Heart anatomy

Recent studies have shown that adenosine may be the main chemical mediator of anginal pain. During ischemia, ATP is degraded to adenosine, which, after diffusion to the extracellular space, causes arteriolar dilation and anginal pain. Adenosine induces angina mainly by stimulating the A₁ receptors in cardiac afferent nerve endings.

Heart rate, myocardial inotropic state, and myocardial wall tension are the major determinants

of myocardial metabolic activity and myocardial oxygen demand. Increases in the heart rate and myocardial contractile state result in increased myocardial oxygen demand. Increases in both afterload (ie, aortic pressure) and preload (ie, ventricular end-diastolic volume) result in a proportional elevation of myocardial wall tension and, therefore, increased myocardial oxygen demand. Oxygen supply to any organ system is determined by blood flow and oxygen extraction. Because the resting coronary venous oxygen saturation is already at a relatively low level (approximately 30%), the myocardium has a limited ability to increase its oxygen extraction during episodes of increased demand. Thus, an increase in myocardial oxygen demand (eg, during exercise) must be met by a proportional increase in coronary blood flow. The ability of the coronary arteries to increase blood flow in response to increased cardiac metabolic demand is referred to as coronary flow reserve (CFR). In healthy people, the maximal coronary blood flow after full dilation of the coronary arteries is roughly 4-6 times the resting coronary blood flow. CFR depends on at least 3 factors: large and small coronary artery resistance, extravascular (ie, myocardial and interstitial) resistance, and blood composition. Myocardial ischemia can result from (1) a reduction of coronary blood flow caused by fixed and/or dynamic epicardial coronary artery (ie, conductive vessel) stenosis, (2) abnormal constriction or deficient relaxation of coronary microcirculation (ie, resistance vessels), or (3) reduced oxygen-carrying capacity of the blood.

Atherosclerosis is the most common cause of epicardial coronary artery stenosis and, hence, angina pectoris. Patients with a fixed coronary atherosclerotic lesion of at least 50% show myocardial ischemia during increased myocardial metabolic demand as the result of a significant reduction in CFR. These patients are not able to increase their coronary blood flow during stress to match the increased myocardial metabolic demand, thus they experience angina. Fixed atherosclerotic lesions of at least 90% almost completely abolish the flow reserve; patients with these lesions may experience angina at rest.

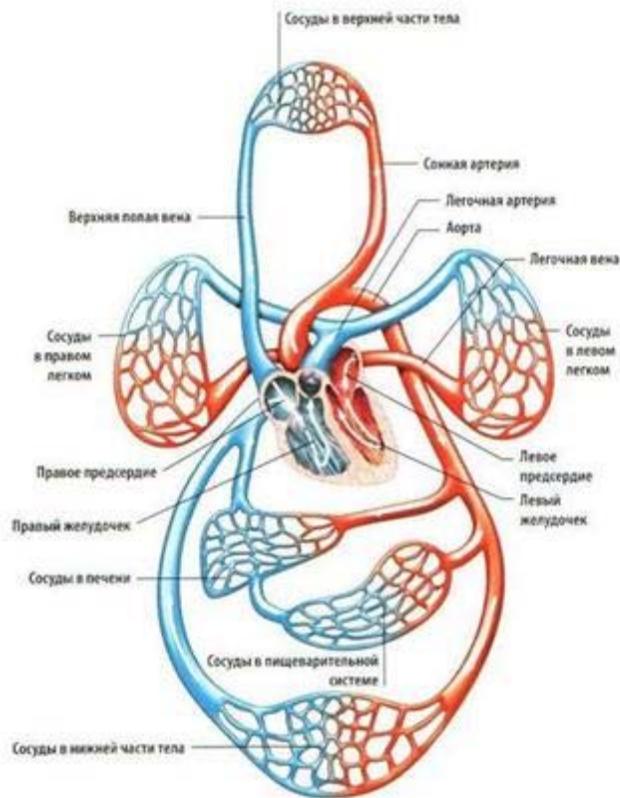

Fig 1a. Structure of cardio-vascular system

Coronary spasm can also reduce CFR significantly by causing dynamic stenosis of coronary arteries. Prinzmetal angina is defined as resting angina associated with ST-segment elevation caused by focal coronary artery spasm. Although most patients with Prinzmetal angina have underlying fixed coronary lesions, some have angiographically normal coronary arteries. Several mechanisms have been proposed for Prinzmetal angina: focal deficiency of nitric oxide production, hyperinsulinemia, low intracellular magnesium levels, smoking cigarettes, and using cocaine.

Approximately 30% of patients with chest pain referred for cardiac catheterization have normal or minimal atherosclerosis of coronary arteries. A subset of these patients demonstrates reduced CFR that is believed to be caused by functional and structural alterations of small coronary arteries and arterioles (ie, resistance vessels). Under normal conditions, resistance vessels are responsible for as much as 95% of coronary artery resistance, with the remaining

5% being from epicardial coronary arteries (ie, conductive vessels). The former is not visualized during regular coronary catheterization. Angina due to dysfunction of small coronary arteries and arterioles is called microvascular angina. Several diseases, such as diabetes mellitus, hypertension, and systemic collagen vascular diseases (eg, systemic lupus erythematosus, polyarteritis nodosa), are believed to cause microvascular abnormalities with subsequent reduction in CFR.

The syndrome that includes angina pectoris, ischemialike ST-segment changes and/or myocardial perfusion defects during stress testing, and angiographically normal coronary arteries is referred to as syndrome X. Most patients with this syndrome are postmenopausal women, and they usually have an excellent prognosis. Syndrome X is believed to be caused by microvascular angina. Multiple mechanisms may be responsible for this syndrome, including (1) impaired endothelial dysfunction, (2) increased release of local vasoconstrictors, (3) fibrosis and medial hypertrophy of the microcirculation, (4) abnormal cardiac adrenergic nerve function, and/or (5) estrogen deficiency.

A number of extravascular forces produced by contraction of adjacent myocardium and intraventricular pressures can influence coronary microcirculation resistance and thus reduce CFR. Extravascular compressive forces are highest in the subendocardium and decrease toward the subepicardium. Left ventricular (LV) hypertrophy together with a higher myocardial oxygen demand (eg, during tachycardia) cause greater susceptibility to ischemia in subendocardial layers.

Myocardial ischemia can also be the result of factors affecting blood composition, such as reduced oxygen-carrying capacity of blood, as is observed with severe anemia (hemoglobin, <8 g/dL), or elevated levels of carboxyhemoglobin. The latter may be the result of inhalation of carbon monoxide in a closed area or of long-term smoking.

Recently, ambulatory ECG monitoring has shown that silent ischemia is a common phenomenon among patients with established coronary artery disease. In one study, as many as 75% of episodes of ischemia (defined as transient ST depression of >1 mm persisting for at least 1 min) occurring in patients with stable angina were clinically silent. Silent ischemia occurs most frequently in early morning hours and may result in transient myocardial contractile dysfunction (ie, stunning). The exact mechanism(s) for silent ischemia is not known. However, autonomic dysfunction (especially in patients with diabetes), a higher pain threshold in some individuals, and the production of excessive quantities of endorphins are among the more popular hypotheses.

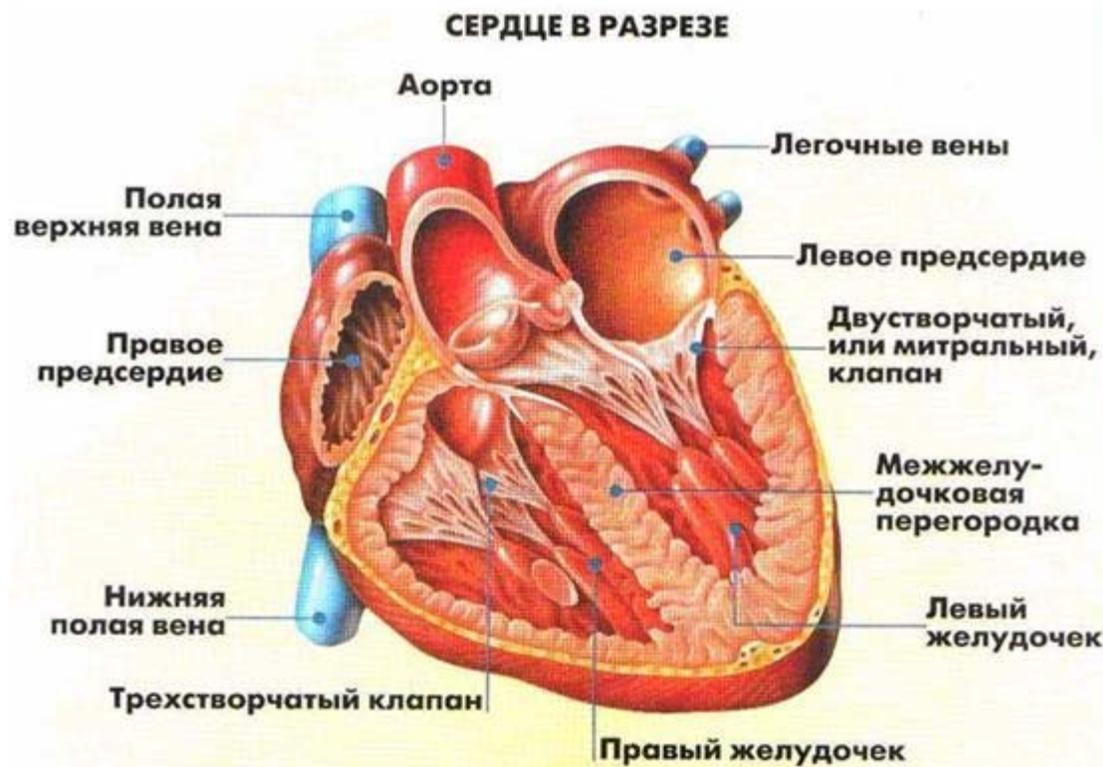

Fig. Heart structure

Frequency: In the US: Approximately 6.3 million Americans are estimated to experience angina. An estimated 350,000 new cases of angina occur every year. Each year, 1.1 million new and recurrent cases of an acute coronary event occur in this country, of which more than 40% are fatal. Roughly, more than 12 million Americans had a history of myocardial infarction (MI) and/or angina pectoris in the year 2000.

Mortality/Morbidity: Coronary artery disease is the single most common cause of death in the United States, accounting for almost one death per minute. More than half of those who die suddenly from coronary artery disease have no previous symptoms.

Race: The rate of angina pectoris in women older than 20 years ranges from 3.9% in non-Hispanic white women to 6.2% in non-Hispanic black women and 5.5% in Mexican American women. The rates of angina pectoris for men in the same ethnic groups are 2.6%, 3.1%, and 4.1%, respectively. Among American Indians aged 65-74 years, the rates (per 1000 persons) of new and recurrent heart attacks are 25.1% for men and 9.1% for women.

Sex: Angina pectoris is more often the presenting symptom of coronary artery disease in women than in men, with a female-to-male ratio of 1.7:1. It has a prevalence of 3.9 million in women and 2.3 million in men. The frequency of atypical presentations is also more common among women compared with men. Women have a slightly higher rate of mortality from coronary artery disease compared with men, in part because of an older age at presentation and

a frequent lack of classic anginal symptoms. The estimated age-adjusted prevalence of angina is greater in women than in men.

Age: The prevalence of angina pectoris increases with age. Age is a strong independent risk factor for mortality.

CLINICAL

History: Most patients with angina pectoris report of retrosternal chest discomfort rather than frank pain. The former is usually described as a pressure, heaviness, squeezing, burning, or choking sensation. Anginal pain may be localized primarily in the epigastrium, back, neck, jaw, or shoulders. Typical locations for radiation of pain are arms, shoulders, and neck. Typically, angina is precipitated by exertion, eating, exposure to cold, or emotional stress. It lasts for approximately 1-5 minutes and is relieved by rest or nitroglycerin. Chest pain lasting only a few seconds is not usually angina pectoris. The intensity of angina does not change with respiration, cough, or change in position. Pain above the mandible and below the epigastrium is rarely anginal in nature.

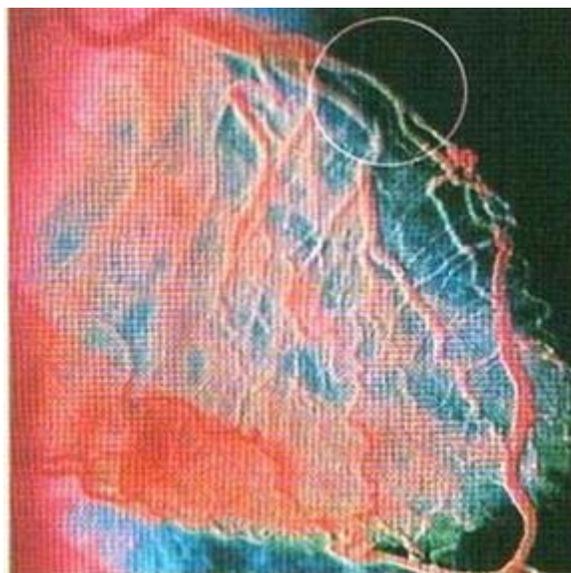

Fig.3 Coronarographia

Ask patients about the frequency of angina, severity of pain, and number of nitroglycerin pills used during angina episodes.

Angina decubitus is a variant of angina pectoris that occurs at night while the patient is recumbent. Some have suggested that it is induced by an increase in myocardial oxygen demand caused by expansion of the blood volume with increased venous return during recumbency.

The Canadian Cardiovascular Society grading scale is used for classification of angina severity, as follows:

Class I - Angina only during strenuous or prolonged physical activity

Class II - Slight limitation, with angina only during vigorous physical activity

Class III - Symptoms with everyday living activities, ie, moderate limitation

Class IV - Inability to perform any activity without angina or angina at rest, ie, severe limitation

The New York Heart Association classification is also used to quantify the functional limitation imposed by patients' symptoms, as follows:

Class I - No limitation of physical activity (Ordinary physical activity does not cause symptoms.)

Class II - Slight limitation of physical activity (Ordinary physical activity does cause symptoms.)

Class III - Moderate limitation of activity (Patient is comfortable at rest, but less than ordinary activities cause symptoms.)

Class IV - Unable to perform any physical activity without discomfort, therefore severe limitation (Patient may be symptomatic even at rest.)

Unstable angina is defined as new-onset angina (ie, within 2 mo of initial presentation) of at least class III severity, significant recent increase in frequency and severity of angina, or angina at rest.

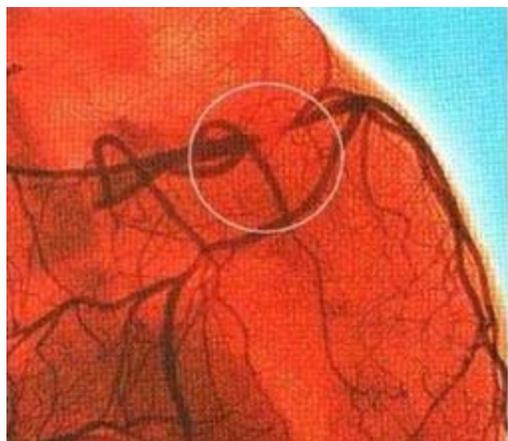

Fig. Angiography

Physical:

For most patients with stable angina, physical examination findings are normal. Diagnosing secondary causes of angina, such as aortic stenosis, is important.

A positive Levine sign (characterized by the patient's fist clenched over the sternum when describing the discomfort) is suggestive of angina pectoris.

Look for physical signs of abnormal lipid metabolism (eg, xanthelasma, xanthoma) or of diffuse atherosclerosis (eg, absence or diminished peripheral pulses, increased light reflexes or arteriovenous nicking upon ophthalmic examination, carotid bruit).

Examination of patients during the angina attack may be more helpful. Useful physical findings include third and/or fourth heart sounds due to LV systolic and/or diastolic dysfunction and mitral regurgitation secondary to papillary muscle dysfunction.

Pain produced by chest wall pressure is usually of chest wall origin.

Causes:

Decrease in myocardial blood supply due to increased coronary resistance in large and small coronary arteries

Significant coronary atherosclerotic lesion in the large epicardial coronary arteries (ie, conductive vessels) with at least a 50% reduction in arterial diameter

Coronary spasm (ie, Prinzmetal angina)

Abnormal constriction or deficient endothelial-dependent relaxation of resistant vessels associated with diffuse vascular disease (ie, microvascular angina)

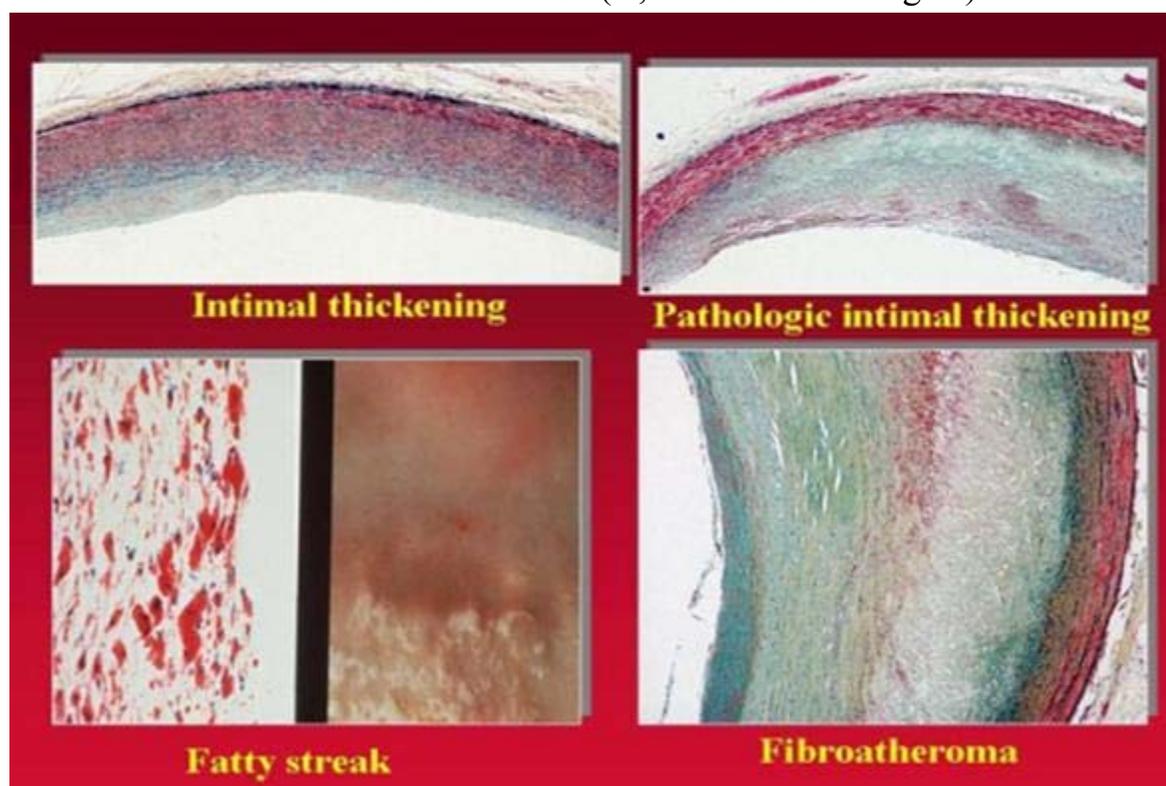

Fig. 4 Pathogenesis of atherosclerosis

Syndrome X

Systemic inflammatory or collagen vascular disease, such as scleroderma, systemic lupus erythematosus, Kawasaki disease, polyarteritis nodosa, and Takayasu arteritis

Increased extravascular forces, such as severe LV hypertrophy caused by hypertension, aortic stenosis, or hypertrophic cardiomyopathy, or increased LV diastolic pressures

Reduction in the oxygen-carrying capacity of blood, such as elevated carboxyhemoglobin or severe anemia (hemoglobin, <8 g/dL)

Congenital anomalies of the origin and/or course of the major epicardial coronary arteries

Structural abnormalities of the coronary arteries

Congenital coronary artery aneurysm or fistula

Coronary artery ectasia

Coronary artery fibrosis after chest radiation

Coronary intimal fibrosis following cardiac transplantation

Risk factors

Major risk factors for atherosclerosis: These include a family history of premature coronary artery disease, cigarette smoking, diabetes mellitus, hypercholesterolemia, or systemic hypertension.

Other risk factors: These include LV hypertrophy, obesity, and elevated serum levels of homocysteine, lipoprotein (a), plasminogen activator inhibitor, fibrinogen, serum triglycerides, or low high-density lipoprotein (HDL).

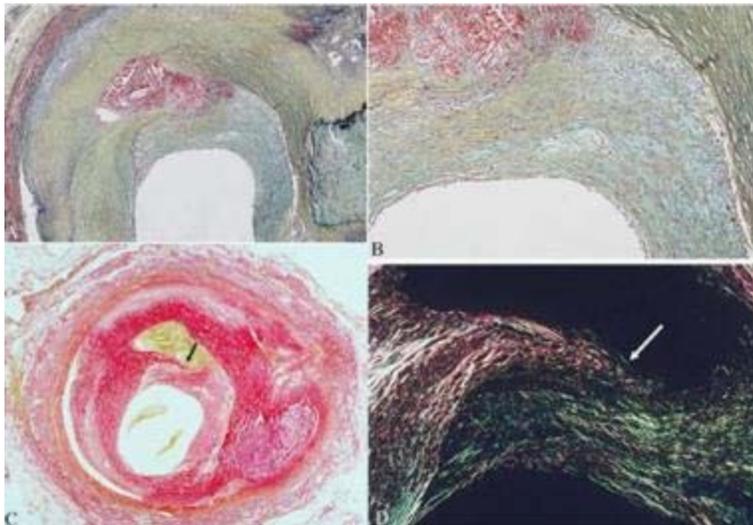

Fig. 5 Pathogenesis of atherosclerosis

Metabolic syndrome: This has recently been characterized by the presence of hyperinsulinemia (fasting glucose level, >110 mg/dL), abdominal obesity (waist circumference, >40 in for men or >35 in for women), decreased HDL cholesterol levels (<40 mg/dL for men or <50 mg/dL for women), hypertriglyceridemia (>150 mg/dL), and hypertension ($>130/85$ mm Hg). Based on data from the 2000 US census, an estimated 47 million Americans have the metabolic syndrome. Patients with the metabolic syndrome have a 3-fold increased risk for coronary atherosclerosis and stroke compared with those without this syndrome.

Precipitating factors: These include factors such as severe anemia, fever, tachyarrhythmias, catecholamines, emotional stress, and hyperthyroidism, which increase myocardial oxygen

demand.

Preventive factors: Factors associated with reduced risk of atherosclerosis are a high serum HDL cholesterol level, physical activity, estrogen, and moderate alcohol intake (1-2 drinks/d).

Imaging Studies:

Chest radiograph findings are usually normal in patients with angina pectoris. However, they may show cardiomegaly in patients with previous MI, ischemic cardiomyopathy, pericardial effusion, or acute pulmonary edema. Calcification of coronary arteries frequently correlates with major coronary artery disease.

Graded exercise stress testing is the most widely used test for the evaluation of patients presenting with chest pain. In patients with established stable angina pectoris, it also can provide prognostic information about the extent of disease.

Exercise stress testing can be performed alone and in conjunction with echocardiography or myocardial perfusion scintigraphy tests. Stress echocardiography has an overall sensitivity of 78% and specificity of 86%; myocardial perfusion scintigraphy has an overall sensitivity of 83% and specificity of 77%. Exercise stress testing alone generally has somewhat lower sensitivity and specificity, but it is cheaper and therefore is a reasonable choice in those with a low probability of disease.

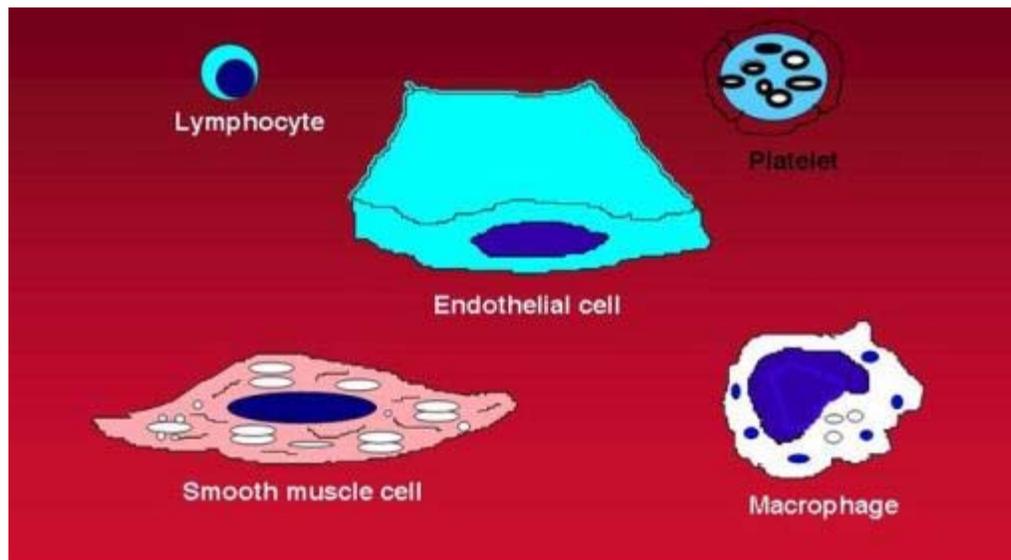

Fig. Cells which take part in atherosclerosis

These test results must be interpreted in the context of the likelihood of the presence of coronary artery disease determined from the patient's history and physical examination findings. In a population with low prevalence, the predictive abilities of these tests are low; however, in patients with a high likelihood of coronary artery disease, the predictive value is much higher.

Stress echocardiography can be used to evaluate segmental wall motion during exercise. It detects changes in regional wall motion that occur during myocardial ischemia. Normal myocardium becomes hyperdynamic during exercise; ischemic segments become hypokinetic or akinetic.

Stress echocardiography has the advantage of simultaneous evaluation of LV function, cardiac dimensions, and valvular disease. It is especially useful in patients with baseline ECG abnormalities and those with systolic murmurs suggestive of aortic stenosis or hypertrophic cardiomyopathy.

It is also helpful for localizing ischemia and evaluating its severity.

Signs of severe coronary artery disease during exercise stress echocardiography include LV dilation, a decrease in global systolic function, and new or worsening mitral regurgitation.

However, with dobutamine stress echocardiography, even in patients with severe coronary artery disease, the LV cavity may not dilate and global systolic function may improve.

A major problem with stress echocardiography is the technical difficulty with obtaining adequate images in some patients.

Thallium Tl 201 and technetium Tc 99m sestamibi are the most frequently used myocardial

perfusion scintigraphy tests. These tests are especially useful in patients with baseline ECG abnormalities, to localize the region of ischemia, and as prognostic indicators. The presence of increased lung uptake upon thallium imaging is associated with a poor prognosis. Increased lung uptake, together with poststress dilation of the LV and multiple perfusion defects, is suggestive of either left main coronary artery disease or severe 3-vessel disease. The number of affected myocardial segments is predictive of long-term survival. Smaller perfusion defects are usually associated with peripheral coronary artery lesions, which are associated with a better prognosis. The absence of perfusion defects even in the presence of symptoms indicates an excellent prognosis.

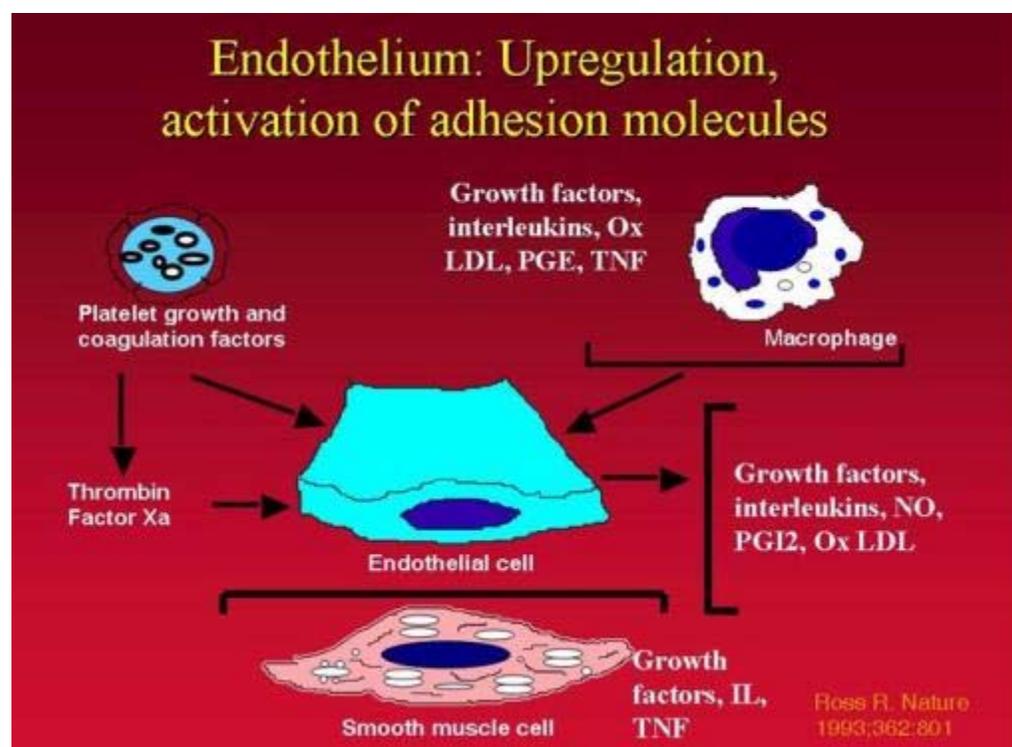

Fig. 9 Pathogenesis of atherosclerosis

The frequency of infarction or death is 1 case per 10,000 stress tests. Absolute contraindications include symptomatic cardiac arrhythmias, severe aortic stenosis, acute MI within the previous 2 days, acute myocarditis, or pericarditis. Discontinue the exercise stress test in the presence of chest pain, a drop in systolic blood pressure of more than 10 mm Hg, severe shortness of breath, fatigue, dizziness or near syncope, ST depression of more than 2 mm, ST elevation of at least 1 mm without diagnostic Q waves, or development of ventricular tachyarrhythmia.

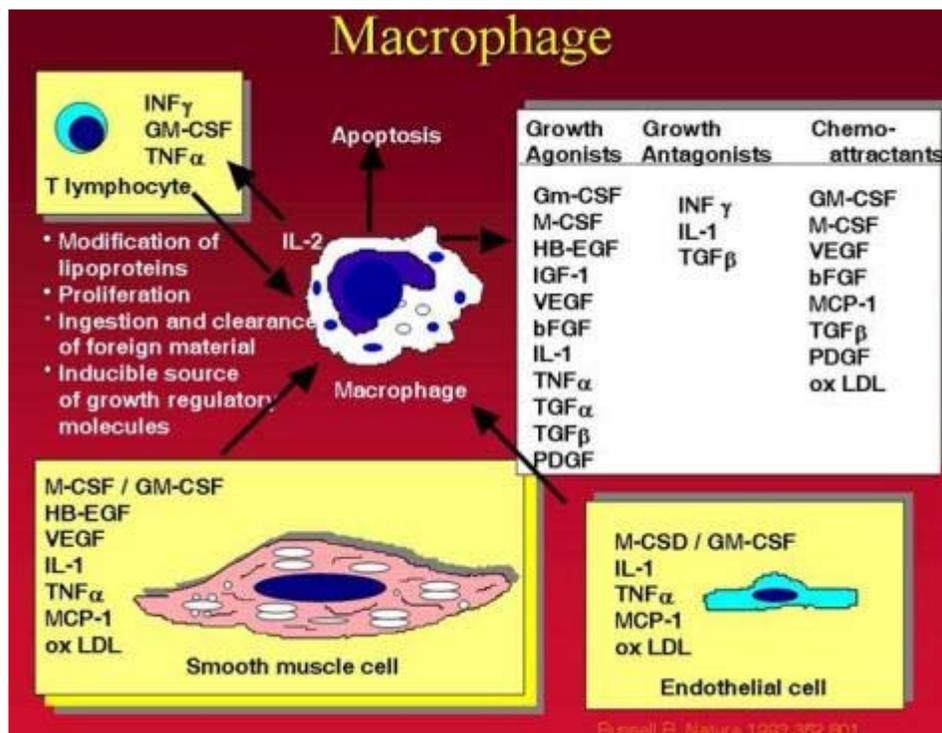

Fig. 10 Pathogenesis of atherosclerosis

Other Tests:

ECG is useful for evaluating persons with angina pectoris; however, findings are variable among patients.

Approximately 50% of patients with angina pectoris have normal findings after a resting ECG. However, abnormalities such as evidence for prior MI, intraventricular conduction delay, various degrees of atrioventricular block, arrhythmias, or ST-T-wave changes may be seen. During an attack of angina pectoris, 50% of patients with normal findings after resting ECG show abnormalities. A 1-mm or greater depression of the ST segment below the baseline, measured 80 milliseconds from the J point, is the most characteristic change. Reversible ST-segment elevation occurs with Prinzmetal angina. Some patients with coronary artery disease may show pseudonormalization of the resting ECG ST-T-wave abnormalities during episodes of chest pain.

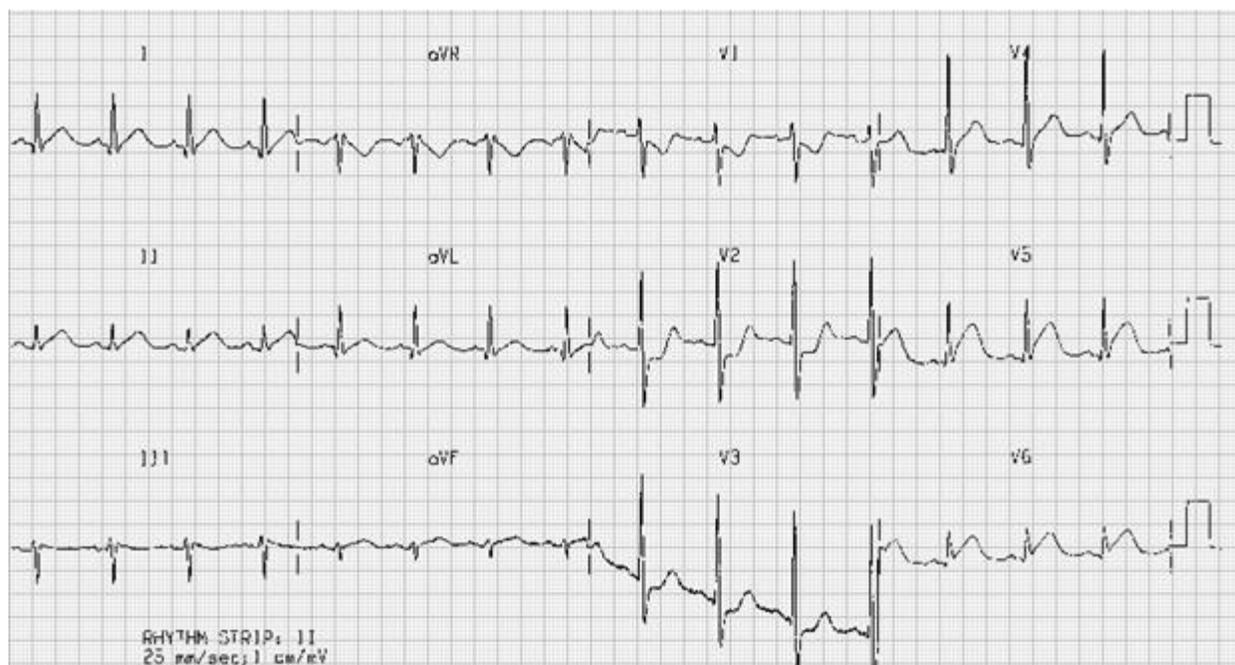

Fig 11. Subendocardial ischemia

Exercise with ECG monitoring alone is the initial procedure of choice in patients without baseline ST-segment abnormalities or in whom anatomic localization of ischemia is not a consideration.

Horizontal or down-sloping ST-segment depression of at least 1 mm, measured 80 milliseconds from the J point, is considered the characteristic ischemic response.

ST-segment depression of more than 2 mm at a low workload or that persists for more than 5 minutes after termination of exercise and a failure of blood pressure to rise or an actual drop in blood pressure are signs of severe ischemic heart disease and a poor prognosis.

Withhold beta-blockers for approximately 48 hours before the stress test, whenever possible. Patients on digoxin and those with LV hypertrophy with repolarization abnormalities more often show positive results. Exercise stress tests have lower sensitivity and specificity in women and in patients with left bundle-branch block.

Pharmacologic agents (eg, dobutamine, dipyridamole, adenosine) can be used in patients who are unable to exercise.

Ambulatory ECG monitoring can be used for diagnostic purposes in patients with chest pain suggestive of Prinzmetal angina but is primarily used to evaluate the frequency of silent ischemia. Silent ischemia has been shown to be an independent predictor of mortality in patients with angina pectoris.

Several studies have shown that calcium in the coronary arteries as detected by electron-beam computed tomography is an important indicator of coronary artery stenosis. In these studies,

the sensitivity of a positive electron-beam computed tomography scan ranged from 85-100% and the specificity varied from 41-76%, while the positive predictive value varied from 55-84% and the negative predictive value varied from 84-100%. However, several studies have shown inconsistent reproducibility in repeated measures of coronary calcium with electron-beam computed tomography. Thus, its proper role at this time remains controversial.

Procedures:

Selective coronary angiography is the definitive diagnostic test for evaluating the anatomic extent and severity of coronary artery disease.

Consider coronary angiography in symptomatic patients with inconclusive noninvasive study results, in survivors of sudden cardiac death, in those who are considered to have a poor prognosis based on the results of noninvasive studies, in those with occupational requirements for a definite diagnosis (eg, pilots), or in patients with coronary artery disease who are severely symptomatic despite maximal medical therapy.

In patients in whom Prinzmetal angina is suggested, provocative testing with ergonovine maleate during coronary angiography may be useful.

Intra-aortic balloon counterpulsation can be used in patients who continue to have unstable angina pectoris despite maximal medical treatment. This procedure should be followed promptly by coronary angiography with possible coronary revascularization.

In patients whose angina is refractory to medical therapy who are not suitable candidates for either percutaneous or surgical revascularization, enhanced external counterpulsation is a safe and noninvasive alternative therapy. It increases coronary perfusion and reduces myocardial oxygen demand by diastolic augmentation of the central aortic pressure. Several studies have shown that patients treated with enhanced external counterpulsation have a significantly reduced number of anginal episodes, improved exercise tolerance, and decreased daily use of nitroglycerin tablets. Its therapeutic effects on quality of life are noted to remain at 1-year follow-up.

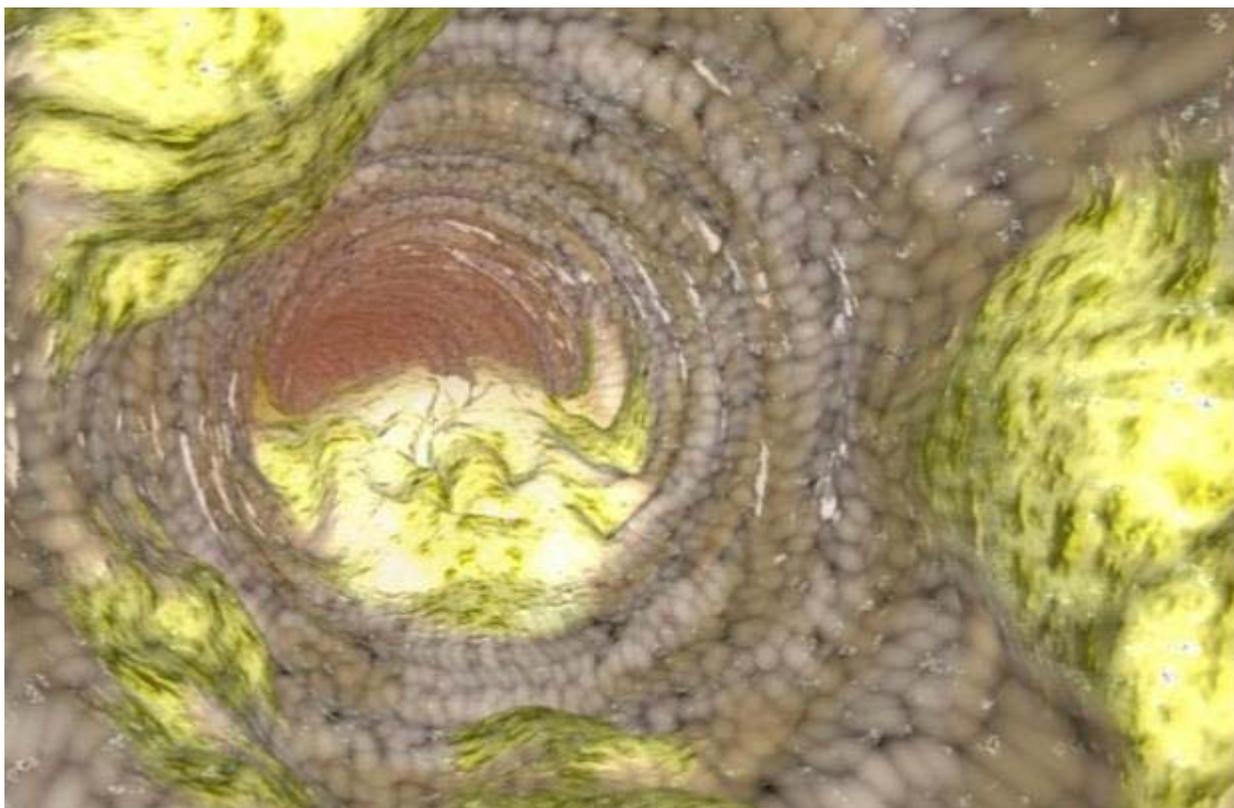

Fig. Vessels atherosclerosis

TREATMENT

Medical Care: The main goals of treatment in angina pectoris are to relieve the symptoms, slow the progression of disease, and reduce the possibility of future events, especially MI and premature death.

General measures

Smoking cessation results in a significant reduction of acute adverse effects on the heart and may reverse, or at least slow, atherosclerosis. Strongly encourage patients to quit smoking, and take an active role in helping them to achieve this goal.

Treat risk factors, including hypertension, diabetes mellitus, obesity, and hyperlipidemia.

Several clinical trials have shown that in patients with established coronary artery disease, reduction of low-density lipoprotein (LDL) level with a beta-hydroxy-beta-methylglutaryl coenzyme A reductase inhibitor (ie, statin) is associated with significant reductions in both mortality rate and major cardiac events.

These benefits are present even in patients with mild-to-moderate elevations of LDL cholesterol level.

Recent trials with cholesterol-lowering agents have confirmed the benefits of the therapeutic LDL lowering in older persons.

Angiographic studies demonstrate that a reduction of the LDL level in patients with coronary artery disease could cause slowing of progression, stabilization, or even regression of coronary artery lesions.

A recent study demonstrates a significant reduction of symptomatic myocardial ischemia in patients with unstable angina or non-Q-wave infarction with the administration of a statin during the early acute phase.

In a more recent study of 10,001 patients with stable coronary artery disease, an aggressive cholesterol-lowering approach with atorvastatin 80 mg daily (mean cholesterol level of 77 mg/dL) compared to a less-aggressive approach with atorvastatin 10 mg daily (mean cholesterol level of 101 mg/dL) resulted in a 2.2% absolute reduction and a 22% relative reduction in the occurrence of a first major cardiovascular event (defined as death from coronary heart disease; nonfatal, non-procedure-related myocardial infarction; resuscitation from cardiac arrest; or fatal or nonfatal stroke). This occurred with a greater incidence of elevated aminotransferase levels with the aggressive cholesterol-lowering approach (1.2% vs 0.2%, $p < 0.001$).

On the basis of several recent studies that have demonstrated the benefits of more aggressive LDL-lowering therapies in high-risk patients with coronary artery disease, the Committee of the National Cholesterol Education Program recently made the following modifications to the Adult Treatment Panel III (ATP III) guidelines.

In high-risk patients, a serum LDL cholesterol level of less than 100 mg/dL is the goal.

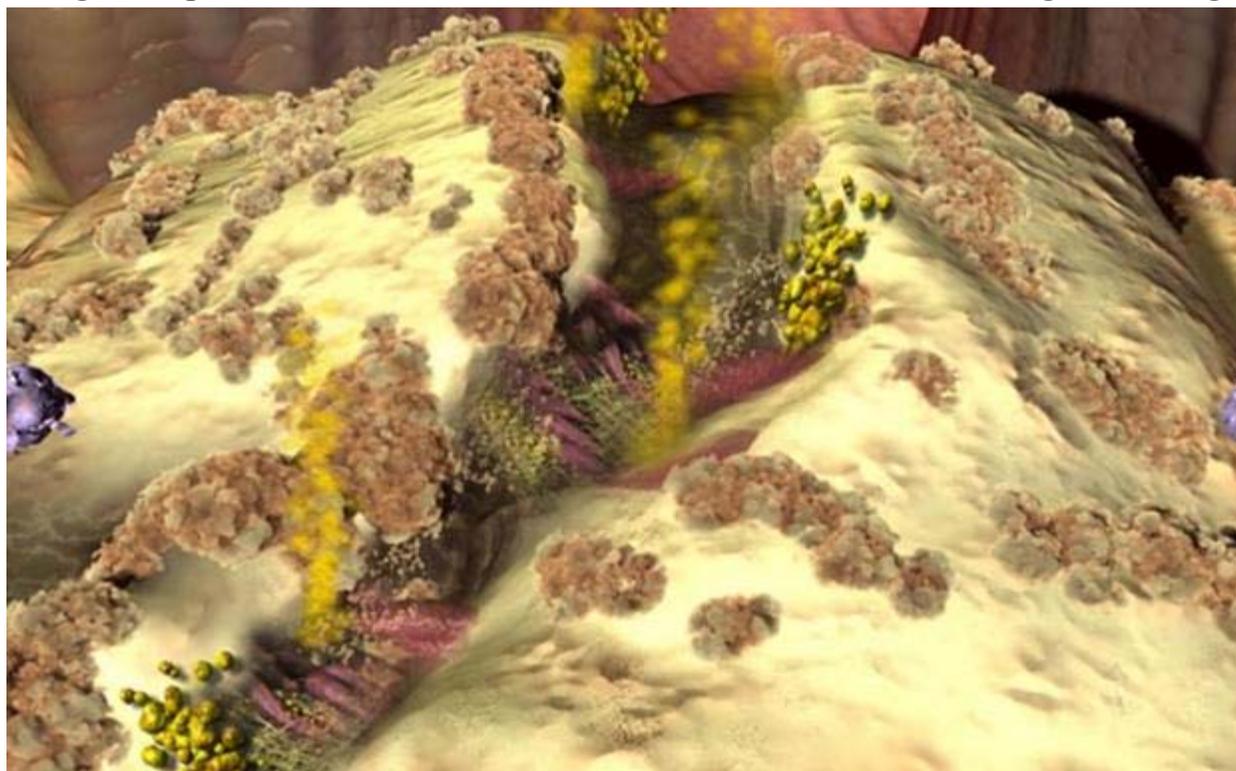

Fig. Vessels atherosclerosis

In very high-risk patients, an LDL cholesterol level goal of less than 70 mg/dL is a therapeutic option. Patients in the category of very high risk are those with established coronary artery disease with one of the following: multiple major risk factors (especially diabetes), severe and poorly controlled risk factors (especially continued cigarette smoking), multiple risk factors of the metabolic syndrome (especially high triglyceride levels [>200 mg/dL] plus non-HDL cholesterol level [>130 mg/dL] with low HDL cholesterol level [<40 mg/dL]), and patients with acute coronary syndromes.

For moderately high-risk persons (2+ risk factors), the recommended LDL cholesterol level is less than 130 mg/dL, but an LDL cholesterol level of 100 mg/dL is a therapeutic option.

Some triglyceride-rich lipoproteins, including partially degraded very LDL levels, are believed to be independent risk factors for coronary artery disease. In daily practice, non-HDL cholesterol level (ie, LDL + very LDL cholesterol [total cholesterol - HDL cholesterol]) is the most readily available measure of the total pool of these atherogenic lipoproteins. Thus, the ATP III has identified non-HDL cholesterol level as a secondary target of therapy in persons with high triglyceride levels (>200 mg/dL). The goal for non-HDL cholesterol level (for persons with serum triglyceride levels >200 mg/dL) is 30 mg/dL higher than the identified LDL cholesterol level goal.

Patients with established coronary disease and low HDL cholesterol levels are at high risk for recurrent events and should be targeted for aggressive nonpharmacological (ie, dietary modification, weight loss, physical exercise) and pharmacological treatment.

A recent study demonstrated that in patients with established coronary artery disease who have low HDL and low-risk LDL levels, drug therapy with medications that raise HDL cholesterol levels and lower triglyceride levels but have no effect on LDL cholesterol levels (eg, gemfibrozil) could significantly reduce the risk of major cardiac events.

Currently, the accepted approach to the management of patients with coronary artery disease and low HDL levels is as follows:

In all persons with low HDL cholesterol levels, the primary target of therapy is to achieve the ATP III guideline LDL cholesterol level goals with diet, exercise, and drug therapy as needed. After reaching the targeted LDL level goal, emphasis shifts to other issues. That is, in patients with low HDL cholesterol levels who have associated high triglyceride levels (>200 mg/dL), the secondary priority is to achieve the non-HDL cholesterol level goal of 30 mg/dL higher than the identified LDL cholesterol level goal. In patients with isolated low HDL cholesterol levels (triglycerides <200 mg/dL), drugs to raise the HDL cholesterol level (eg, gemfibrozil,

nicotinic acid) can be considered.

Exercise training results in improvement of symptoms, increase in the threshold of ischemia, and improvement of patients' sense of well-being. However, before enrolling a patient in an exercise-training program, perform an exercise tolerance test to establish the safety of such a program.

Consider enteric-coated aspirin at a dose of 80-325 mg/d for all patients with stable angina who have no contraindications to its use. In patients in whom aspirin cannot be used because of allergy or gastrointestinal complications, consider clopidogrel.

Although early observational studies suggested a cardiovascular protective effect with the use of hormone replacement therapy, recent large randomized trials failed to demonstrate any benefit with hormone replacement therapy in the primary or secondary prevention of cardiovascular disease.

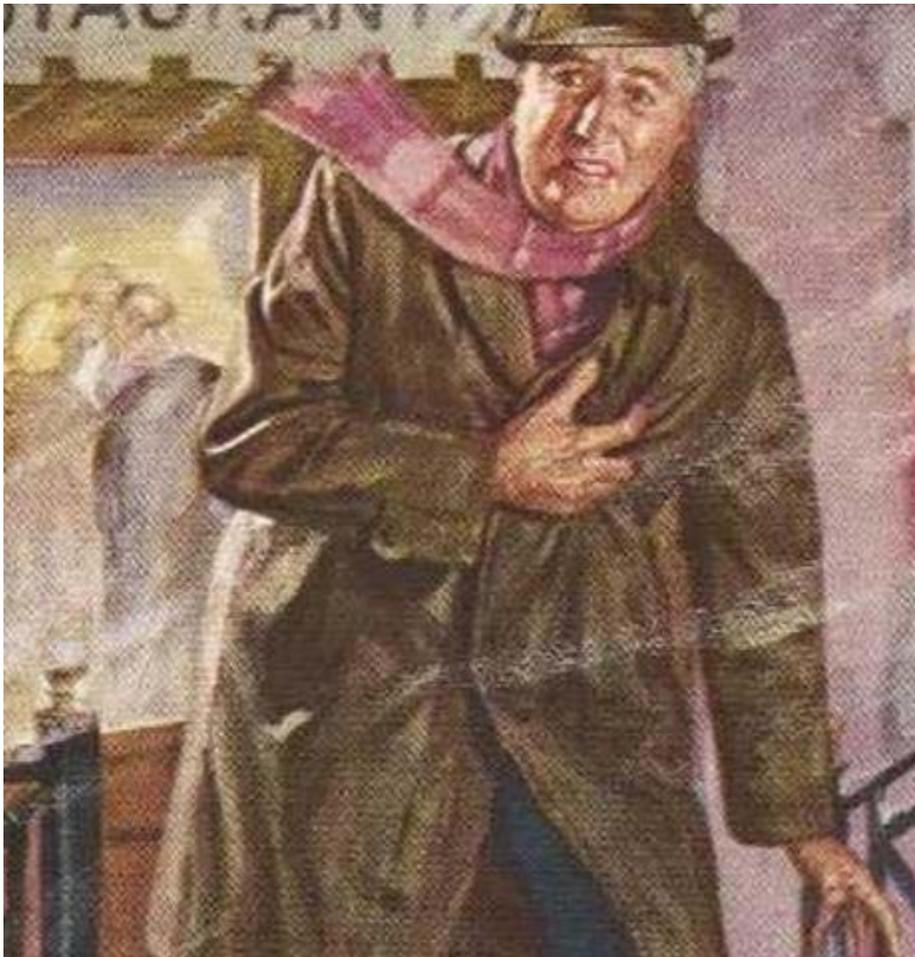

Fig. Patient with IHD

In fact, these studies even demonstrated an increased risk of coronary artery disease and stroke in patients on hormone replacement therapy.

The Women's Health Initiative study demonstrated that the use of hormone replacement therapy

for 1 year in 10,000 healthy postmenopausal women is associated with 7 more instances of coronary artery disease, 8 more strokes, 8 more pulmonary emboli, 8 more invasive breast cancers, 5 fewer hip fractures, and 6 fewer colorectal cancers.

Based on these data, the risks and benefits of hormone replacement therapy must be assessed on an individual basis for each patient.

Sublingual nitroglycerin has been the mainstay of treatment for angina pectoris. Sublingual nitroglycerin can be used for acute relief of angina and prophylactically before activities that may precipitate angina. No evidence indicates that long-acting nitrates improve survival in patients with coronary artery disease.

Beta-blockers are also used for symptomatic relief of angina and prevention of ischemic events. They work by reducing myocardial oxygen demand and by decreasing the heart rate and myocardial contractility. Beta-blockers have been shown to reduce the rates of mortality and morbidity following acute MI.

Long-acting heart rate–slowing calcium channel blockers can be used to control anginal symptoms in patients with a contraindication to beta-blockers and in those in whom symptomatic relief of angina cannot be achieved with the use of beta-blockers, nitrates, or both. Avoid short-acting dihydropyridine calcium channel blockers because they have been shown to increase the risk of adverse cardiac events.

Anginal symptoms in patients with Prinzmetal angina can be treated with calcium channel blockers with or without nitrates. In one study, supplemental vitamin E added to a calcium channel blocker significantly reduced anginal symptoms among such patients.

In patients with syndrome X and hypertension, ACE inhibitors may normalize thallium perfusion defects and increase exercise capacity.

Surgical Care:

Revascularization therapy (ie, coronary revascularization) can be considered in patients with left main artery stenosis greater than 50%, 2- or 3-vessel disease and LV dysfunction (ejection fraction, <45%), poor prognostic signs during noninvasive studies, or severe symptoms despite maximum medical therapy. The 2 main coronary revascularization procedures are percutaneous transluminal coronary angioplasty, with or without coronary stenting, and coronary artery bypass grafting.

Patients with 1- or 2-vessel disease and normal LV function who have anatomically suitable lesions are candidates for percutaneous transluminal coronary angioplasty and coronary stenting. Restenosis is the major complication, with symptomatic restenosis occurring in 20-25% of patients. Restenosis mostly occurs during the first 6 months after the procedure and

can be managed by repeat angioplasty. Several recent trials have demonstrated that the use of drug-eluting stents (eg, sirolimus-eluting stents, paclitaxel-coated stents) can remarkably reduce the rate of in-stent restenosis. Recently, with the introduction of these drug-coated stents, patients with multivessel coronary artery disease are more frequently treated with percutaneous revascularization as opposed to the surgical revascularization.

Patients with single-vessel disease and normal ventricular function treated with percutaneous transluminal coronary angioplasty show improved exercise tolerance and fewer episodes of angina compared with those who receive medical treatment. However, no difference in the frequency of MI or death has been shown between these two groups.

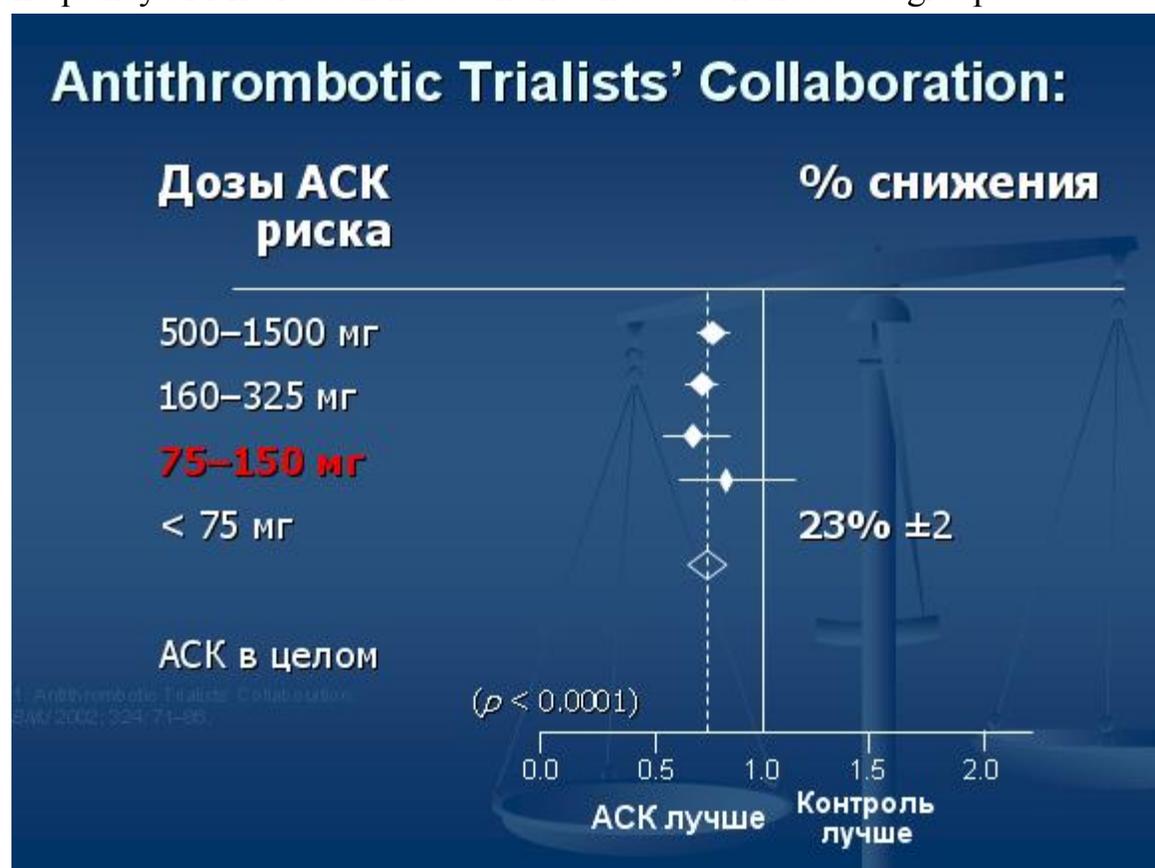

Fig. Pathogenesis of atherosclerosis

Patients with significant left main coronary artery disease, 2- or 3-vessel disease and LV dysfunction, diabetes mellitus, or lesions anatomically unsuitable for percutaneous transluminal coronary angioplasty have better results with coronary artery bypass grafting. The overall operative mortality rate for coronary artery bypass grafting is approximately 1.3%. The rate of graft patency 10 years after surgery is less than 50% for vein grafting, although more than 90% of grafts using internal mammary arteries are patent at 10 years. In recent years, interest has increased regarding surgery without cardiopulmonary bypass (ie, off-pump) in an attempt to avoid the morbidity associated with cardiopulmonary bypass. A recent randomized

study demonstrated that off-pump coronary surgery was as safe as on-pump surgery and caused less myocardial damage. However, the graft-patency rate was lower at 3 months in the off-pump group than in the on-pump group.

Recently, laser transmyocardial revascularization has been used as an experimental therapy for the treatment of severe, chronic, stable angina refractory to medical or other therapies. This technique has been performed with either an epicardial surgical technique or by a percutaneous approach. In both approaches, a series of transmural endomyocardial channels are created to improve myocardial perfusion. The surgical transmyocardial revascularization technique has been associated with symptomatic relief for end-stage chronic angina in the short term. However, no published data address the long-term efficacy of surgical transmyocardial revascularization. Nonetheless, this technique appears to provide at least symptomatic relief for end-stage chronic angina in the short term.

Diet: A diet low in saturated fat and dietary cholesterol is the mainstay of the Step I and Step II diet from the American Heart Association.

Activity: The level of activity that aggravates anginal symptoms is different for each patient. However, most patients with stable angina can avoid symptoms during daily activities simply by reducing the speed of activity.

MEDICATION

The goals of pharmacotherapy are to reduce morbidity and to prevent complications.

Drug Category: *Antiplatelet agents* -- Prevent thrombus formation by inhibiting platelet aggregation. Aspirin is proven beneficial in primary and secondary prevention of coronary artery disease. In patients with aspirin intolerance, use clopidogrel. Clopidogrel is also used in combination with aspirin after coronary stent placement. Recently, clopidogrel use in addition to aspirin has been shown to be significantly superior to aspirin alone in patients with acute coronary syndrome without ST-segment elevation MI.

Drug Name	Aspirin (Bayer, Empirin, Anacin) -- Prevents platelet aggregation by irreversible cyclooxygenase inhibition with subsequent suppression of thromboxane A ₂ . Antiplatelet effect can last as long as 7 d.
------------------	--

Adult Dose	81-325 mg PO qd
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; liver damage; hypoprothrombinemia; vitamin K deficiency; bleeding disorders; asthma Because of association with Reye syndrome, do not use in children (<16 y) with flu
Interactions	Antacids and urinary alkalinizers may decrease effects; corticosteroids decrease salicylate serum levels; anticoagulants may cause additive hypoprothrombinemic effects and increased bleeding time; may antagonize uricosuric effects of probenecid and increase toxicity of phenytoin and valproic acid; doses >2 g/d may potentiate glucose-lowering effect of sulfonylurea drugs
Pregnancy	D - Unsafe in pregnancy
Precautions	May cause transient decrease in renal function and aggravate chronic kidney disease; avoid use in patients with severe anemia, history of blood coagulation defects, or taking anticoagulants; adverse effects include prolonged bleeding time, rhinitis, asthma, urticaria, and exacerbation of gout; monitor BP, BUN, and uric acid level; consider discontinuing 7 d before surgery
Drug Name	Clopidogrel (Plavix) -- Selectively inhibits ADP binding to platelet receptor and subsequent ADP-mediated activation of

	GPIIb/IIIa complex, thereby inhibiting platelet aggregation. Consider in patients with contraindication to aspirin.
Adult Dose	75 mg PO qd
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; active pathological bleeding
Interactions	Naproxen associated with increased occult GI blood loss; prolongs bleeding time; safety of coadministration with warfarin not established
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Caution in patients at increased risk of bleeding from trauma, surgery, or other pathological conditions; caution in patients with lesions with propensity to bleed (eg, ulcers); adverse effects include rash, diarrhea, purpura, GI ulcers, neutropenia, and rare cases of agranulocytosis; consider discontinuing 7 d before surgery

Drug Category: *Beta-adrenergic blocking agents* -- Work by competing with endogenous catecholamines for beta-adrenergic receptors. Reduce myocardial oxygen consumption via several effects, including decrease in resting and exercise heart rates and reductions in myocardial contractility and afterload. Classified as nonselective, beta-1 selective, and having intrinsic sympathomimetic effects.

Drug Name	Metoprolol (Lopressor, Toprol XL) -- Selective beta1-adrenergic receptor
------------------	---

	blocker that decreases automaticity of contractions. Is lipophilic and penetrates CNS.
Adult Dose	50-200 mg PO bid
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; uncompensated CHF; bradycardia; asthma; cardiogenic shock; AV conduction abnormalities
Interactions	Aluminum salts, barbiturates, NSAIDs, penicillins, calcium salts, cholestyramine, and rifampin may decrease bioavailability and plasma levels, possibly resulting in decreased pharmacologic effects; sparfloxacin, phenothiazines, astemizole, calcium channel blockers, quinidine, flecainide, and contraceptives may increase toxicity; may increase toxicity of digoxin, flecainide, clonidine, epinephrine, nifedipine, prazosin, verapamil, and lidocaine
Pregnancy	B - Usually safe but benefits must outweigh the risks.
Precautions	Beta-adrenergic blockade may mask signs and symptoms of acute hypoglycemia and may decrease clinical signs of hyperthyroidism; abrupt withdrawal may exacerbate symptoms of hyperthyroidism, including thyroid storm; monitor patient closely and withdraw drug slowly; during IV administration, carefully monitor BP, heart rate, and ECG; adverse effects include

	hypotension, decreased libido, impotence, lethargy, depression, and decreased HDL; may cause less bronchial tree and arterial smooth muscle constriction
Drug Name	Atenolol (Tenormin) -- Selectively blocks beta-1 receptors with little or no effect on beta-2 receptors. Is hydrophilic and does not penetrate CNS.
Adult Dose	50-200 mg PO qd
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; CHF; pulmonary edema; cardiogenic shock; AV conduction abnormalities; heart block (without pacemaker)
Interactions	Aluminum salts, barbiturates, calcium salts, cholestyramine, NSAIDs, penicillins, and rifampin may decrease effects; haloperidol, hydralazine, loop diuretics, and MAOIs may increase toxicity
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Beta-adrenergic blockade may hide symptoms of acute hypoglycemia and mask signs of hyperthyroidism; abrupt withdrawal may exacerbate symptoms of hyperthyroidism and cause thyroid storm; monitor patients closely and withdraw drug slowly; adverse effects include bradycardia, hypotension, decreased libido, impotence, and decreased HDL; beta1-selective blockers may cause less bronchial tree and arterial smooth muscle constriction; titrate

	dose carefully to level of patient tolerance and effectiveness
Drug Name	Propranolol (Inderal) -- Nonselective beta-blocker that is lipophilic (penetrates CNS). Although generally short-acting agent, long-acting preparations also available.
Adult Dose	IR: 40-160 mg PO bid SR: 60-320 mg PO qd
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; history of bronchospasm; uncompensated CHF; bradycardia; cardiogenic shock; AV conduction abnormalities
Interactions	Aluminum salts, barbiturates, NSAIDs, penicillins, calcium salts, cholestyramine, and rifampin may decrease effects; calcium channel blockers, cimetidine, loop diuretics, and MAOIs may increase toxicity; may increase toxicity of hydralazine, haloperidol, benzodiazepines, and phenothiazines
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Beta-adrenergic blockade may mask signs of acute hypoglycemia and hyperthyroidism; abrupt withdrawal may exacerbate symptoms of hyperthyroidism, including thyroid storm; withdraw drug slowly and monitor closely; adverse effects include bronchial constriction, Raynaud phenomenon, hypotension, decreased

	libido, impotence, lethargy, depression, and decreased HDL; caution in Wolff-Parkinson-White syndrome and renal or hepatic dysfunction
--	--

Drug Category: *Calcium channel blockers* -- Reduce transmembrane flux of calcium via calcium channels. Cause smooth muscle relaxation, resulting in peripheral arterial vasodilation and afterload reduction. Indicated when symptoms persist despite treatment with beta-blockers or when beta-blockers are contraindicated. Also indicated in patients with Prinzmetal angina with or without nitrates.

Drug Name	Amlodipine (Norvasc) -- During depolarization, inhibits calcium ions from entering slow channels and voltage-sensitive areas of vascular smooth muscle and myocardium.
Adult Dose	5-10 mg PO qd
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; severe CHF; sick sinus syndrome; second- or third-degree AV block; hypotension (<90 mm Hg systolic)
Interactions	Fentanyl may increase hypotensive effects; may increase cyclosporine levels; H2 blockers (eg, cimetidine) may increase toxic effects
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Severe aortic stenosis, CHF, hepatic dysfunction; adverse effects include headache, edema, flushing, palpitation, drowsiness, and fatigue

Drug Name	Diltiazem (Cardizem CD, Dilacor) -- During depolarization, inhibits calcium ions from entering slow channels and voltage-sensitive areas of vascular smooth muscle and myocardium.
Adult Dose	IR: 120-360 mg PO divided tid/qid SR: 120-480 mg PO qd
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; severe CHF; sick sinus syndrome; second- or third-degree AV block; hypotension (<90 mm Hg systolic)
Interactions	May increase carbamazepine, digoxin, cyclosporine, and theophylline levels; when administered with amiodarone, may cause bradycardia and decrease in cardiac output; when given with beta-blockers may increase cardiac depression; cimetidine may increase levels
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Caution in impaired renal or hepatic function; may increase LFT levels, and hepatic injury may occur; adverse effects include constipation, AV conduction block, worsening of heart failure, peripheral edema, bradycardia, and AV dissociation
Drug Name	Verapamil (Calan, Covera) -- During depolarization, inhibits calcium ion from entering slow channels or voltage-sensitive areas of vascular smooth muscle and myocardium.

Adult Dose	IR: 80-120 mg PO tid/qid SR: 120-240 mg PO qd/bid
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; severe CHF; sick sinus syndrome; second- or third-degree AV block; hypotension (<90 mm Hg systolic)
Interactions	May increase carbamazepine, digoxin, theophylline, and cyclosporine levels; amiodarone can cause bradycardia and decrease in cardiac output; when administered concurrently with beta-blockers may increase cardiac depression; cimetidine may increase levels
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Hepatocellular injury may occur; transient elevations of transaminases with and without concomitant elevations in alkaline phosphatase and bilirubin have occurred (elevations have been transient and may disappear with continued treatment); monitor liver function periodically; adverse effects include constipation, AV dissociation, worsening heart failure, bradycardia, negative inotropism, and hypotension

Drug Category: *Short-acting nitroglycerins* -- Suitable for immediate relief of exertional or rest angina. Can also be used for prophylaxis several minutes before planned exercise to avoid angina. Reduce myocardial oxygen demand by reduction of LV and arterial pressure, primarily by reducing preload.

Drug Name	Nitroglycerin (Nitrostat, Nitro-bid, Nitrol) -- Causes relaxation of vascular smooth muscle by stimulating intracellular cyclic GMP production. Result is decrease in BP.
Adult Dose	0.3-0.6 mg SL prn 0.4 mg metered-dose spray PO prn 0.1-0.8 mg/h patch TD qd
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; severe anemia; shock; postural hypotension; head trauma; closed-angle glaucoma; cerebral hemorrhage; hypertrophic obstructive cardiomyopathy
Interactions	Concurrent sildenafil (Viagra) may cause severe hypotension and death; aspirin may increase serum concentrations; calcium channel blockers may cause markedly symptomatic orthostatic hypotension (dose adjustment of either agent may be necessary)
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Caution in coronary artery disease and low systolic BP; adverse effects include hypotension, flushing, headache, light-headedness, and tolerance (8- to 12-h nitrate-free interval is most effective method to prevent development of tolerance); high IV doses may cause methemoglobinemia, heparin resistance, and ethanol intoxication; ischemia may worsen upon withdrawal

Drug Category: *Long-acting nitroglycerins* -- Reduce LV preload and afterload by venous and arterial dilation, which subsequently reduces myocardial oxygen consumption and relieves angina. Also cause dilation of epicardial coronary arteries, which is beneficial in patients with coronary spasm. In addition, nitroglycerin has antithrombotic and antiplatelet effects in patients with angina pectoris. No evidence suggests that nitrates improve survival or slow progression of coronary artery disease.

Drug Name	Isosorbide (Isordil, ISMO) -- Relaxes vascular smooth muscle by stimulating intracellular cyclic GMP. Decreases LV pressure (ie, preload) and arterial resistance (ie, afterload). Reduces cardiac oxygen demand by decreasing LV pressure and dilating arteries.
Adult Dose	Isosorbide dinitrate: 2.5-10 mg SL prn IR 10-30 mg PO bid/tid SR 80-120 mg PO qd IR Isosorbide mononitrate: 10-20 mg PO bid SR 30-120 mg PO qd
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; severe anemia; closed-angle glaucoma; postural hypotension; head trauma; cerebral hemorrhage
Interactions	Alcohol may cause severe hypotension and cardiovascular collapse; aspirin may increase serum concentrations and actions; calcium channel blockers may increase symptomatic orthostatic

	hypotension (adjust dose of either agent); may decrease effects of heparin
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Tolerance to vascular and antianginal effects of nitrates may develop; minimize tolerance by using smallest effective dose or pulse therapy (intermittent dosing) or by alternating with other coronary vasodilators (take last daily dose of short-acting agent no later than 7 pm); caution when administering to patients with glaucoma

Drug Category: *Angiotensin-converting enzyme inhibitors* -- Recently shown to reduce rates of death, MI, stroke, and need for revascularization procedures in patients with coronary artery disease or diabetes mellitus and at least one other cardiovascular risk factor, irrespective of the presence of hypertension or heart failure.

Drug Name	Ramipril (Altace) -- Prevents conversion of angiotensin I to angiotensin II, a potent vasoconstrictor, resulting in lower aldosterone secretion.
Adult Dose	2.5-5 mg PO qd; not to exceed 20 mg/d
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; history of angioedema
Interactions	May increase digoxin, lithium, and allopurinol levels; probenecid may increase levels; coadministration with diuretics increases hypotensive effects; NSAIDs may reduce hypotensive effects
Pregnancy	C - Safety for use during pregnancy has not been established.

<p>Precautions</p>	<p>Category D in second and third trimesters of pregnancy; adverse effects include persistent cough, angioedema, hypotension, and prerenal azotemia; caution in renal impairment, valvular stenosis, or severe CHF</p>
---------------------------	--

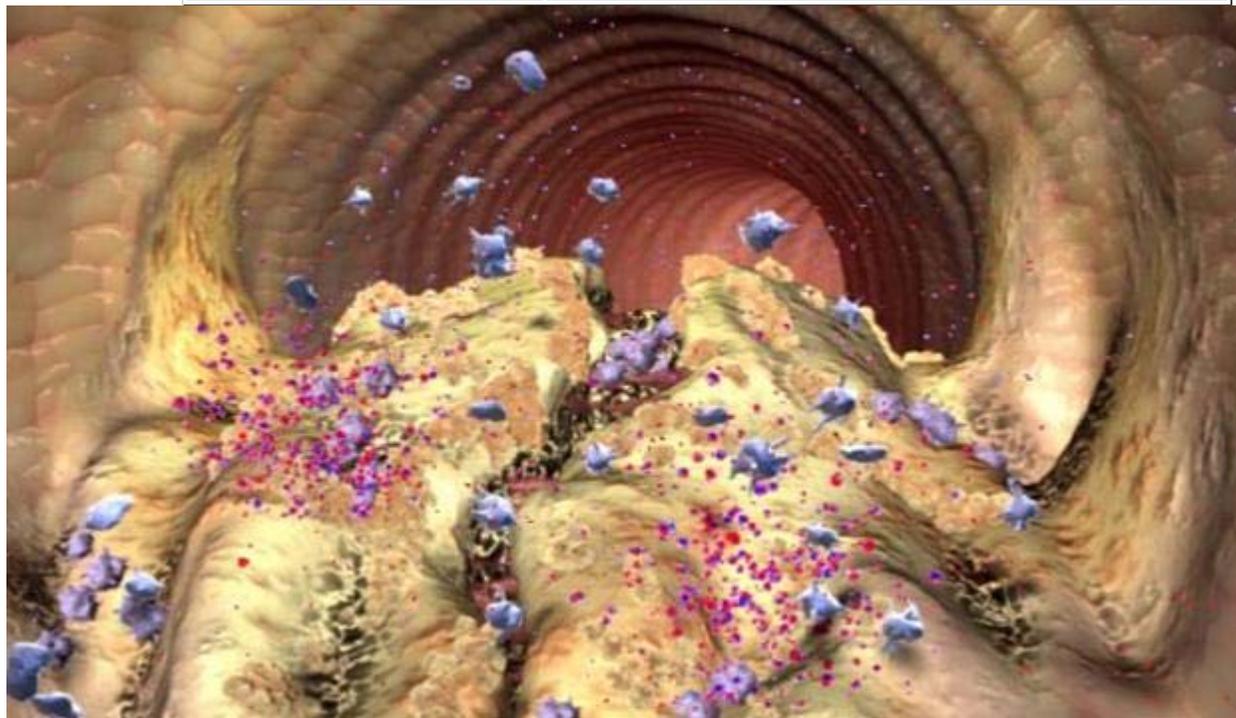

Fig Thrombosis of coronary artery

Drug Category: *Anti-ischemic agents, miscellaneous* -- Ranolazine elicits action unlike beta-blockers, calcium antagonists, or nitrates. It does not affect hemodynamics or contractile and conduction parameters.

<p>Drug Name</p>	<p>Ranolazine (Ranexa) -- Cardioselective anti-ischemic agent (piperazine derivative) that partially inhibits fatty acid oxidation. Also inhibits late sodium current into myocardial cells and prolongs QTc interval. Indicated for chronic angina unresponsive to other antianginal treatments. Used in combination with amlodipine, beta-blockers, or nitrates. Unlike beta-blockers, calcium channel blockers,</p>
-------------------------	--

	and nitrates, does not reduce blood pressure or heart rate. Effect on angina rate or exercise tolerance appears to be smaller in women than in men. Absorption is highly variable but unaffected by food.
Adult Dose	500 mg PO bid initially; if necessary, may increase to 1000 mg PO bid
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; preexisting QT prolongation; hepatic impairment (Child-Pugh class A [mild], B [moderate], or C [severe]); QT-prolonging drugs (see Interactions); potent or moderate CYP4503A inhibitors (eg, ketoconazole, diltiazem)
Interactions	CYP4503A and P-gp substrate; potent CYP3A inhibitors (eg, ketoconazole at 200 mg bid) increase levels approximately 3.2-fold, moderate CYP3A inhibitors (eg, diltiazem at 180-360 mg/d) increase levels approximately 1.8- to 2.3-fold, and verapamil (a CYP3A and P-gp inhibitor) increases levels approximately 2-fold; caution with other P-gp inhibitors (eg, ritonavir, cyclosporine); toxicity may occur when coadministered with other drugs that increase QTc interval (eg, class I and III antiarrhythmic agents, certain macrolide and quinolone antibiotics, phenothiazines, TCAs) Inhibits CYP4503A, CYP 4502D6, and P-gp; may increase plasma levels of digoxin, simvastatin, dextromethorphan,

	TCAs, and antipsychotics
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Causes dose-related QTc-interval prolongation (obtain baseline and follow-up ECGs to monitor for torsades de pointes and potential for sudden death; mild and moderate hepatic impairment increases QTc interval compared with normal hepatic function at same plasma level; increases blood pressure by approximately 15 mm Hg in persons with severe renal impairment; common adverse effects include dizziness, headache, constipation, and nausea

FOLLOW-UP

Deterrence/Prevention:

Coronary atherosclerosis is the main preventable cause of mortality in the United States. A rigorous effort to address correctable risk factors is the mainstay of preventive cardiovascular medicine.

Smoking cessation is the single most effective preventive intervention to reduce coronary atherosclerosis prevalence. It has been associated with a coronary artery disease reduction of 7-47% in primary prevention settings.

Aggressive treatment of diabetes mellitus, hypertension, LV hypertrophy, hyperlipidemia, and obesity has an important role in the prevention of coronary artery disease.

The most important recent development in coronary atherosclerosis risk modification is the introduction of inhibitors of beta-hydroxy-beta-methylglutaryl coenzyme A reductase.

Reductions of total and LDL cholesterol levels by 25% and 35%, respectively, can achieve a similar reduction in rates of total and coronary mortality, MI, and need for coronary revascularization.

Complications:

Complications of angina pectoris include unstable angina, MI, and death.

Prognosis:

Important prognostic indicators in patients with angina pectoris include LV function, severity and location of atherosclerotic lesions, and response of symptoms to medical treatment.

LV function is the strongest predictor of long-term survival. Elevated LV end-diastolic pressure and volume along with reduced LV ejection fraction (<40%) are poor prognostic signs.

Critical lesions of left main and proximal left anterior descending coronary arteries are associated with a greater risk. Mortality rates are also directly associated with the number of epicardial arteries involved.

Unstable angina, recent MI, or both is a sign of atherosclerotic plaque instability, which is a strong predictor of increased risk of short-term coronary events.

A number of signs during noninvasive testing are predictive of a higher risk of coronary events, including ST-segment depression of more than 2 mm at a low workload, ST-segment depression that persists for more than 5 minutes after termination of exercise, and failure of blood pressure to rise or an actual drop in blood pressure.

Patients who continue to smoke after an MI have a 22-47% increased risk of reinfarction and death.

In general, Prinzmetal angina and syndrome X are associated with excellent long-term prognoses.

Patient Education:

Educating patients about the benefits of smoking cessation, a low-cholesterol diet, physical activity, and periodic screening for diabetes mellitus and hypertension is the prime component of a long-term management plan.

For excellent patient education resources, visit eMedicine's Circulatory Problems Center, Cholesterol Center, Heart Center, and Statins Center. Also, see eMedicine's patient education articles Angina Pectoris, High Cholesterol, Understanding Your Cholesterol Level, Lifestyle Cholesterol Management, Understanding Cholesterol-Lowering Medications, Chest Pain, Coronary Heart Disease, and Heart Attack.

MISCELLANEOUS**Medical/Legal Pitfalls:**

In patients with stable angina pectoris, even the most carefully performed history and physical examination have limitations. Classification of these patients solely on the basis of history and physical examination findings may lead to serious mistakes. Some type of stress testing is usually indicated to confirm the diagnosis and quantitate the severity of ischemia.

In women, elderly persons, and diabetic patients, coronary artery disease may manifest with atypical presentations other than angina pectoris, such as silent ischemia or infarction. Physicians should use a careful approach when evaluating these patients.

Classical and untypical variants of the acute myocardial infarction, criteria for diagnosis. Differential programs of treatment of the uncomplicated myocardial infarction, physical rehabilitation

Background: Myocardial infarction (MI) is the irreversible necrosis of heart muscle secondary to prolonged ischemia. This usually results from an imbalance of oxygen supply and demand. The appearance of cardiac enzymes in the circulation generally indicates myocardial necrosis. MI is considered, more appropriately, part of a spectrum referred to as acute coronary syndromes (ACSs), which also includes unstable angina and non–ST-elevation MI (NSTEMI). Patients with ischemic discomfort may or may not have ST-segment elevation. Most of those with ST-segment elevation will develop Q waves. Those without ST elevations will ultimately be diagnosed with unstable angina or NSTEMI based on the presence of cardiac enzymes.

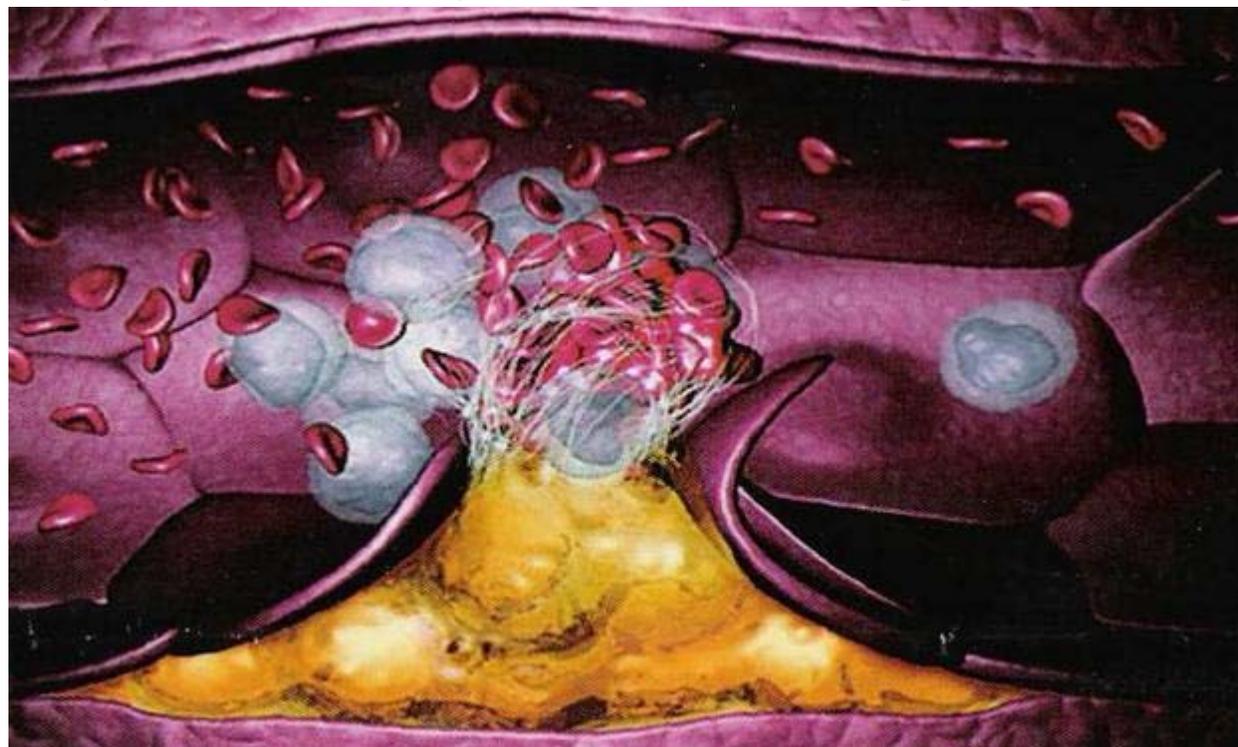

Fig. Pathogenesis of MI

MI may lead to impairment of systolic function or diastolic function and to increased predisposition to arrhythmias and other long-term complications.

Pathophysiology: Atherosclerosis is the disease primarily responsible for most ACS cases. Approximately 90% of MIs result from an acute thrombus that obstructs an atherosclerotic coronary artery. Plaque rupture is considered to be the major trigger of coronary thrombosis. Following plaque rupture, platelet activation and aggregation, coagulation pathway activation, and endothelial vasoconstriction occur and lead to coronary thrombosis and occlusion.

Atherogenesis

Consider nonatherosclerotic causes of acute MIs in younger patients or if no evidence of atherosclerosis is noted. Such causes include coronary emboli from sources such as an infected cardiac valve, coronary occlusion secondary to vasculitis, primary coronary vasospasm (variant angina), cocaine use, or other factors leading to mismatch of oxygen supply and demand, as may occur with a significant GI bleed.

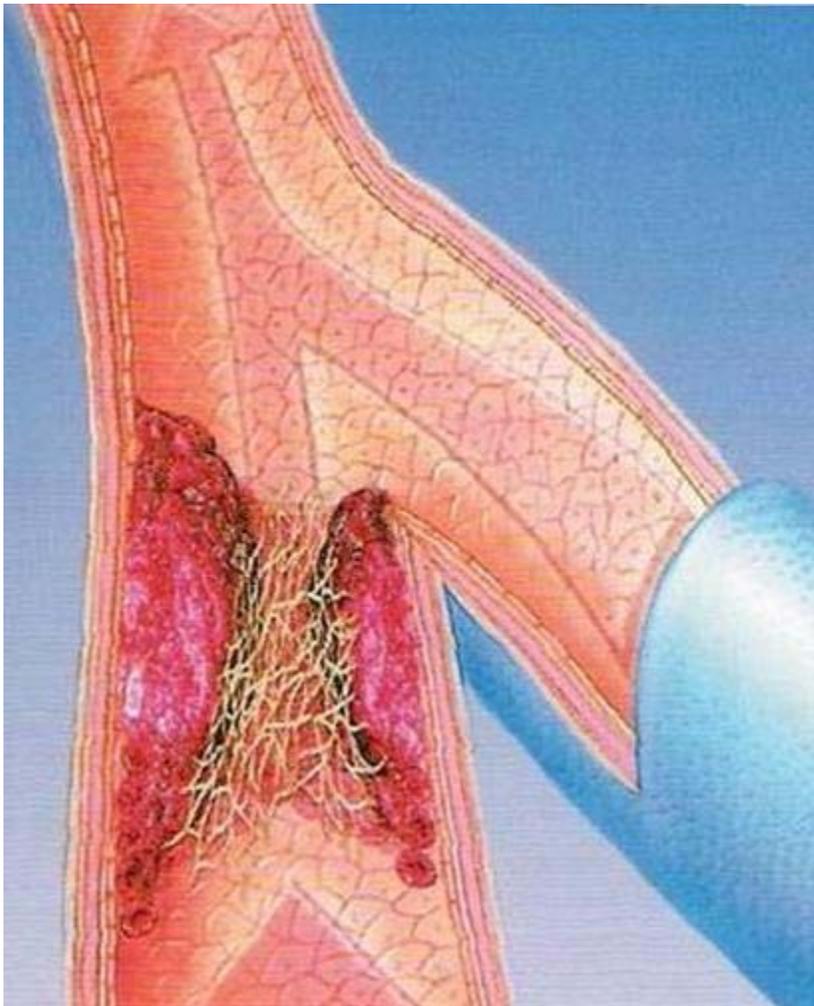

Fig. Atherogenesis

Frequency: In the US: Approximately 1.5 million cases of MI occur each year.
Internationally: Cardiovascular diseases cause 12 million deaths throughout the world each

year, according to the third monitoring report of the World Health Organization, 1991-93. They cause half of all deaths in several developed countries and are one of the main causes of death in many developing countries; they are the major cause of death in adults everywhere.

Mortality/Morbidity: Cardiovascular disease is the leading cause of death in the United States; approximately 500,000-700,000 deaths related to the coronary artery occur each year. Ischemic heart disease is the leading cause of death worldwide. Approximately 6.3 million deaths due to heart disease occurred in 1990 worldwide, which represents 29% of all deaths. The prevalence of coronary artery disease (CAD) is increasing rapidly in nonindustrialized countries.

Race: Cardiovascular disease is the leading cause of morbidity and mortality among African American, Hispanic, and white populations in the United States.

Sex: A male predominance in incidence exists up to approximately age 70 years, when the sexes converge to equal incidence.

Premenopausal women appear to be somewhat protected from atherosclerosis, possibly owing to the effects of estrogen.

Age: Incidence increases with age. Most patients who develop an acute MI are older than 60 years. Elderly people also tend to have higher rates of morbidity and mortality from their infarcts.

CLINICAL

History:

Chest pain

This is usually described as a substernal pressure sensation that also may be described as squeezing, aching, burning, or even sharp pain.

Prolonged chest discomfort lasting longer than 30 minutes is most compatible with infarction.

Radiation to the left arm or neck is common.

The sensation is precipitated by exertion and relieved by rest and nitroglycerin.

Chest pain may be associated with nausea, vomiting, diaphoresis, dyspnea, fatigue, or palpitations.

Atypical chest pain is common, especially in patients with diabetes and in elderly patients.

However, any patient may present with atypical symptoms. These symptoms are considered the anginal equivalent for that patient.

Shortness of breath

Shortness of breath may be the patient's anginal equivalent or a symptom of heart failure.

It is due to elevated end-diastolic pressures secondary to ischemia, which may then lead to

elevated pulmonary pressures.

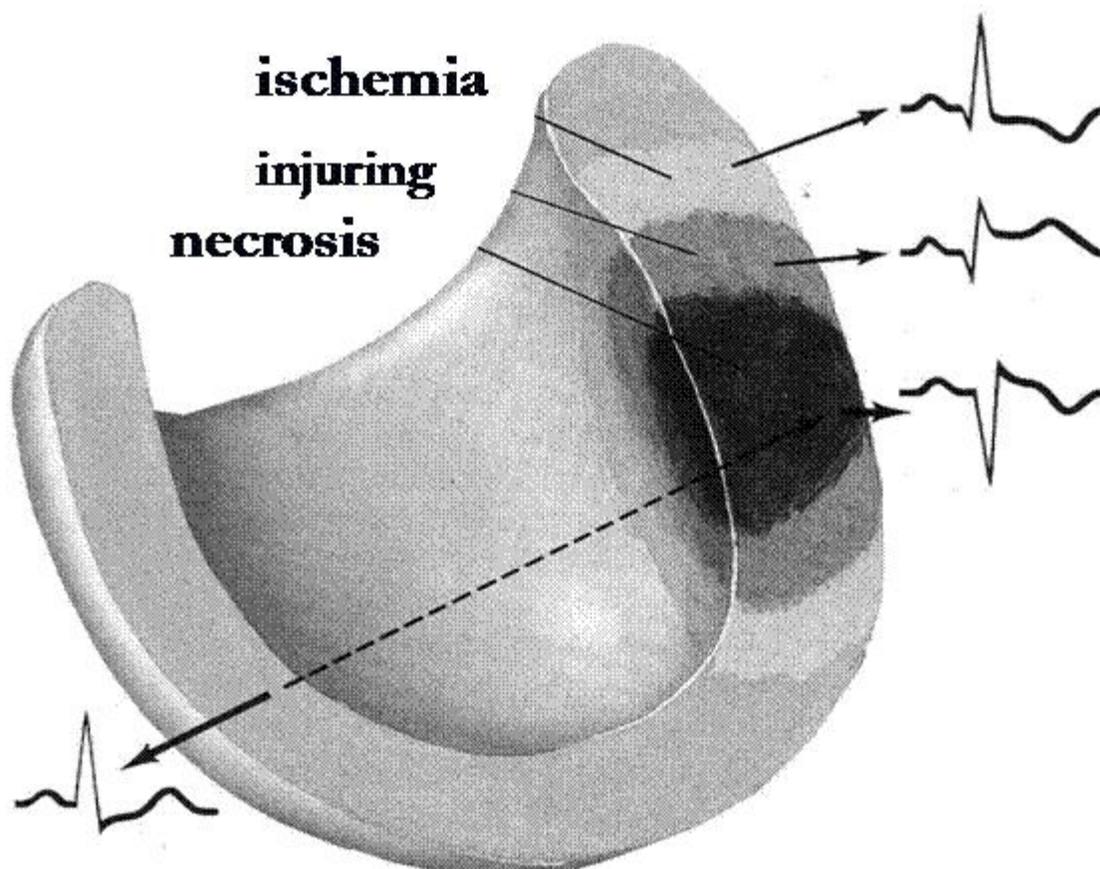

Fig. ECG changes in MI

Atypical presentations

Atypical presentations are common and frequently lead to misdiagnoses.

A patient may, for example, present with abdominal discomfort or jaw pain as his or her anginal equivalent.

An elderly patient may present with altered mental status.

Low threshold should be maintained when evaluating high- and moderate-risk patients, as their anginal equivalents may mimic other presentations.

Women tend to present more commonly with atypical symptoms such as sharp pain, fatigue, weakness, and other nonspecific complaints.

Physical: Physical examination findings can vary; one patient may be comfortable in bed, with normal examination results, while another may be in severe pain with significant respiratory distress requiring ventilatory support.

Low-grade fever may be present.

Hypotension or hypertension can be observed depending on the extent of the MI.

Fourth heart sound (S₄) may be heard in patients with ischemia. With ischemia, diastolic

dysfunction is the first physiologically measurable effect and this can then cause a stiff ventricle and an audible S4.

Dyskinetic cardiac bulge (in anterior wall MI) can occasionally be palpated.

Systolic murmur can be heard if mitral regurgitation (MR) or ventricular septal defect (VSD) develops.

Other findings include cool, clammy skin and diaphoresis.

Signs of congestive heart failure (CHF) may be found, including the following:

Third heart sound (S3) gallop

Pulmonary rales

Lower extremity edema

Elevated jugular venous pressure

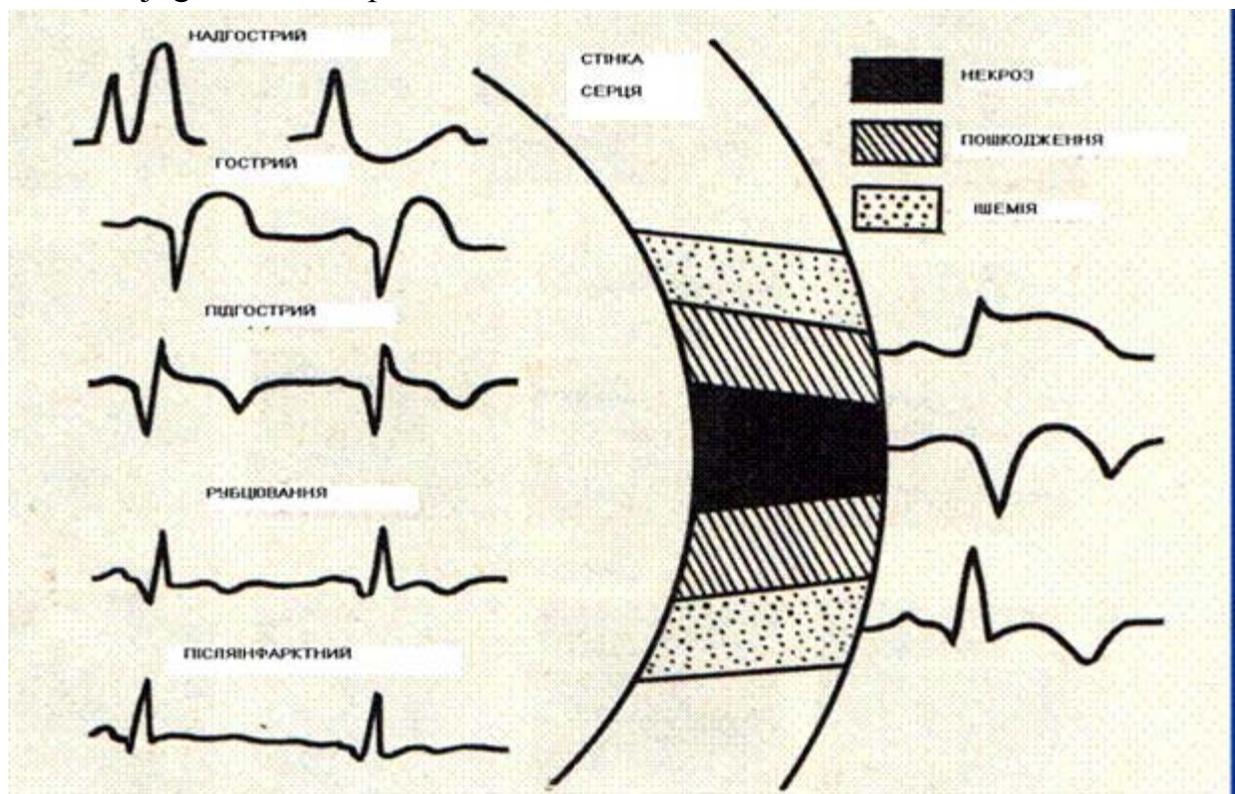

Fig Stages of MI

Causes: Atherosclerosis with occlusive or partially occlusive thrombus formation, Nonmodifiable risk factors for atherosclerosis, Age, Sex, Family history of premature coronary heart disease, Modifiable risk factors for atherosclerosis, Smoking or other tobacco use, Diabetes mellitus, Hypertension, Dyslipidemia, Obesity, New and other risk factors for atherosclerosis, Elevated homocysteine levels, Male pattern baldness. Sedentary lifestyle and/or lack of exercise, Psychosocial stress, Presence of peripheral vascular disease, Poor oral hygiene, Nonatherosclerotic causes, Vasculitis, Coronary emboli, Congenital coronary anomalies, Coronary trauma, Coronary spasm, Drug use (cocaine), Factors that increase oxygen

requirement, such as heavy exertion, fever, or hyperthyroidism , Factors that decrease oxygen delivery, such as hypoxemia of severe anemia

Other Problems to be Considered:

Pneumonia

Pancreatitis

Lab Studies:

Cardiac enzymes: In patients with suspected MI, obtain cardiac enzymes at regular intervals, starting upon admission and serially for as long as 24 hours.

Creatine kinase level

Creatine kinase comprises 3 isoenzymes, including creatine kinase with muscle subunits (CK-MM), which is found mainly in skeletal muscle; creatine kinase with brain subunits (CK-BB), predominantly found in the brain; and myocardial muscle creatine kinase (CK-MB), which is found mainly in the heart.

Serial measurements of CK-MB isoenzyme levels were previously the standard criterion for diagnosis of MI. CK-MB levels increase within 3-12 hours of onset of chest pain, reach peak values within 24 hours, and return to baseline after 48-72 hours. Levels peak earlier (wash out) if reperfusion occurs. Sensitivity is approximately 95%, with high specificity. However, sensitivity and specificity are not as high as for troponin levels, and the trend has favored using troponins for the diagnosis of MI.

Troponin levels

Troponin levels are now considered the criterion standard in defining and diagnosing MI, according to the American College of Cardiology (ACC)/American Heart Association (AHA) consensus statement on MI (Braunwald, 2000).

Cardiac troponin levels (troponin-T and troponin-I) have a greater sensitivity and specificity than CK-MB levels in detecting MI. They have important diagnostic and prognostic roles.

Positive troponin levels are considered virtually diagnostic of MI in the most recent ACC/AHA revisions, as they are without equal in combined specificity and sensitivity in this diagnosis.

Serum levels increase within 3-12 hours from the onset of chest pain, peak at 24-48 hours, and return to baseline over 5-14 days.

Myoglobin levels

Urine myoglobin levels rise within 1-4 hours from the onset of chest pain.

Myoglobin levels are highly sensitive but not specific, and they may be useful within the context of other studies and in early detection of MI in the ED.

Complete blood cell count

Obtain a CBC count if MI is suspected to rule out anemia as a cause of decreased oxygen supply and prior to giving thrombolytics.

Leukocytosis is also common, but not universal, in the setting of acute MI.

A platelet count is necessary if a IIb/IIIa agent is considered; furthermore, the patient's WBC count may be elevated modestly in the setting of MI, signifying an acute inflammatory state.

Chemistry profile

In the setting of MI, closely monitor potassium and magnesium levels.

Creatinine level is also needed prior to initiating treatment with an angiotensin-converting enzyme (ACE) inhibitor.

Lipid level profile: This may be helpful if obtained upon presentation because levels can change after 12-24 hours of an acute illness.

C-reactive protein (CRP) levels: Consider measuring CRP levels and other markers of inflammation upon presentation if an ACS is suspected.

Imaging Studies:

Chest radiography

Upon presentation, obtain a chest radiograph to assess the patient's heart size and the presence or absence of decompensated CHF with or without pulmonary edema.

A chest radiograph may also assist in diagnosing concomitant disease, such as pneumonia in an elderly patient, as a precipitating cause for MI.

Echocardiography

An echocardiogram may play an important role in the setting of MI.

Regional wall motion abnormalities can be identified, which are especially helpful if the diagnosis is questionable.

An echocardiogram can also define the extent of the infarction and assess overall left ventricle (LV) and right ventricle (RV) function. In addition, an echocardiogram can identify complications, such as acute MR, LV rupture, or pericardial effusion.

Myocardial perfusion imaging

Prior to discharge, obtain myocardial perfusion imaging to assess the extent of residual ischemia if the patient has not undergone cardiac catheterization. The extent of ischemia can guide further therapy as to whether to proceed with catheterization or to continue conservative therapy.

Myocardial perfusion has been shown to be a valuable method for triage of patients with chest pain in the ED. Significant variability exists among centers, and the results of the trials can be applied only to those centers with proven reliability and experience.

Cardiac angiography

Cardiac catheterization defines the patient's coronary anatomy and the extent of the disease. Most investigators recommend that all patients with MI should undergo cardiac catheterization, if it is available.

Patients with cardiogenic shock, intractable angina despite medications, or severe pulmonary congestion should undergo cardiac catheterization immediately.

Other Tests:

The electrocardiogram (ECG) is the most important tool in the initial evaluation and triage of patients in whom an ACS is suspected (see Images 1-3). It is confirmatory of the diagnosis in approximately 80% of cases.

Obtain an ECG immediately if MI is considered or suspected.

Video Localization of MI

In patients with inferior MI, record a right-sided ECG to rule out RV infarct.

Qualified personnel should review the ECG as soon as possible.

Perform ECGs serially upon presentation to evaluate progression and assess changes with and without pain.

Obtain daily serial ECGs for the first 2-3 days and additionally as needed.

Convex ST-segment elevation with upright or inverted T waves is generally indicative of MI in the appropriate clinical setting.

ST depression and T-wave changes may also indicate evolution of NSTEMI.

TREATMENT

Medical Care: Initial therapy for acute MI is directed toward restoration of perfusion in order to salvage as much of the jeopardized myocardium as possible. This may be accomplished

through medical or mechanical means, such as angioplasty or coronary artery bypass grafting. Further treatment is based on (1) restoration of the balance between the oxygen supply and demand to prevent further ischemia, (2) pain relief, and (3) prevention and treatment of any complications that may arise.

Thrombolytic therapy has been shown to improve survival rates in patients with acute MI if administered in a timely fashion in the appropriate group of patients. If PCI capability is not available or will cause a delay greater than 90 minutes, then the optimal approach is to administer thrombolytics within 12 hours of onset of symptoms in patients with ST-segment elevation greater than 0.1 mV in 2 or more contiguous ECG leads, new left bundle-branch block (LBBB), or anterior ST depression consistent with posterior infarction. Tissue plasminogen activator (t-PA) is superior to streptokinase in achieving a higher rate of coronary artery patency; however, the key to efficacy lies in the speed of the delivery of therapy. Recent trials show a high patency rate if a IIb/IIIa receptor antagonist is combined with a half dose of a thrombolytic agent as the initial reperfusion strategy. The reduced dose of a thrombolytic agent combined with a potent platelet inhibitor may prove to be the preferred method for medical reperfusion. Larger clinical trials are pending.

Aspirin and/or antiplatelet therapy Aspirin has been shown to decrease mortality and re-infarction rates after MI. Administer aspirin immediately, which the patient should chew if possible upon presentation. Continue aspirin indefinitely unless an obvious contraindication, such as a bleeding tendency or an allergy, is present. Clopidogrel may be used as an alternative in cases of a resistance or allergy to aspirin. Recent data from the CLARITY trial (CLOpidogrel as Adjunctive Reperfusion Therapy Thrombolysis in Myocardial Infarction [TIMI] 28) suggest that adding clopidogrel to this regimen is safe and effective. The clopidogrel dose used was 300 mg.

Administer a platelet glycoprotein (GP) IIb/IIIa-receptor antagonist, in addition to acetylsalicylic acid and unfractionated heparin (UFH), to patients with continuing ischemia or with other high-risk features and to patients in whom a percutaneous coronary intervention (PCI) is planned. Eptifibatid and tirofiban are approved for this use. Abciximab also can be used for 12-24 hours in patients with unstable angina or NSTEMI in whom a PCI is planned within the next 24 hours.

Beta-blockers reduce the rates of reinfarction and recurrent ischemia and possibly reduce the mortality rate if administered within 12 hours after MI. Administer routinely to all patients with MI unless a contraindication is present.

Heparin (and other anticoagulant agents) has an established role as an adjunctive agent in

patients receiving t-PA but not with streptokinase. Heparin is also indicated in patients undergoing primary angioplasty. Little data exist with regard to efficacy in patients not receiving thrombolytic therapy in the setting of acute MI. Low-molecular-weight heparins (LMWHs) have been shown to be superior to UFHs in patients with unstable angina or NSTEMI.

Nitrates have no apparent impact on mortality rate in patients with ischemic syndromes. Their utility is in symptomatic relief and preload reduction. Administer to all patients with acute MI within the first 48 hours of presentation, unless contraindicated (ie, in RV infarction).

ACE inhibitors reduce mortality rates after MI. Administer ACE inhibitors as soon as possible as long as the patient has no contraindications and remains in stable condition. ACE inhibitors have the greatest benefit in patients with ventricular dysfunction. Continue ACE inhibitors indefinitely after MI. Angiotensin-receptor blockers may be used as an alternative in patients who develop adverse effects, such as a persistent cough, although initial trials need to be confirmed.

Surgical Care:

Percutaneous coronary intervention

PCI is the treatment of choice in most patients with STEMI, assuming a door to needle time of less than 90 minutes. PCI provides greater coronary patency (>96% thrombolysis in myocardial infarction [TIMI] 3 flow), lower risk of bleeding, and instant knowledge about the extent of the underlying disease. Studies have shown that primary PCI has a mortality benefit over thrombolytic therapy.

The choice of primary PCI should be individualized to each institution and to the patient's presentation and timing.

The widespread use of stenting and adjunctive IIb/IIIa therapy are improving the results of primary PCI. A recently published trial showed that, in patients with acute MI, coronary stenting and abciximab lead to a greater degree of myocardial salvage and a better clinical outcome than fibrinolysis with thrombolytic therapy. Improvement of long- and short-term outcomes, however, depends highly on the speed with which reperfusion is achieved.

Primary PCI is also the treatment of choice in patients with cardiogenic shock, patients in whom thrombolysis failed, and those with high risk of bleeding or contraindications to thrombolytic therapy.

Only an experienced operator should perform primary PTCA, and PTCA should be performed only where the appropriate facilities are available. Operators should have at least 75 cases per year, while the center should perform at least 200 cases per year as per the recommendations of

the ACC.

Emergent or urgent coronary artery graft bypass surgery is indicated in patients in whom angioplasty fails and in patients who develop mechanical complications such as a VSD, LV, or papillary muscle rupture.

Consultations:

ED personnel should initiate evaluation and treatment, including administering a thrombolytic agent.

Obtain cardiology consultation immediately if primary PCI is considered. Otherwise, cardiology consultation may be obtained as needed and upon admission. Consultation may be obtained sooner if the patient presents with significant heart failure, mechanical complications, arrhythmias, or other complicating factors.

Diet: Initially, keep the patient on nothing by mouth (NPO) until his or her condition has been stabilized and treated. Following initial therapy and admission, a dietitian should instruct the patient regarding appropriate diet, as recommended by the AHA.

A low-salt, low-fat, and low-cholesterol diet is generally recommended.

Activity: Confine patients to bed rest to minimize oxygen consumption until reperfusion and initial therapy are complete. This usually lasts about 24-48 hours; after that, the patient's activity may be accelerated slowly as tolerated and as the clinical situation allows.

Initiate cardiac rehabilitation prior to discharge.

MEDICATION

The goals of pharmacotherapy are to reduce morbidity and to prevent complications.

Drug Category: *Salicylates* -- The antiplatelet effects of these agents may improve mortality rate.

Drug Name	Aspirin (Anacin, Ascriptin, Bayer Aspirin) -- Early administration of aspirin in patients with acute MI has been shown to reduce cardiac mortality rate by 23% in first mo.
Adult Dose	160-325 mg PO or chewed
Pediatric Dose	10-15 mg/kg/dose PO q4-6h
Contraindications	Documented hypersensitivity, liver damage; hypoprothrombinemia; vitamin K deficiency; bleeding disorders; asthma Because of association with Reye

	syndrome, do not administer to children (<16 y) who have flu
Interactions	Antacids and urinary alkalinizers can decrease pharmacologic effects; corticosteroids decrease serum levels by increasing salicylate clearance; other anticoagulants can have an additive hypoprothrombinemic effect and may increase bleeding time; may antagonize uricosuric effects of probenecid and increase free phenytoin and valproic acid levels, increasing their toxicity; in doses >2 g/d, may alter pancreatic beta-cell function and potentiate glucose-lowering effect of sulfonylurea drugs
Pregnancy	D - Unsafe in pregnancy
Precautions	Caution in patients with chronic renal insufficiency—may cause transient decrease in renal function and aggravate chronic kidney diseases; patients with severe anemia, history of blood coagulation defects, or taking anticoagulants should avoid

Drug Category: *Vasodilators* -- These agents relieve chest discomfort by improving myocardial oxygen supply, which in turn dilates epicardial and collateral vessels, improving blood supply to the ischemic myocardium.

Drug Name	Nitroglycerin (Nitro-Bid) -- Causes relaxation of vascular smooth muscle via stimulation of intracellular cyclic guanosine monophosphate production, causing decrease in BP.
------------------	--

Adult Dose	400 mcg SL or spray q5min, repeat up to 3 times; if symptoms persist, 5-10 mcg/min IV infusion; titrate to 10% reduction in MAP or symptom relief, limiting adverse effects of hypotension
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; severe anemia; shock; postural hypotension; head trauma; closed-angle glaucoma; cerebral hemorrhage; known history of RV MI
Interactions	Aspirin may increase serum concentrations; calcium channel blockers may cause marked symptomatic orthostatic hypotension (dose adjustment of either agent may be necessary)
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Exercise caution in patients with CAD or low systolic BP

Drug Category: *Analgesics* -- Pain control is essential to quality patient care. Analgesics ensure patient comfort, promote pulmonary toilet, and have sedating properties, which are beneficial for patients who experience pain.

Drug Name	Morphine sulfate (Duramorph, Astramorph, MS Contin) -- DOC for narcotic analgesia due to its reliable and predictable effects, safety profile, and ease of reversibility with naloxone. Administered IV, may be dosed in a number of ways and commonly is titrated until desired effect.
Adult Dose	2 mg IV q5-15min, titrate to symptomatic relief or adverse effects (eg, lethargy, hypotension, respiratory depression)

Pediatric Dose	0.1-0.2 mg/kg IV q2-4h prn
Contraindications	Documented hypersensitivity; hypotension; potentially compromised airway in which establishing rapid airway control would be difficult
Interactions	Phenothiazines may antagonize analgesic effects; tricyclic antidepressants, MAOIs, and other CNS depressants may potentiate adverse effects
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Avoid using this drug in patients with hypotension, emesis, constipation, respiratory depression, nausea, or urinary retention; exercise caution in patients with atrial flutter and other supraventricular tachycardias; has vagolytic action and may increase ventricular response rate; mental status changes, respiratory depression, and shock are possible adverse effects

Drug Category: *Anticoagulants* -- Unfractionated intravenous heparin and fractionated low molecular weight subcutaneous heparins are the two choices for initial anticoagulation therapy.

Drug Name	Heparin -- Augments activity of antithrombin III and prevents conversion of fibrinogen to fibrin. Does not actively lyse but is able to inhibit further thrombus formation. Prevents reaccumulation of clot after spontaneous fibrinolysis.
Adult Dose	70 IU/kg IV bolus, followed by 15 mcg/kg/h infusion, adjust to maintain aPTT 1.5-2 times control

Pediatric Dose	<p>Loading dose: 50 IU/kg/h IV</p> <p>Maintenance infusion: 15-25 mcg/kg/h IV; increase dose by 2-4 IU/kg/h q6-8h prn using aPTT results</p>
Contraindications	<p>Documented hypersensitivity, subacute bacterial endocarditis; active bleeding; history of heparin-induced thrombocytopenia</p>
Interactions	<p>Digoxin, nicotine, tetracycline, and antihistamines may decrease effects; NSAIDs, aspirin, dextran, dipyridamole, and hydroxychloroquine may increase toxicity</p>
Pregnancy	<p>C - Safety for use during pregnancy has not been established.</p>
Precautions	<p>Observe for prolonged or excessive bleeding at venipuncture sites; some preparations contain benzyl alcohol as preservative, and benzyl alcohol used in large amounts has been associated with fetal toxicity (gasping syndrome); use of preservative-free heparin recommended in neonates; use with caution in patients with shock or severe hypotension</p>
Drug Name	<p>Enoxaparin (Lovenox) -- Enhances inhibition of factor Xa and thrombin by increasing antithrombin III activity. In addition, preferentially increases inhibition of factor Xa.</p>
Adult Dose	<p>1 mg/kg SC bid</p>
Pediatric Dose	<p>Not established</p>

Contraindications	Documented hypersensitivity; major bleeding; history of heparin-induced thrombocytopenia
Interactions	Platelet inhibitors or oral anticoagulants, such as aspirin, NSAIDs, dipyridamole, salicylates, sulfapyrazone, and ticlopidine, increase risk of bleeding and should be used with care in patients taking enoxaparin
Pregnancy	B - Usually safe but benefits must outweigh the risks.
Precautions	Caution in recent surgery, GI lesions that may be prone to bleeding, hematologic conditions, uncontrolled hypertension, diabetic retinopathy, or vitreous hemorrhage; caution in patients with renal insufficiency because elimination delayed, increasing anticoagulant effect; if thromboembolic event occurs despite LMWH prophylaxis, discontinue drug and initiate appropriate therapy; reversible elevation of hepatic transaminases seen occasionally; heparin-induced thrombocytopenia has been seen with LMWH; for significant bleeding complications, 1 mg of protamine sulfate reverses effect of approximately 1 mg of enoxaparin

Drug Category: *Thrombolytics* -- The main objective is to restore circulation through a previously occluded vessel by the rapid and complete removal of a pathologic intraluminal thrombus or embolus that has not been dissolved by the endogenous fibrinolytic system.

Drug Name	Alteplase, t-PA (Activase) -- Fibrin-specific
------------------	---

	<p>agent with brief half-life of 5 min.</p> <p>Adjunctive therapy with IV heparin necessary to maintain patency of arteries recanalized by t-PA, especially during first 24-48 h.</p>
Adult Dose	<p>15 mg IV initial bolus, followed by 50 mg IV over next 30 min, and then 35 mg IV over next h; total dose not to exceed 100 mg</p>
Pediatric Dose	<p>Not established</p>
Contraindications	<p>Documented hypersensitivity; active internal bleeding; recent intracranial or intraspinal surgery or trauma; intracranial neoplasm; AV malformation or aneurysm; history of cerebrovascular accident within last 2 mo; seizure at onset of stroke; suspicion of subarachnoid hemorrhage; bleeding diathesis; serious head trauma; severe uncontrolled hypertension; do not administer to patients with history of intracranial hemorrhage</p>
Interactions	<p>Heparin, which has been administered with and after alteplase infusions to reduce risk of reocclusion, may cause bleeding complications, monitor closely for bleeding, especially at arterial puncture sites; drugs that alter platelet function (eg, aspirin, abciximab, dipyridamole) may increase risk of bleeding if administered prior to, during, or after</p>
Pregnancy	<p>C - Safety for use during pregnancy has not been established.</p>

Precautions	Adverse effects include hemorrhage, particularly intracranial; elderly patients are at greatest risk
Drug Name	Streptokinase (Kabikinase, Streptase) -- Acts with plasminogen to convert plasminogen to plasmin. Plasmin degrades fibrin clots, as well as fibrinogen and other plasma proteins. Increase in fibrinolytic activity that degrades fibrinogen levels for 24-36 h occurs with IV infusion of streptokinase. Adjunctive therapy with heparin not needed.
Adult Dose	1.5 million IU in 50 cc D5W IV over 60 min
Pediatric Dose	Administer as in adults
Contraindications	Documented hypersensitivity; active internal bleeding; intracranial neoplasm; aneurysm; bleeding diathesis; severe uncontrolled arterial hypertension
Interactions	Antifibrinolytic agents may decrease effects; antiplatelet agents and anticoagulants may increase risk of bleeding
Pregnancy	D - Unsafe in pregnancy
Precautions	Use with caution in patients with severe hypertension, those receiving medication via IM administration, and those who had trauma or surgery in previous 10 d; measure hematocrit, platelet count, aPTT, TT, PT, or fibrinogen levels before therapy initiated; either TT or aPTT should be less than twice normal control value following infusion and before instituting heparin; do

	not take BP in lower extremities, it may dislodge possible deep vein thrombus; monitor PT, aPTT, TT, or fibrinogen 4 h after initiation of therapy
Drug Name	Reteplase (Retavase) -- Recombinant plasminogen activator that forms plasmin after facilitating cleavage of endogenous plasminogen. In clinical trials, has been comparable to alteplase in achieving TIMI 2 or 3 patency at 90 min. Heparin and aspirin usually administered concomitantly and after reteplase.
Adult Dose	10 IU IV over 2 min, followed by second 10-IU IV dose after 30 min
Pediatric Dose	Not recommended
Contraindications	Documented hypersensitivity; uncontrolled hypertension; recent intracranial surgery; malformation of aneurysm; bleeding diathesis
Interactions	May increase effects of warfarin, heparin, and aspirin
Pregnancy	B - Usually safe but benefits must outweigh the risks.
Precautions	Caution in cardiovascular arrhythmias, hypotension, and perfusion arrhythmias
Drug Name	Anistreplase (Eminase) -- Non-fibrin-specific agent that activates conversion of plasminogen to plasmin and has half-life of 90 min. However, does not have any benefit over streptokinase, although has higher rate of allergic and bleeding complications. Easier to administer than

	t-PA, has lower cost (\$1500), and does not require heparinization.
Adult Dose	30 IU over 2-5 min
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; recent intracranial surgery; uncontrolled hypertension; vascular malformation; aneurysm
Interactions	Increases effects of anticoagulants and aspirin
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Caution in cardiovascular arrhythmias, hypotension, and perfusion arrhythmias

Drug Category: *Beta-adrenergic blockers* -- This category of drugs has the potential to suppress ventricular ectopy due to ischemia or excess catecholamines. In the setting of myocardial ischemia, beta-blockers have antiarrhythmic properties and reduce myocardial oxygen demand secondary to elevations in heart rate and inotropy.

Drug Name	Metoprolol (Lopressor) -- Selective beta1-adrenergic receptor blocker that decreases automaticity and contractions. Goals of treatment are reduction in heart rate to 60-80 bpm. During IV administration, carefully monitor BP, heart rate, and ECG.
Adult Dose	5 mg IV slow infusion q5min; not to exceed 15 mg or desired heart rate 25 mg PO bid usual initial dose, up to 100 mg bid; titrate to desired effect
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; decompensated CHF; bradycardia;

	bronchial asthma; cardiogenic shock; AV conduction abnormalities
Interactions	Aluminum salts, barbiturates, NSAIDs, penicillins, calcium salts, cholestyramine, and rifampin may decrease bioavailability and plasma levels, possibly resulting in decreased pharmacologic effect; astemizole (recalled from US market), calcium channel blockers, quinidine, flecainide, and contraceptives may increase cardiotoxicity; digoxin, flecainide, acetaminophen, clonidine, epinephrine, nifedipine, prazosin, haloperidol, phenothiazines, and catecholamine-depleting agents may increase toxicity
Pregnancy	B - Usually safe but benefits must outweigh the risks.
Precautions	Do not use in cocaine-related ischemia; beta-adrenergic blockade may reduce signs and symptoms of acute hypoglycemia and may decrease clinical signs of hyperthyroidism; abrupt withdrawal may exacerbate symptoms of hyperthyroidism, including thyroid storm, monitor patient closely and withdraw drug slowly; during IV administration, carefully monitor BP, heart rate, and ECG
Drug Name	Esmolol (Brevibloc) -- Useful drug for patients at risk of experiencing complications from beta-blockers, particularly reactive airway disease, mild-to-moderate LV dysfunction, and peripheral vascular disease. Its short half-life of 8 min

	allows for titration to desired effect with ability to stop quickly if necessary.
Adult Dose	0.1 mg/kg/min IV starting maintenance dose, titrate in increments of 0.05 mg/kg/min q10-15min to total dose of 0.2 mg/kg/min
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; decompensated CHF; bradycardia; cardiogenic shock; AV conduction abnormalities
Interactions	Aluminum salts, barbiturates, NSAIDs, penicillins, calcium salts, cholestyramine, and rifampin may decrease bioavailability and plasma levels, possibly resulting in decreased pharmacologic effect; astemizole (recalled from US market), calcium channel blockers, quinidine, flecainide, and contraceptives may increase cardiotoxicity; digoxin, flecainide, acetaminophen, clonidine, epinephrine, nifedipine, prazosin, haloperidol, phenothiazines, and catecholamine-depleting agents may increase toxicity
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Do not use in cocaine-related ischemia; beta-adrenergic blockade may decrease signs and symptoms of acute hypoglycemia and clinical signs of hyperthyroidism; abrupt withdrawal may exacerbate symptoms of hyperthyroidism,

	including thyroid storm, withdraw drug slowly and monitor patient closely
--	---

Drug Category: *Angiotensin-converting enzyme (ACE) inhibitors* -- These agents may prevent conversion of angiotensin I to angiotensin II, a potent vasoconstrictor, resulting in lower aldosterone secretion.

Drug Name	Captopril (Capoten) -- Has short half-life, which makes it important drug for initiation of ACE inhibitor therapy. Can be started at low dose and titrated upward as needed and as patient tolerates.
Adult Dose	6.25 mg PO tid initially; may titrate to total 450 mg/d
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity
Interactions	Patients receiving diuretic therapy, other vasodilator agents, agents causing renin release, agents increasing potassium, or agents affecting sympathetic activity should be monitored carefully
Pregnancy	D - Unsafe in pregnancy
Precautions	Administer with caution in patients with renal insufficiency and those with borderline low BP; may worsen renal function, especially in patients with bilateral renal artery stenosis; administer cautiously in patients with aortic stenosis because afterload reduction may worsen coronary perfusion

Drug Category: *Platelet aggregation inhibitors* -- These agents prevent acute cardiac ischemic complications in unstable angina unresponsive to conventional therapy.

Drug Name	Abciximab (ReoPro) -- Chimeric human-murine monoclonal antibody. Binds to
------------------	---

	receptor with high affinity and reduces platelet aggregation by 80%. Inhibition of platelet aggregation persists for as long as 48 h after infusion stopped.
Adult Dose	0.25 mcg/kg bolus IV, followed by 0.125 mcg/kg/min infusion for 12 h
Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; bleeding diathesis; thrombocytopenia (<100,000 platelets/mL); recent trauma; intracranial tumor; severe uncontrolled hypertension; history of vasculitis; cerebrovascular accident within 2 y
Interactions	Anticoagulants, antiplatelets, and thrombolytics may increase toxicity
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Bleeding complications are rare and usually related to use of standard-dose heparin instead of weight-based dosing; severe thrombocytopenia has been associated with abciximab within first 24 h of use
Drug Name	Tirofiban (Aggrastat) -- Nonpeptide antagonist of glycoprotein IIb/IIIa receptor. Reversible antagonist of fibrinogen binding. When administered IV, >90% of platelet aggregation inhibited.
Adult Dose	0.4 mcg/kg/min IV for 30 min, then continue at 0.1 mcg/kg/min; administer half dose in patients with severe renal insufficiency (CrCl <30 mL/min)

Pediatric Dose	Not established
Contraindications	Documented hypersensitivity; severe hypertension (SBP >200 mm Hg); active internal bleeding; history of intracranial hemorrhage; intracranial neoplasm; AV malformation or aneurysm; acute pericarditis; bleeding diathesis; trauma or stroke within previous 30 d; platelet count <100,000/mL; history of thrombocytopenia following prior exposure to this product; serum creatinine >2 mg/dL (for 180-mcg/kg bolus and 2-mcg/kg/min infusion) or >4 mg/dL (for 135-mcg/kg bolus and 0.5-mcg/kg/min infusion)
Interactions	Heparin and aspirin increase risk of bleeding compared with heparin and aspirin alone; if using with other drugs that affect hemostasis (eg, warfarin), monitor patients closely
Pregnancy	C - Safety for use during pregnancy has not been established.
Precautions	Most common complications are bleeding events; caution in patients with platelet count <150,000/mL and in patients with hemorrhagic retinopathy; monitor platelet counts, serum creatinine, hemoglobin, hematocrit, and PT/aPTT before treatment, within 6 h after loading infusion, and at least daily thereafter (or more frequently if evidence of significant decline); because these agents inhibit platelet aggregation, exercise caution when using concurrently with drugs that affect hemostasis (eg,

	<p>thrombolytics, ticlopidine, NSAIDs, warfarin, dipyridamole, clopidogrel)</p> <p>Measure ACT and maintain aPTT at 50-70 s unless PCI necessary; maintain ACT at 250-300 s during PCI; if platelets decrease to <100,000/mL, perform additional platelet counts to exclude pseudothrombocytopenia; if thrombocytopenia confirmed, discontinue GP IIb/IIIa inhibitors and heparin and appropriately monitor and treat condition; to monitor UFH, monitor aPTT 6 h after start of heparin infusion and adjust to maintain aPTT at 1.5-2 times control</p>
Drug Name	Eptifibatide (Integrilin) -- Cyclic peptide that reversibly inhibits platelet aggregation by binding to IIb/IIIa receptor.
Adult Dose	<p>Unstable angina: 180 mcg/kg IV bolus, followed by 2 mcg/kg/min continuous infusion until discharge or surgery</p> <p>Patients undergoing PCI: 135 mcg/kg IV bolus before PCI, followed by 0.5 mcg/kg/min continuous infusion</p>
Pediatric Dose	Not established
Contraindications	<p>Documented hypersensitivity; severe hypertension (SBP >200 mm Hg); active internal bleeding; history of intracranial hemorrhage; intracranial neoplasm; AV malformation or aneurysm; acute pericarditis; bleeding diathesis; trauma or stroke within previous 30 d; platelet count <100,000/mL; history of thrombocytopenia following prior exposure to this product;</p>

	<p>serum creatinine >2 mg/dL (for 180-mcg/kg bolus and 2-mcg/kg/min infusion) or >4.0 mg/dL (for 135-mcg/kg bolus and 0.5-mcg/kg/min infusion)</p>
Interactions	<p>Heparin and aspirin increase risk of bleeding compared with heparin and aspirin alone; if using concurrently with other drugs that affect hemostasis (eg, warfarin), monitor patients closely</p>
Pregnancy	<p>C - Safety for use during pregnancy has not been established.</p>
Precautions	<p>Most common complications are bleeding events; exercise caution in patients with platelet count <150,000/mL and in patients with hemorrhagic retinopathy; because these agents inhibit platelet aggregation, exercise caution with concurrent use of drugs that affect hemostasis (eg, thrombolytic agents, ticlopidine, NSAIDs, warfarin, dipyridamole, clopidogrel)</p> <p>Measure ACT and maintain aPTT at 50-70 s unless PCI necessary; maintain ACT at 250-300 s during PCI; if platelets decrease to <100,000/mL, perform additional platelet counts to exclude pseudothrombocytopenia; if thrombocytopenia confirmed, discontinue GP IIb/IIIa inhibitors and heparin and appropriately monitor and treat condition; to monitor UFH, monitor aPTT 6 h after start of heparin infusion and adjust to maintain aPTT to 1.5-2 times control</p>

FOLLOW-UP

Further Inpatient Care: Admit patients with MI to a coronary care unit. Monitor patients carefully for arrhythmia, recurrent ischemia, and other possible complications. The patient may be transferred to a telemetry unit 24-48 hours after admission if no complications occur.

Hospitalize the patient for approximately 4-5 days after MI. Patients who undergo primary PCI or have an immediate cardiac catheterization may be discharged sooner if their hospital course is without incident.

Perform a coronary angiography on high-risk patients prior to discharge to evaluate their need for revascularization.

In the case of patients who have not had a cardiac catheterization and have no complications, perform a submaximal stress test prior to discharge to assess their subsequent risk.

Further Outpatient Care:

Arrange for follow-up within 2 weeks of discharge.

Arrange for cardiac rehabilitation.

In/Out Patient Meds:

The long-term use of aspirin in patients who have had an MI results in significant reduction in subsequent mortality rate.

Beta-blocker therapy has confirmed therapeutic benefit in survivors of acute MI. This therapy is most beneficial in patients with the highest risk.

ACE inhibitor use in patients with known CAD has been shown to reduce mortality rate.

Many trials have shown a clear benefit of lipid-lowering therapy in the secondary and primary prevention of CAD. The National Cholesterol Education Panel has set guidelines for target cholesterol levels. In general, patients who have experienced MI should achieve low-density lipoprotein (LDL) level less than 100 mg/dL, high-density lipoprotein (HDL) level greater than 40 mg/dL, and triglyceride level less than 200 mg/dL. High-risk patients should be treated to a target LDL level of less than 70 mg/dL.

Schwartz et al recently showed in the MIRACL trial that initiating atorvastatin during hospitalization for an ACS, irrespective of lipid levels, reduces the frequency of recurrent ischemic events. This treatment significantly reduced the frequency of the combined end point of death, recurrent death, MI, or worsening unstable angina requiring hospitalization.

Clopidogrel should be prescribed for a year following discharge if the patient has no contraindications and cost is not prohibitive. To reduce the risk of bleeding, the aspirin dose can be reduced to 81 mg.

Transfer: A patient in whom thrombolytic therapy fails should be transferred to a facility

where cardiac catheterization and angioplasty facilities are available.

Deterrence/Prevention:

Smoking cessation Cigarette smoking is a major risk factor for CAD. Risk of recurrent coronary events decreases 50% at 1 year after smoking cessation.

Provide all patients who smoke with guidance, education, and the support needed to avoid smoking.

Bupropion has been shown to increase the chances of patients' success in achieving smoking cessation.

Alcohol consumption

Mild alcohol consumption has been associated with a decreased risk of stroke and MI.

Cautiously consider recommending and discussing alcohol use on a case-by-case basis.

Antioxidant therapy, including vitamin E, has not shown clear benefit in the prevention of coronary events.

Do not use long-term anticoagulant (ie, warfarin) therapy routinely in post-MI patients but as an alternative in patients who cannot take antiplatelet agents. Patients with known LV thrombus, atrial fibrillation, or severe wall motion abnormalities have shown benefit from long-term anticoagulation, maintaining the international normalized ratio (INR) between 2 and 3.

Do not start post-MI patients on postmenopausal hormone therapy (HRT). Patients already taking HRT for more than 1 year may be continued on this therapy without increased risk.

COMPLICATIONS:

A number of arrhythmias occur after MI, ranging from benign to fatal. Arrhythmias are common in the setting of MI and are a major cause of morbidity and mortality. Close monitoring and immediate treatment of arrhythmias may be the most important part of the treatment of a post-MI patient within the first 48 hours. Pay close attention to exacerbating factors, such as electrolyte disturbances (especially potassium and magnesium), hypoxemia, drugs, or acidosis, and correct them accordingly.

Ventricular fibrillation and/or ventricular tachycardia occurring within the first 48 hours may be due to ischemia; however, if ventricular arrhythmias occur later, then further workup is indicated. Immediate cardioversion is the treatment of choice. Accelerated idioventricular arrhythmia is a ventricular arrhythmia that may occur in response to reperfusion. This rhythm has a benign prognosis and usually does not require therapy.

Supraventricular arrhythmias are also common. Sinus bradycardia may be due to drugs, ischemia, or a vagal response. Sinus tachycardia may be due to pain, anxiety, drugs, or other

causes. Atrial fibrillation and other atrial tachycardias may also occur. Treat any tachycardia by correcting the cause first or by pharmacotherapy, because persistent tachycardias may lead to further ischemia.

Conduction abnormalities may result from ischemia, necrosis, or chronotropic drugs, or as a vagal response. Recognition and treatment of these abnormalities are important in short- and long-term outcomes. Possible therapies include medications, such as atropine, or even placement of a transvenous pacemaker if indicated. Conduction disturbances are seen more commonly in the setting of inferior MI but are more ominous when seen with an anterior infarct.

Recurrent ischemia may be due to incomplete reperfusion. Postinfarct angina occurs in 20-30% of patients. This is an indication to proceed to cardiac catheterization followed by mechanical revascularization as needed.

CHF can be due to systolic dysfunction or diastolic dysfunction in the setting of MI. The severity of the heart failure and systolic dysfunction depends on the extent of the infarct and the presence of any other complications, such as acute mitral regurgitation. Aggressive treatment is indicated to avoid worsening of the situation. Treatment may include any or all of the following: nitrates, morphine, diuretics, ACE inhibitors, and other vasodilators if needed. Digoxin has no role in the setting of acute CHF due to ischemia.

Cardiogenic shock is defined as a systolic BP less than 90 mm Hg in the presence of organ hypoperfusion. The mortality rate due to cardiogenic shock is as high as 70% in some series. Patients usually require inotropic agents, such as dopamine or dobutamine, and occasionally an intraaortic balloon pump is required. Patients presenting with cardiogenic shock should proceed directly to the catheterization lab, if available, for mechanical revascularization. Acute MR is most common in the setting of an inferoposterior MI. This is secondary to ischemia, necrosis, or rupture of the LV papillary muscle (especially the posteromedial papillary muscle). This can lead to mild-to-severe MR with CHF. Diagnosis can be made on physical examination, but an echocardiogram is necessary to confirm the diagnosis and assess the severity, which helps in the choice of therapy. Treatment consists of aggressive afterload reduction, intraaortic balloon pump insertion, and immediate surgical repair.

[Video Rupture of chorda](#)

Ventricular rupture occurs in the interventricular septum or the LV free wall. Both are

catastrophic events with mortality rates greater than 90%. Prompt recognition, stabilization, and surgical repair are crucial to any hope of survival. Ventricular rupture is more common in women, patients with hypertension, and those receiving NSAIDs or steroids. An echocardiogram can usually define the abnormality, and a right heart catheterization can show an oxygen saturation step-up in the case of a septal rupture.

Other complications include pericarditis, ventricular aneurysms, mural thrombi, and hypertension. Recognition and treatment can be life saving.

Prognosis:

Acute MI is associated with a 30% mortality rate; half of the deaths occur prior to arrival at the hospital.

An additional 5-10% of survivors die within the first year after their MI.

Approximately half of all patients with an MI are rehospitalized within 1 year of their index event.

Overall, prognosis is highly variable and depends largely on the extent of the infarct, the residual LV function, and whether the patient underwent revascularization.

Patient Education:

Diet

Diet plays an important role in the development of CAD. Educate post-MI patients about the role of a low-cholesterol and low-salt diet.

Educate patients about the AHA dietary guidelines regarding a low-fat, low-cholesterol diet.

A dietitian should see and evaluate all post-MI patients prior to their discharge.

Smoking cessation

Educate all post-MI patients regarding the critical role of smoking in the development of CAD.

Smoking cessation classes should be offered to help patients avoid smoking after their MI.

For excellent patient education resources, visit eMedicine's Cholesterol Center. Also, see eMedicine's patient education articles High Cholesterol, Understanding Your Cholesterol Level, Lifestyle Cholesterol Management, Understanding Cholesterol-Lowering Medications, Chest Pain, Coronary Heart Disease, and Heart Attack.

MISCELLANEOUS

Medical/Legal Pitfalls:

Failure to make the diagnosis of an MI is the leading cause of litigation against ED physicians and cardiologists.

Consider atypical presentations in elderly patients, patients with diabetes, and women. Assess all patients carefully, especially if they have significant cardiac risk factors.

Review all ECGs that are obtained in a prompt fashion because time is crucial.

Obtain cardiology consultation whenever the diagnosis is questionable.

Consider an echocardiogram to assess wall motion abnormalities in difficult cases with nondiagnostic ECGs, such as with an LBBB.

Special Concerns:

Right ventricular infarction

Approximately one third of patients with inferior MI develop RV infarction. RV infarction presents a special challenge because the adjunctive therapy, other than reperfusion, is somewhat different.

A right-sided ECG with greater than 1 mm ST elevation in V3R or V4R leads describes an RV infarct. An echocardiogram may be helpful in confirming the diagnosis. On physical examination, signs of right heart failure, such as elevated jugular venous pulsation, right-sided S3, Kussmaul sign, or hypotension, may be present, and the patient may have clear lung fields. The patient becomes volume dependent to maintain adequate LV and RV filling. Occasionally, dobutamine may be needed, or even an intraaortic balloon pump for hemodynamic support. Avoid nitrates or any medications that lower preload in this setting. A pulmonary artery catheter can be helpful in guiding therapy.

Elderly patients

Elderly patients with acute MI are at increased risk of developing complications. Treat these patients aggressively.

Elderly patients have an increased risk of bleeding with thrombolytic therapy, but they also have the most to gain from this therapy.

Very elderly patients should undergo primary angioplasty if available, but they should receive thrombolytics if excessive delay is anticipated before angioplasty can be performed.

Valvular Heart Disease

Primary valvular heart disease ranks well below coronary heart disease, stroke, hypertension, obesity, and diabetes as major threats to the public health. Nevertheless, it is the source of significant morbidity and mortality. Rheumatic fever is the dominant cause of valvular heart disease in developing countries. Its prevalence has been estimated to range from as low as 1.0 per 100,000 school-age children in Costa Rica to as high as 150 per 100,000 in China. Rheumatic heart disease accounts for 12–65% of hospital admissions related to cardiovascular disease and 2–10% of hospital discharges in some developing countries. Prevalence and mortality rates vary among communities even within the same country as a function of crowding and the availability of medical resources and population-wide programs for detection and treatment of Group A streptococcal pharyngitis. In economically deprived areas, tropical and subtropical climates (particularly on the Indian subcontinent), Central America, and the Middle East, rheumatic valvular disease progresses more rapidly than in more-developed nations and frequently causes serious symptoms in patients <20 years of age. This accelerated natural history may be due to repeated infections with more virulent strains of rheumatogenic streptococci.

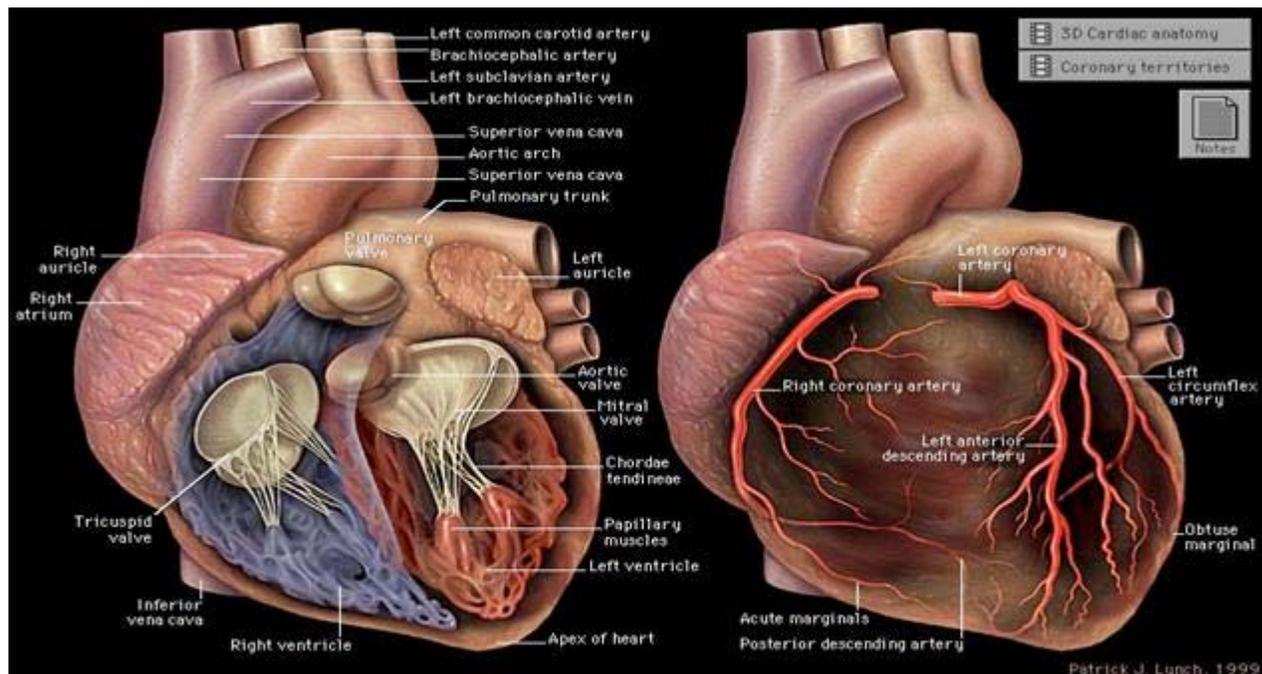

Fig. Heart anatomy

TS, a relatively uncommon valvular lesion in North America and Western Europe, is more common in tropical and subtropical climates, especially in southern Asia and in Latin America.

As of the year 2000, worldwide death rates for rheumatic heart disease approximated 5.5 per 100,000 population ($n = 332,000$), with the highest rates reported from Southeast Asia. Although there have been reports of recent isolated outbreaks of streptococcal infection in North America, valve disease in developed countries is now dominated by degenerative or inflammatory processes that lead to valve thickening, calcification, and dysfunction. The prevalence of valvular heart disease increases with age. Important left-sided valve disease may affect as many as 12–13% of adults over the age of 75.

The incidence of infective endocarditis has increased with the aging of the population, the more widespread prevalence of vascular grafts and intracardiac devices, the emergence of more virulent multidrug-resistant microorganisms, and the growing epidemic of diabetes. Infective endocarditis has become a more frequent cause of acute valvular regurgitation.

Bicuspid aortic valve disease affects as many as 1–2% of the population, and an increasing number of childhood survivors of congenital heart disease present later in life with valvular dysfunction. The past several years have witnessed significant improvements in surgical outcomes with progressive refinement of relatively less-invasive techniques. Percutaneous heart valve replacement or repair is under active clinical investigation.

Mitral regurgitation

Mitral regurgitation affects more than 2 million people in the USA. The main causes are classified as degenerative (with valve prolapse) and ischaemic (ie, due to consequences of coronary disease) in developed countries, or rheumatic (in developing countries). This disorder generally progresses insidiously, because the heart compensates for increasing regurgitant volume by left-atrial enlargement, causes left-ventricular overload and dysfunction, and yields poor outcome when it becomes severe. Doppler-echocardiographic methods can be used to quantify the severity of mitral regurgitation. Yearly mortality rates with medical treatment in patients aged 50 years or older are about 3% for moderate organic regurgitation and about 6% for severe organic regurgitation. Surgery is the only treatment proven to improve symptoms and prevent heart failure. Valve repair improves outcome compared with valve replacement and reduces mortality of patient with severe organic mitral regurgitation by about 70%. The best short-term and long-term results are obtained in asymptomatic patients operated on in advanced repair centres with low operative mortality (<1%) and high repair rates (≥ 80 —90%). These results emphasise the importance of early detection and assessment of mitral regurgitation.

Mitral regurgitation is defined as systolic retrograde flow from the left ventricle into the left atrium. Although a trivial form of this valve disease is often seen in healthy people, epidemiological data show that moderate or severe regurgitation is the most frequent valve disease in the USA and is the second most common form of valvular heart disease needing surgery in Europe. Despite substantial reduction in the incidence of rheumatic heart disease, mitral regurgitation is a growing public health problem. Moderate or severe regurgitation is frequent, its prevalence increases with age, and it was estimated to affect 2.0—2.5 million people in the USA in 2000—a number expected to almost double by 2030 because of population ageing and growth. Although no large epidemiological studies are available, mitral regurgitation is prevalent in young adults in countries with endemic rheumatic fever. Substantial progress has been achieved to improve its diagnosis, quantification, and surgical treatment. Improved knowledge of clinical outcome of patients with mitral regurgitation

resulted in refined surgical indications. Hence, mitral regurgitation is a disease in which restoration of life expectancy can often be achieved, an encouraging outcome that emphasises the importance of early detection, assessment, and prompt consideration for treatment of patients with this condition. Challenges in management of patients with mitral regurgitation remain—elderly patients and those with disease due to ischaemic heart disease are often not offered surgery; valve repair—the preferred surgical method—is insufficiently done; new interventional techniques—minimally invasive or percutaneous—are under investigation. However, the general absence of clinical trials means evidence to guide treatment is weak.

All lesions that cause mitral regurgitation do so by reduction or elimination of the normal systolic coaptation between anterior and posterior mitral leaflets, which normally ensures mitral competence. Consistent anatomical and functional descriptors of mitral lesions are essential to assess surgical reparability but overlapping and poorly defined terminology has caused confusion. Causes and mechanisms are not synonymous and a particular cause might produce regurgitation by different mechanisms (table). Surgical correction of this valve disease is dependent on both cause and mechanism, which affect reparability. Causes are generally classified as ischaemic (mitral regurgitation due to consequences of coronary disease, not fortuitous association of both) and non-ischaemic (all other causes). Mechanisms are grossly classified as functional (mitral valve is structurally normal and disease results from valve deformation caused by ventricular remodelling) or organic (intrinsic valve lesions). They can be subclassified by leaflet movement (Carpentier's classification)—type I (normal valve movement, such as annular dilatation or leaflet perforation); type II (excessive movement); and type III (restrictive movement: IIIa—diastolic restriction such as rheumatic disease; IIIb—systolic restriction as in functional disease). Carpentier also proposed a simple lesion localisation classification.

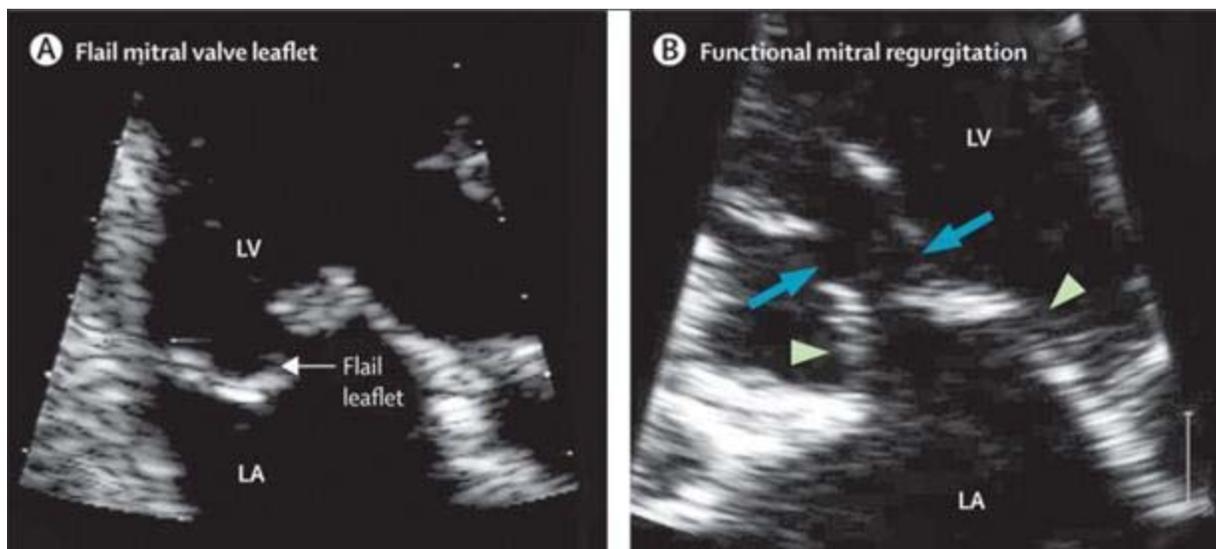

Schematic anatomical mitral-valve presentation

(A) Atrial view of a healthy mitral valve. Posterior leaflet has a shorter length but occupies a longer circumference than the anterior leaflet. Mitral annulus around the leaflet is part of the aortic-mitral fibrosa superiorly, is asymmetric, and short in its anteroposterior dimension. Leaflet segmentation starts with A1—P1 close to the anterolateral commissure, with A2—P2 centrally, and A3—P3 close to the posteromedial commissure. The normally apposing leaflets make up the mitral smile. (B) Example of a flail posterior leaflet affecting the P2 segment with ruptured chordae. Note the bulge and excess tissue of the flail segment and the annular enlargement mostly along the posterior part of its circumference. (C) Initial step of surgical valve repair. Resection of the flail segment can be triangular (as shown) or quadrangular and leaves the healthy P1 and P3 segments available for reattachment and repair. (D) Posterior leaflet has been restored by approximation of the remaining segment after resection of the flail segment and the mitral annular dimensions have been restored by an annuloplasty ring. In this example an incomplete ring has been used with its extremities sutured to the trigonal regions of the aortic-mitral fibrosa. The mitral smile and competence have been restored.

Major causes of surgical mitral regurgitation in western countries are degenerative (primary myxomatous disease, primary flail leaflets, annular calcification), representing 60—70% of cases, followed by ischaemic mitral regurgitation (20%), endocarditis (2—5%), rheumatic (2—5%), and miscellaneous causes (cardiomyopathies, inflammatory diseases, drug-induced, traumatic, congenital). Ischaemic disease probably represents a large proportion of the

non-surgical disease burden. Nomenclature and mechanisms of major causes are summarised below.

Degenerative mitral regurgitation is usually related to mitral-valve prolapse and rarely to isolated mitral annular calcification. Mitral-valve prolapse is an abnormal systolic valve movement into the left atrium (≥ 2 mm beyond saddle-shaped annular level). This excessive movement can be seen with other causes such as endocarditis. Prolapse might be of moderate magnitude (leaflet tips remain in the left ventricle—ie, billowing mitral valve) or can be severe (eversion of leaflet tip into left atrium—ie, flail leaflet—usually caused by ruptured chordae). The main phenotypes of mitral prolapse are diffuse myxomatous degeneration (mitral-valve prolapse syndrome or Barlow's disease, sometimes with posterior annular translocation into left atrium) or primary flail leaflets with ruptured chordae affecting the posterior leaflet in 70% of cases, and accompanied by myxomatous degeneration localised to the flail segment and generally normal valve morphology elsewhere. Myxomatous degeneration remodels valve tissue by increasing the spongiosa layer and valve water content and thickness, with mucopolysaccharide and matrix changes, as a functional manifestation of metalloproteinase alterations. These mitral tissue changes and prolapse might be genetically transmitted and X-chromosome linked. Degenerative mitral regurgitation is the most reparable form, warranting early and careful assessment.

Echocardiographic appearance of the two main anatomical types of mitral regurgitation from apical views centred on the mitral valve

(A) An example of a flail posterior leaflet with the tip of the leaflet floating in the left atrium. Note the otherwise grossly normal anterior leaflet. (B) An example of functional mitral regurgitation. Strut chordae (long arrows) to the anterior and posterior leaflets exert an abnormal traction on the body of the leaflets, which displaces (arrowheads) the leaflets towards the ventricular apex, creating an area of tenting above the mitral annulus and an incomplete coaptation. LA=left atrium. LV=left ventricle.

The ischaemic form of this disease rarely results from an organic mechanism (papillary-muscle rupture) and is rarely acute. Frequently, it is functional (structurally normal leaflets) and chronic, epitomising left-ventricular disease that causes valvular dysfunction. Papillary-muscle dysfunction plays little part in the generation of functional mitral regurgitation, which is mostly caused by apical and inferior-papillary-muscle displacement due to ischaemic left-ventricular remodelling. Because chordae are non-extensible, papillary-muscle displacement exerts traction on leaflets through strut chordae implanted on the body of leaflets, resulting in tethered and apically displaced leaflets (tenting). Coupled with annular flattening, enlargement, and decreased contraction, mitral valve tenting results in coaptation loss that yields functional mitral regurgitation. Asymmetric tenting due to regional scarring (inferior infarction) might explain commissural jets of ischaemic disease. Rheumatic mitral regurgitation—past the acute phase—causes chordal and leaflet retraction, which, amplified by annular dilatation, results in coaptation loss. Postinflammatory and postradiation mitral regurgitations have similar mechanisms. Retraction of tissue is a major limitation to successful valve repair.

Endocarditic mitral regurgitation might be caused by ruptured chordae or perforations. In all causes, annular enlargement is common, is located mostly or exclusively on the posterior part of the annular circumference, and surgical repair almost always requires annuloplasty.

Pathophysiology and progression

The degree of mitral regurgitation is defined by lesion severity (measured as effective regurgitant orifice [ERO] area) and the yielding volume overload (measured as regurgitant volume [RVol]), but it is also affected by the driving force (left-ventricular systolic pressure) and left-atrial compliance.⁵ Thus, in acute disease, the large regurgitant orifice converts ventricular energy mostly into potential energy (left-atrial pressure V-wave) due to non-compliant left atrium. In chronic regurgitation, the enlarged left atrium is compliant, the V-wave is often small, and ventricular energy is converted mostly into kinetic energy (large RVol). This process of atrial enlargement and increased compliance probably explains atrial pressure reduction and clinical improvement after initial heart failure caused by acute mitral regurgitation.

The ERO area is not necessarily fixed and can be dynamic. Increased loading or contractility can cause the ERO area to increase or decrease slightly. With valve prolapse, the area is very dynamic, increasing progressively during systole, and is sometimes purely end-systolic. In

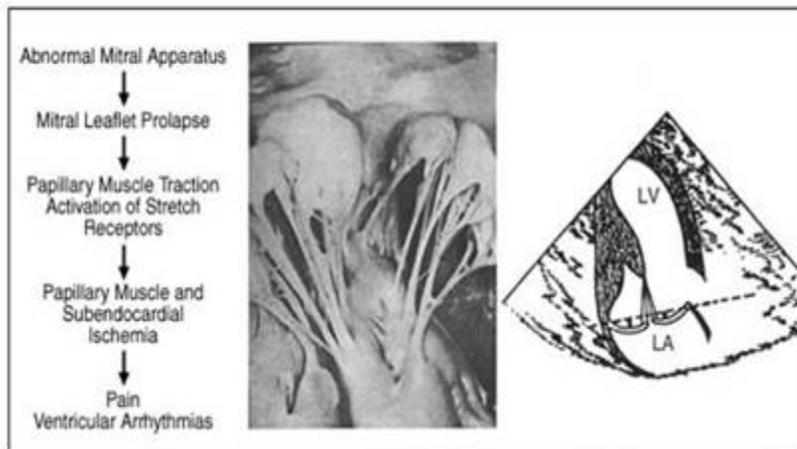

functional mitral regurgitation, ERO area is dynamic during systole, with large area during short isovolumic contraction and relaxation phases caused by lesser ventricular pressure apposing leaflets. This type of regurgitation is also dynamic with decreased loading or inotrope administration, and might disappear with these interventions, whereas exercise most often results in augmentation of ERO area. Long-term progression of organic disease is about 5—7 mL per year for RVol and is determined by ERO area progression caused by new lesions or annular enlargement. Thus, mitral regurgitation is self-sustained, causing atrial and annular enlargement, which in turn leads to increased ERO area.

The ventricular and atrial consequences of organic mitral regurgitation are initiated by volume overload with increased preload and left-ventricular and left-atrial enlargement. Impedance to ejection is reduced despite normal or increased vascular resistances, whereas myocardial afterload (end-systolic wall stress) is normal with an end-systolic volume that is normal to slightly increased. Thus, in organic disease, altered left-ventricular function might coexist with normal or high ejection fraction. Borderline normal ejection fraction, between 50—60%, already implies overt left-ventricular dysfunction. Ventricular dysfunction should be suspected when end-systolic dimensions are large but is often masked by a large ejection volume and is revealed after surgical elimination of mitral regurgitation, with a postoperative average immediate ejection fraction drop of about 10%. Diastolic ventricular dysfunction is difficult to characterise, but seems to reduce exercise capacity.

Physiology of functional mitral regurgitation is even more complex than that of organic mitral regurgitation since ventricular dysfunction predates the regurgitation. Nevertheless, functional mitral regurgitation further increases atrial pressure, which leads to pulmonary hypertension and heart failure. With increased atrial pressure and low driving force, functional regurgitation often has low RVol and can be silent.

Mitral Valve Prolapse

Long Axis View of the
Same Valve Illustrated in Figure 13

Whether functional regurgitation affects remodelling and dysfunction is uncertain but is suspected because of the high mortality associated with increased severity of mitral regurgitation.

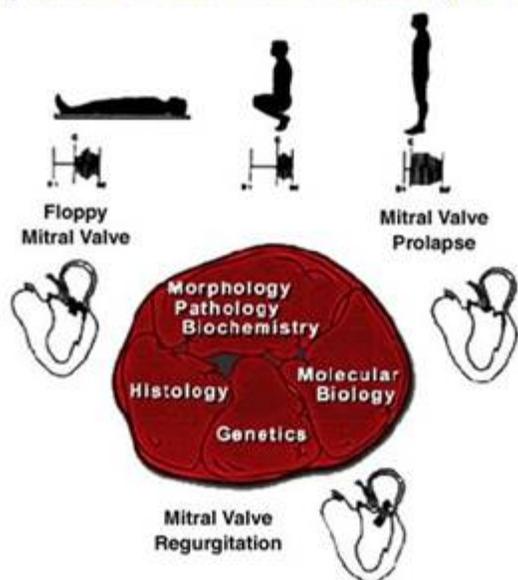

Progression or recurrence after annuloplasty is weakly related to annular enlargement but strongly to increased mitral tenting caused by ventricular remodelling, papillary-muscle displacement, and increased chordal traction; however, rates of progression are unknown.

Assessment

Initial clinical assessment looks for symptoms, signs of heart failure, and physical signs of severe mitral regurgitation—ie, displaced apical impulse, systolic thrill, loud systolic murmur, S3, early diastolic rumble, and cardiomegaly with left-atrial enlargement on chest radiography

and atrial fibrillation. These signs are important but not specific enough to rely solely on them to suggest surgery.

Spectrum of Mitral Valve Disease (1 of 2)

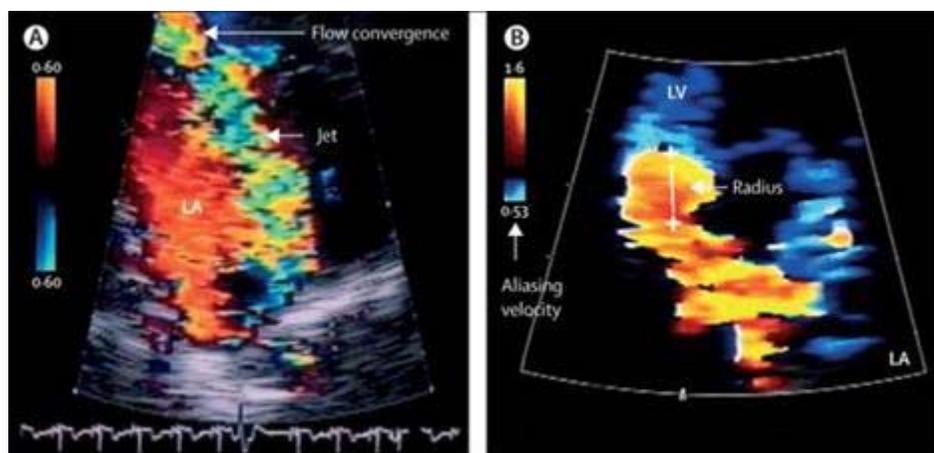

Prognosis in Mitral Valve Prolapse

- Often benign
- Rare complications
 - Endocarditis
 - Progressive MR
 - Acute
 - Chronic
 - Thromboembolism
 - Atrial and ventricular arrhythmias

Doppler echocardiography is the main method for assessment of patients with mitral regurgitation. Transthoracic or transoesophageal echocardiography provides functional anatomical information that is crucial for assessment of reparability by defining cause, mechanism, presence of calcification, and localisation of lesions. Transoesophageal echocardiography provides better imaging quality than transthoracic echocardiography but its ability to detect details such as ruptured chordae rarely changes management. Transoesophageal echocardiography essentially provides incremental clinically meaningful information (such as reparability) when transthoracic echocardiography is of poor quality or when complex,

calcified, or endocarditic lesions are suspected. Thus, transoesophageal echocardiography is rarely used on an outpatient basis and is mostly used intraoperatively for lesion verification and to monitor surgical results. Real-time three-dimensional echocardiography has at present insufficient image resolution but pilot data suggest that it allows quantitative assessment of structures that are not easily measurable by two-dimensional echocardiography, such as mitral annulus. Although emerging technologies such as transoesophageal echocardiography three-dimensional imaging have great potential, they need to be rigorously tested.

Doppler echocardiography provides crucial information about mitral regurgitation severity (table). Comprehensive integration of colour-flow imaging and pulsed and continuous wave doppler echocardiography is necessary because jet-based assessment has major limitations (figure). Quantitative assessment of regurgitation is feasible by three methods—quantitative doppler echocardiography based on mitral and aortic stroke volumes, quantitative two-dimensional echocardiography based on left-ventricular volumes, and flow-convergence analysis measuring flow with colour-flow imaging proximal to the regurgitant orifice (proximal isovelocity surface area method; figure). These methods allow measurement of ERO area and RVol and have important prognostic value. Severe mitral regurgitation is diagnosed with an ERO area of at least 40 mm² and RVol of at least 60 mL per beat; and moderate regurgitation with ERO area 20—39 mm² and RVol 30—59 mL per beat. Outcome data suggest that a smaller volume mitral regurgitation and smaller ERO area (≥ 30 mL and ≥ 20 mm², respectively) are associated with severe outcome in patients with ischaemic disease; therefore, thresholds for severe disease are cause-dependent. Consistency in all measures of mitral regurgitation severity is essential to appropriately grade disease severity (table). Haemodynamic assessment is completed with doppler measurement of cardiac index and pulmonary pressure.

Use of colour-flow imaging for assessment of mitral regurgitation

(A) Jet imaging in left atrium. The jet is eccentric and is displayed with mosaic colours, whereas the normal

flow is of uniform colour. It fills only part of the left atrium and might underestimate the regurgitation. The observation of a large flow convergence should lead to suspicion of severe regurgitation. (B) Measurement of the flow convergence with colour-flow imaging. The baseline of the colour scale has been brought down to decrease the aliasing velocity to 53 cm/s (velocity at the blue-yellow border), which allows the flow convergence (yellow) to be seen. The radius (r) of the flow convergence is used in the formula for calculation of the instantaneous regurgitant flow (258 mL/s). $\text{Flow} = 6.28 \times V_{\text{aliasing}} \times r^2 = 6.28 \times 53 \times 0.882 = 258 \text{ mL/s}$. Division of this value by the jet velocity allows calculation of the effective regurgitant orifice of mitral regurgitation.

LA=left atrium. LV=left ventricle.

Doppler echocardiography also measures left-ventricular and left-atrial consequences of mitral regurgitation. End-diastolic left-ventricular diameter and volume indicate volume overload whereas end-systolic dimension shows volume overload and ventricular function. Patients with left-ventricular ejection fraction less than 60% or end-systolic diameter of at least 40—45 mm are regarded as having overt left-ventricular dysfunction. Left-atrial diameter indicates volume overload but also conveys important prognostic information. Left-atrial volume was recommended as the preferred measure of atrial overload, (at least 40 mL/m² for severe dilatation) and predicts the occurrence of atrial fibrillation.

Exercise tests are used to define functional capacity. One in five asymptomatic patients shows severe functional limitations during cardiopulmonary exercise. Peak oxygen consumption compared with that expected for age, sex, and weight objectively measures functional limitations versus normal reference values. Other exercise modalities, such as supine-bike exercise, examine changes in severity of mitral regurgitation with activity, especially seen in ischaemic and functional disease and might reveal poor prognosis when ERO area increases. Standard postexercise echocardiography was used to detect exertional ventricular volume increase as a predictor of postoperative left-ventricular dysfunction, but difficulties in measurement of monoplane ventricular volumes hinder this approach. Other stress tests are rarely used. Dobutamine echocardiography reduces mitral regurgitation universally, but in selected patients with ischaemic disease it might reveal viability and ischaemia.

MRI shows mitral regurgitation jets, with limitations similar to those of colour-flow imaging; quantitative measurements are possible but validation studies are few. This imaging method is unique in revealing ventricular scars and in assessment of viability in ischaemic disease and is useful in measurement of ventricular volumes but its incremental diagnostic role remains unknown.

Detection of hormonal activation is important in many cardiac diseases. Atrial natriuretic peptide has little specificity for mitral regurgitation and is strongly activated by arrhythmias, irrespective of mitral regurgitation severity. B-type natriuretic peptide is of greater value than atrial natriuretic peptide in patients with regurgitation. Its activation in organic disease is

determined by the consequences—mostly left-atrial enlargement, symptoms, rhythm, and left-ventricular function—rather than the severity of regurgitation. Importantly, its activation is associated with poor outcome and should alert clinicians. Strong B-type natriuretic peptide activation is noted in functional mitral regurgitation linked to the severity of end-systolic ventricular changes and of mitral regurgitation. Subtle sympathetic activation and altered β receptors in organic disease might indicate left-ventricular dysfunction but are usually less prominent than in functional disease.

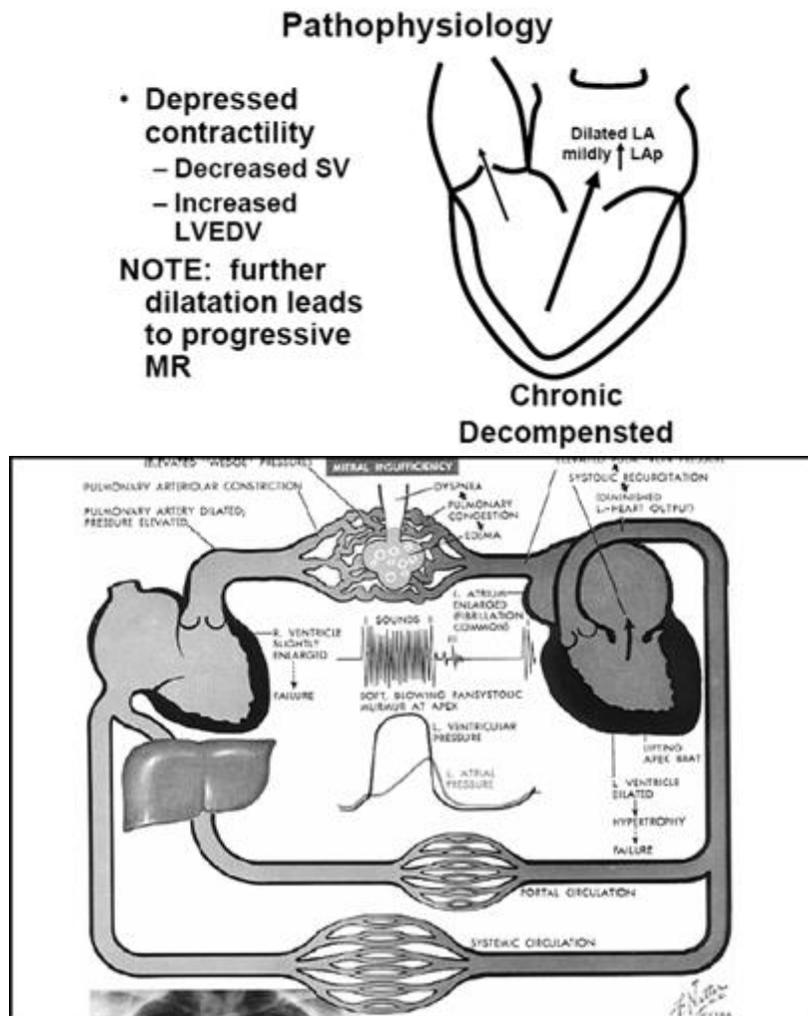

Cardiac catheterisation is not consistently used by institutions and might be overused in some.³ In academic centres, it is rarely used to define haemodynamics, which are usually provided by doppler echocardiography. Left ventriculography and right-heart catheterisation are rarely needed for assessment of mitral regurgitation. Conversely, in most patients aged 45 years or older, coronary angiography is routinely done preoperatively.

Natural history and clinical outcome

Although a few prospective studies are available, most data for mitral regurgitation outcome are extracted from observational series. Clinical outcome under medical management and after surgery is different in organic and functional disease.

Natural history of organic regurgitation has been poorly defined, largely because of limitations in severity assessment. Old studies, before echocardiography, showed a wide range in 5-year survival rates from 27% to 97%, probably related to variations in severity. Most data (table) were from studies of patients diagnosed with mitral regurgitation due to flail leaflets, most of whom had severe regurgitation. Such patients have ventricular enlargement causing the notable volume overload and incur excess mortality overall; mortality was especially high in patients with class III—IV symptoms but also notable in those with no or minimum symptoms. A sudden death rate of 1.8% per year overall varied from as high as 12.0% per year in patients with class III—IV symptoms who had not undergone surgery to 0.8% per year in asymptomatic patients with normal ejection fraction and sinus rhythm. Patients in some mitral regurgitation subsets have low mortality, such as young patients (<50 years) even with severe mitral regurgitation or those of all ages with initially a moderate disorder. Conversely, in a prospective study of asymptomatic patients with long-term follow-up, those with severe regurgitation proven by quantitative measurements showed increased mortality under medical management.⁹ Thus, older patients (≥ 50 years) with severe (defined as ERO area ≥ 40 mm²) organic mitral regurgitation are at increased risk of mortality (yearly rates of about 3% for moderate regurgitation vs 6% for the severe organic form). For morbid complications, all studies substantiated the adverse effect of severe regurgitation. Patients with flail leaflet and in general

those with severe mitral regurgitation had, under medical management, yearly cardiac event rates of 10—12%—including about 9% for heart failure and 5% for atrial fibrillation. Within 10 years of diagnosis, cardiac events arise in most patients with severe mitral regurgitation, and death occurs or cardiac surgery is needed in at least 90%, making surgery an almost unavoidable consideration in such patients. The risk of stroke is low, but in excess of that expected in old patients and is strongly linked to occurrence of atrial fibrillation, and thus to left-atrial size. Predictors of reduced survival under medical management are symptoms (class III or IV), even if transient, reduced ejection fraction, severe mitral regurgitation with ERO area of 40 mm² or more, and hormonal activation, although not as well substantiated. Predictors of cardiac events are atrial fibrillation, left-atrial enlargement of at least 40—50 mm diameter, flail leaflet or large ERO area—all markers of severe mitral regurgitation—and, during exercise, reduced peak oxygen consumption and possibly reduced right ventricular function.

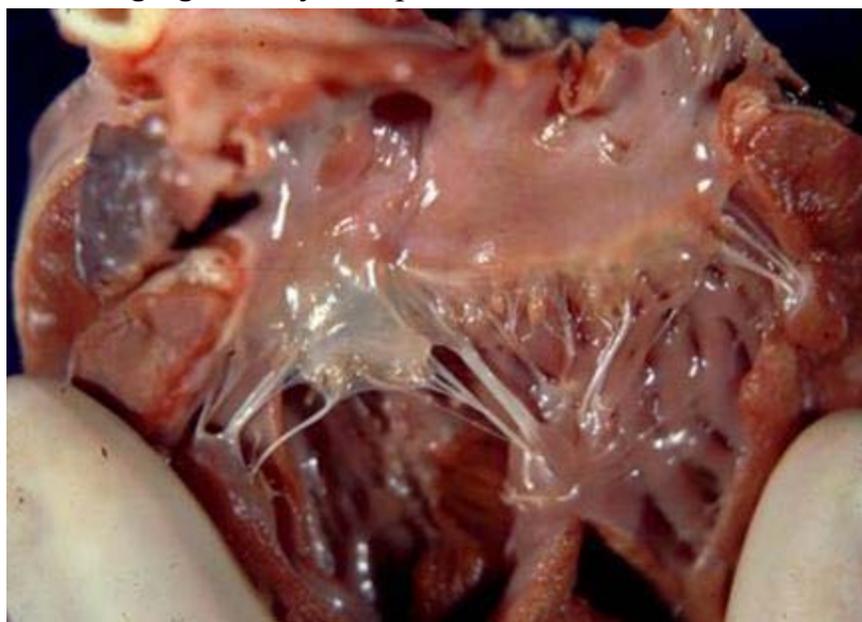

Clinical outcome after surgery depends on patient-specific, disease-related, and surgery-related factors. Early postoperative mortality is largely affected by age, but improvement of surgical results reduced the risk to about 1% for patients younger than 65 years, 2% for those aged

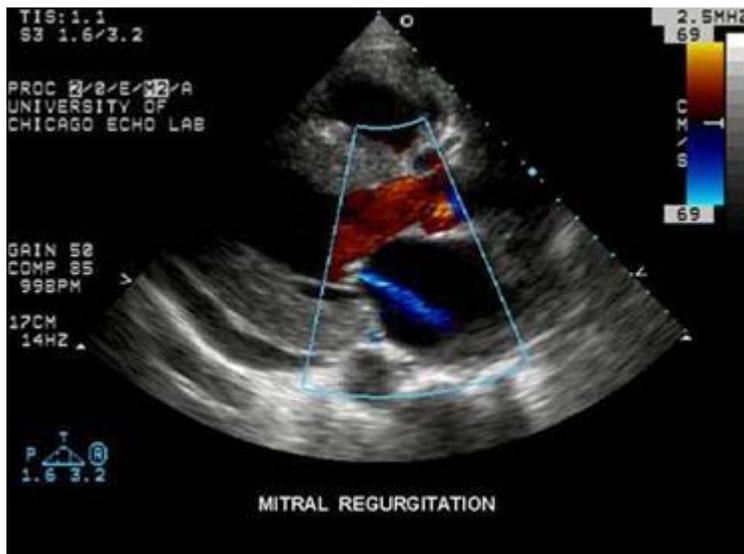

65—75 years, and 4—5% for older than 75 years. Increased surgical risk is also linked to preoperative severe symptoms or heart failure whereas ejection fraction has less effect. Surgery-related determinants of operative risk are governed by mitral reparability, which ensures reduced risk, whereas risk is increased with concomitant coronary artery bypass grafting. Other associated procedures, such as tricuspid repair or replacement, or those aimed at treatment or prevention of atrial fibrillation need a longer bypass time, which can increase risk. Long-term, patient-related factors continue to affect outcome, particularly coronary disease or reduced renal function. Age determines mortality but restoration of life expectancy is similar in young and old patients. After surgery, patients with severe symptoms before surgery continue to have increased mortality despite symptom relief, whereas in those with no or few symptoms, restoration of life expectancy can be achieved. Similarly, patients with overt preoperative ventricular dysfunction have increased postoperative mortality, especially with ejection fraction less than 50%. Generally, a 10% early postoperative reduction in ejection fraction happens after elimination of volume overload, whereas end-systolic characteristics (volume, wall stress) are unchanged. This reduction is lowest after valve repair and is minimised by preservation of subvalvular apparatus during valve replacement. Nevertheless, 25—30% of patients with mitral regurgitation present with postoperative left-ventricular dysfunction, especially those with preoperative ejection fraction of less than 60% or end-systolic diameter at least of 40—45 mm. Occasional unexpected ventricular dysfunctions arise in patients with ejection fraction greater than 60% and no perfect predictor has been identified. Hence, in some centres, prevention of postoperative left-ventricular dysfunction relies on performance of early surgery when no sign of left-ventricular alteration is present.

Coronary disease (even in the absence of angina) increases the risk of left-ventricular dysfunction despite the performance of coronary artery bypass grafting. Although no clinical trial has compared outcomes of patients randomised to repair versus replacement, observational evidence suggests that the major surgical determinant of improved long-term outcome is valve repair, which allows restoration of life expectancy and reduces the risk of heart failure after surgery. Although mitral regurgitation can recur after repair, reoperation rates do not differ after repair compared with replacement. Thus, mitral valve repair is widely regarded as the preferred mode of correction of organic mitral regurgitation, especially degenerative.

For ischaemic mitral regurgitation, the natural history of the functional form is incompletely defined whereas that of papillary-muscle rupture is known to be rapidly fatal. Whether functional regurgitation intrinsically causes poor outcome, or whether it indicates left-ventricular alterations, is still disputed. However, association of severe ischaemic mitral

regurgitation with severe outcomes, independent of ejection fraction, age, and presentation, suggests that the regurgitation is indeed causal of the poor outcome. This prognostic role of mitral regurgitation is now substantiated by results from studies of patients with acute or chronic myocardial infarction, by clinical trials and by population studies. Another important concept is that even modest regurgitation is associated with substantially increased mortality, a fact proved by quantitative data. ERO area of ischaemic mitral regurgitation independently predicts excess mortality. Patients with an area larger than 20 mm² incur about a two-fold increase in mortality risk and about a four-fold increase in the risk of heart failure compared with those with a similar ischaemic left-ventricular dysfunction but no mitral regurgitation. The better predictive value of ERO area than that of RVol is explained by the strong link between ERO area and filling pressure. Increase in ERO area with exercise might additionally affect clinical outcome, survival, and heart failure. Nevertheless, a clinical trial is needed to determine whether surgical correction of the valvular consequence (ischaemic mitral regurgitation) improves mortality and heart failure in this mainly ventricular disease. Clinical outcome of functional disease caused by cardiomyopathy is not well defined but few data suggest that mitral regurgitation yields poor outcomes.

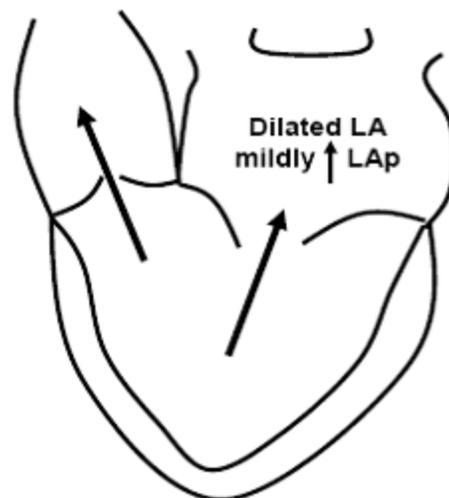

When MR is big, so are the indices:

ECHOinContext

Pathophysiology

 - Increased preload
 - Increased afterload
 - Increased total stroke volume AND forward stroke volume AND LVESV returns to normal
- **Increased LA size**
 - Increased LA compliance
 - Larger volume at lower pressure

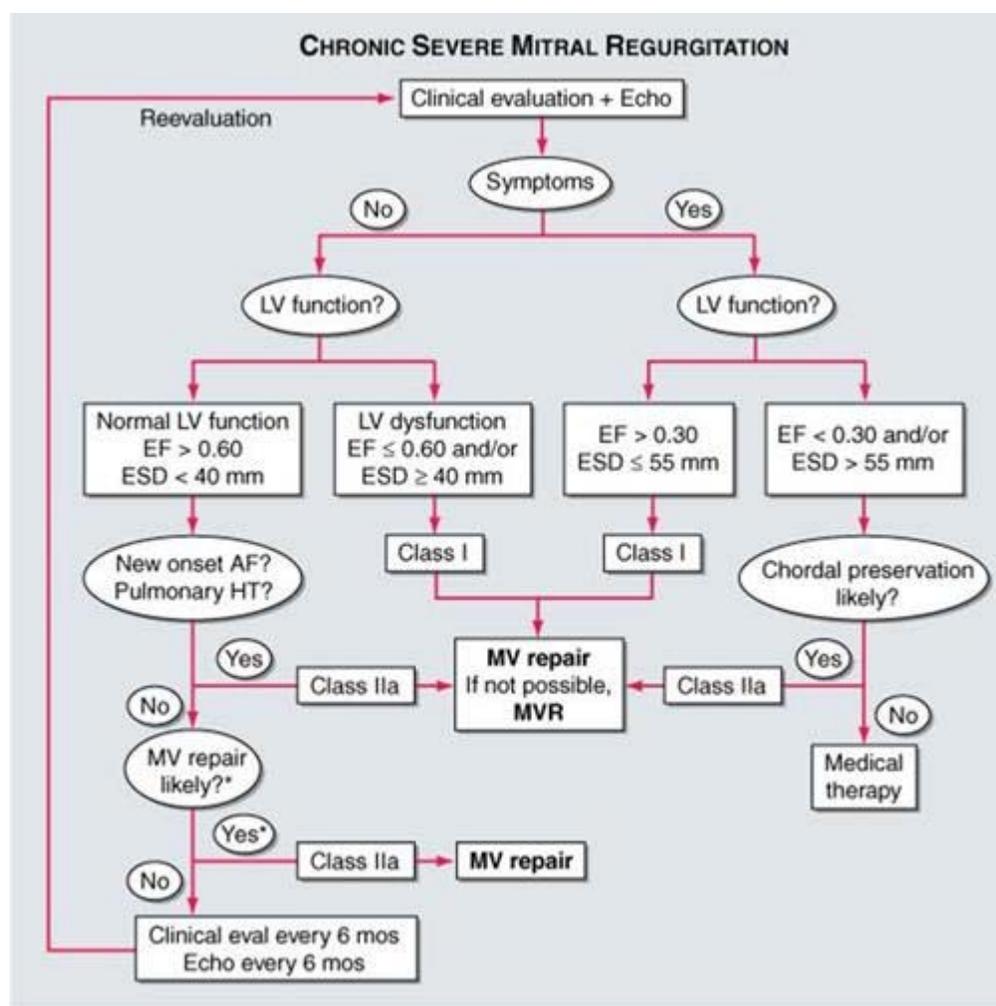

**Chronic
Compensated**

Fig Mitral regurgitation

Outcomes after surgery for functional disease remain suboptimum. Operative mortality is still high despite definite surgical improvements. Long-term mortality and heart failure rates are high, although not unexpected in patients with coronary disease, previous myocardial infarction, reduced ventricular function, and vascular comorbidity. These suboptimum outcomes explain uncertainties in surgical indications. However, with low operative mortality, postoperative heart failure and symptomatic improvements are possible.

Treatment

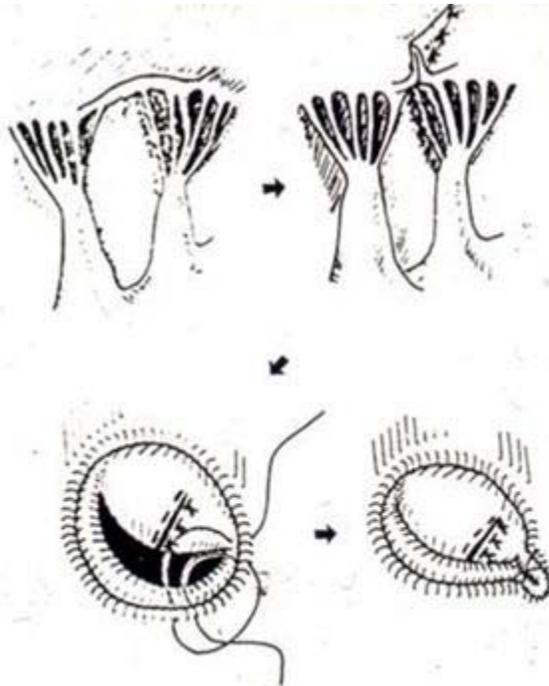

The natural history of untreated organic and functional mitral regurgitation emphasises the importance of treatment of patients with severe regurgitation. Because the effects of various treatments on survival have not been tested in randomised clinical trials, the value of any approach is estimated on the basis of outcome studies.

Treatment of Symptomatic Mitral Regurgitation

- **Medical therapy**
 - Diuretics
 - Vasodilators
 - ACE inhibitors
- **Surgical therapy**
 - **MV replacement**
 - relief of symptoms
 - MVR survival similar to natural history
 - Operative mortality 8-10%
 - 10 year survival 50%
 - **Mitral valve repair**
 - Operative mortality 2-4%
 - 10 year survival 80%
 - Preservation of mitral apparatus!!!!!!!!!!!!!!!
 - No risk of thrombotic complications

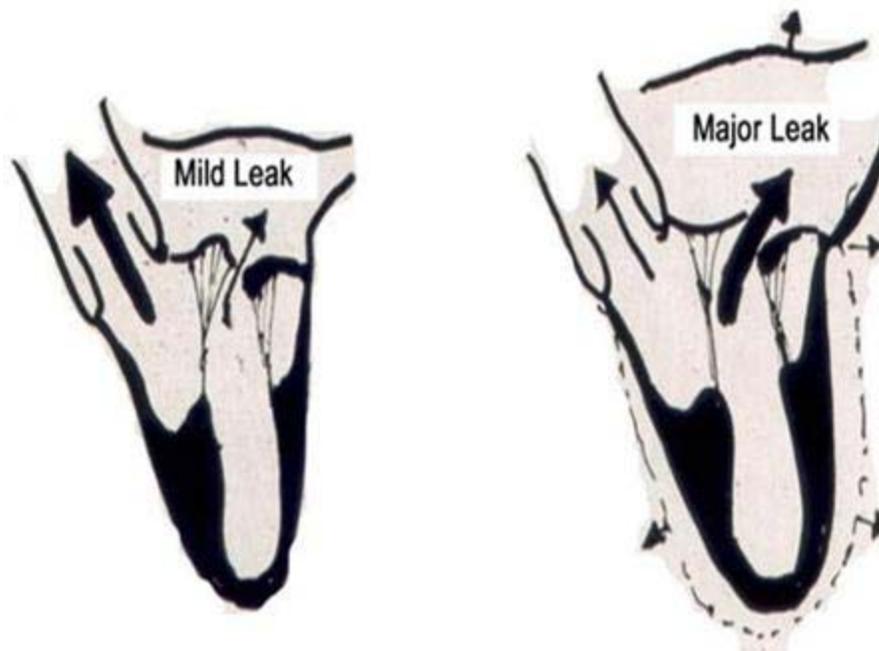

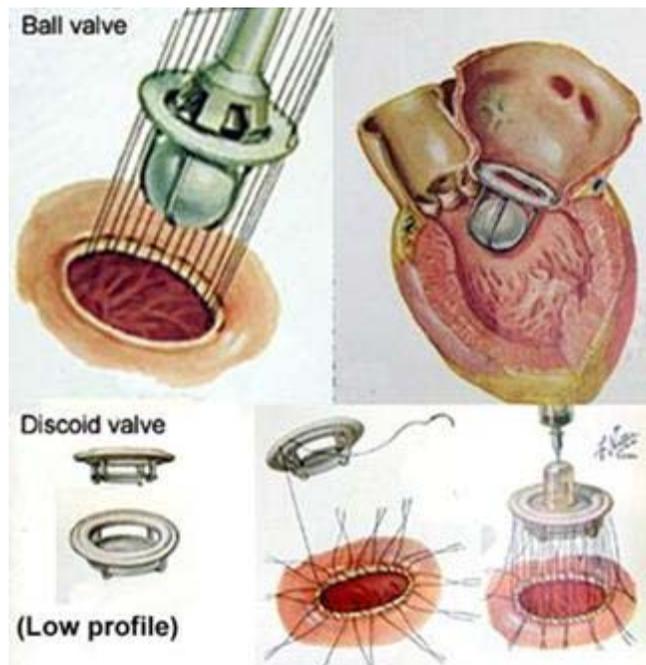

Fig Management strategy for patients with chronic severe mitral regurgitation. *Mitral valve (MV) repair may be performed in asymptomatic patients with normal left ventricular (LV) function if performed by an experienced surgical team and if the likelihood of successful MV repair is >90%. AF, atrial fibrillation; Echo, echocardiography; EF, ejection fraction; ESD, end-systolic dimension; eval, evaluation; HT, hypertension; MVR, mitral valve replacement. (From Bonow *et al.*)

Medical treatment aims to prevent progression of organic disease. Prevention of endocarditis is directed at forestalling catastrophic infectious complications and sudden mitral regurgitation progression associated with endocarditis. Diuretics often reduce or eliminate symptoms of disease but such improvement should not unduly reassure physicians. Patients who had transiently severe symptoms and improved with treatment continue to be at high risk and

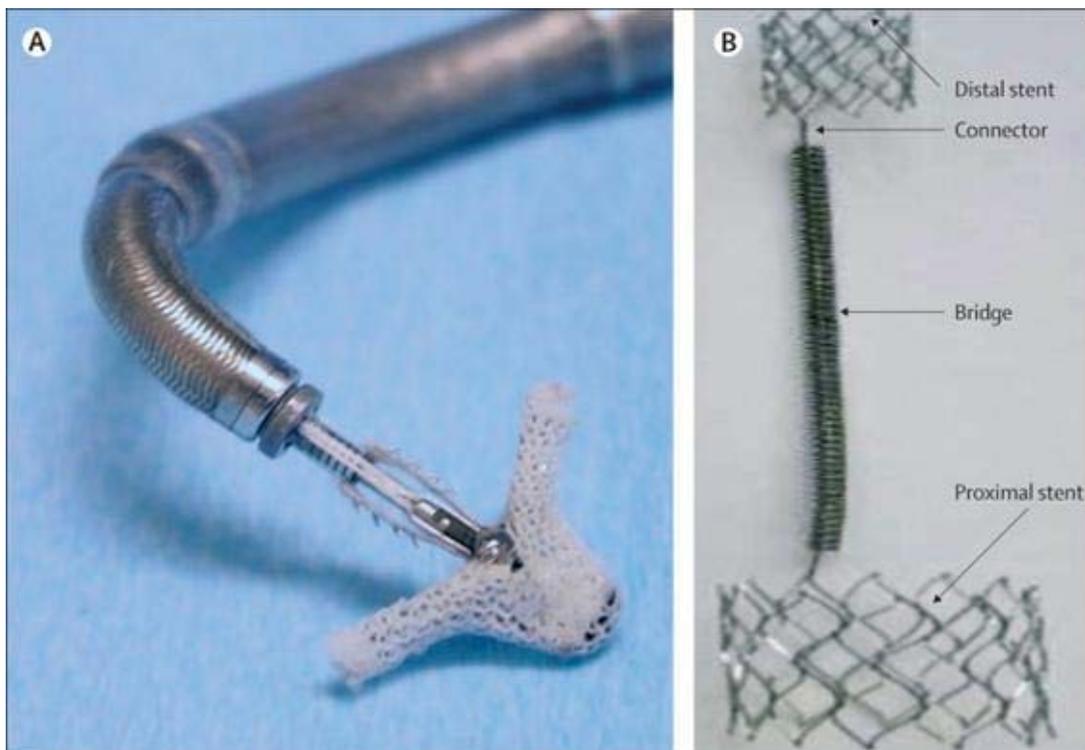

should be promptly assessed for surgery.

Treatment of organic mitral regurgitation with vasodilators has been advocated on the basis of experimental studies showing reductions in acute RVol and even ERO area with blood pressure reduction. Acutely ill patients with mitral regurgitation benefit from vasodilator treatment. However, despite some encouraging data, translation to chronic treatment of organic disease is unresolved because reported series were small, rarely randomised, and contradictory in conclusions. Activation of the tissue (not systemic) renin-angiotensin myocardial system was shown in organic mitral regurgitation. Consistent pilot studies suggest potential of drugs blocking tissue renin-angiotensin system to stabilise organic disease severity and consequences. The effect of such treatments on clinical outcome remains to be shown. β blockade in organic mitral regurgitation has only been tested in animal models and remains conjectural. Conversely, in functional disease, medical treatment has been better studied than in organic disease. Maximum medical treatment of patients with heart failure and left-ventricular dysfunction reduces functional mitral regurgitation. Specifically β blockade—with carvedilol or long-acting metoprolol—and inhibition of angiotensin-converting enzyme reduce functional mitral regurgitation severity. These therapies are recommended for treatment of left-ventricular dysfunction. Thus, non-urgent surgical indications should be reviewed after maximum medical treatment has taken effect.

Interventional treatment is not yet approved for clinical use and remains investigational. Percutaneous revascularisation of patients with ischaemic regurgitation is possible but patients are often left with residual regurgitation that affects prognosis so that more effective treatment is necessary. Resynchronisation treatment in left-ventricular dysfunction with delayed conduction might improve functional mitral regurgitation. Two specific interventional approaches to treatment are discussed here.

Valvular edge-to-edge attachment mimics the surgical procedure proposed by Alfieri and colleagues, creating a tissue bridge between anterior and posterior leaflets. Percutaneously, this technique uses a clip or sutures deployed through trans-septal catheterisation. Experimental studies have shown success and reliable clip or suture placement through the trans-septal approach ([figure](#)). Early trials also suggest safety and feasibility with close echocardiographic guidance in centres with much experience of interventional valvular procedures. Data for how well this intervention works are preliminary but encouraging,¹²⁸ suggesting that more than 80% of patients can be discharged from hospital with a clip, and mild or little mitral regurgitation. A randomised trial comparing percutaneous clip and surgery is in progress. The edge-to-edge technique has important limitations. First, the application of this technique is

restricted to localised prolapse of the central segment of the anterior and posterior leaflets. Second, annular dilatation is not addressed by the procedure and might cause residual regurgitation.

Percutaneous devices used for treatment of mitral regurgitation

(A) Percutaneous clip introduced by venous and trans-septal approach into the left atrium and through the mitral orifice. The clip then grabs both leaflets, resuspending them with prolapse. (B) Percutaneous coronary sinus cinching device introduced through the jugular vein into the coronary sinus. The distal stent (smallest) then the proximal stent are deployed. With time the bridge shrinks and cinches the annulus.

Annuloplasty aimed at reduction of annular dilatation is under investigation mostly with coronary sinus cinching. Technically, stabilisation of material with sufficient constraining force to obtain more than 20% diameter reduction is a challenge. Most devices are composed of anchoring devices placed in the distal and proximal coronary sinus and an intermediate tensioning or supporting element. Experimentally, reduction of mitral regurgitation is achievable, but clinical results are preliminary. Feasibility through a jugular approach and safety seem to be acceptable. Potential limitations are those of annuloplasty (incomplete valve tenting correction) and those of coronary sinus approach that might reduce only part of the annular circumference with an effectiveness limited by the 1–2 cm sinus-annular distance. Because of safety concerns related to proximity of the coronary sinus and circumflex artery with potential artery compression, non-coronary sinus approaches to annuloplasty and

percutaneous ventricular remodelling-constraint devices are being investigated.

On the basis of the success of balloon valvuloplasty for mitral stenosis, percutaneous treatment of mitral regurgitation is expected to be successful but this success will necessitate complex development that needs strong cardiologist—engineer collaboration and rigorous assessment.

Surgical treatment of mitral regurgitation is the only approach with defined clinical success, providing sustained relief of symptoms or heart failure. However, no randomised trial has been done to prove mortality or cardiac event reduction. The standard surgical approach is a median sternotomy, but sometimes only partial sternotomy or minimally invasive surgery through thoracoscopic approach can be used.

Valve repair includes an array of valvular, subvalvular, and annular procedures aimed at restoration of leaflet coaptation (ie, valvular normal function) and elimination of mitral regurgitation. These surgical techniques are more successful with redundant than with retracted or calcified leaflets. For valve prolapse, typical repair is resection (triangular or quadrangular) of the prolapsed posterior leaflet segment whereas the anterior leaflet is rarely resected. Subvalvular support can be obtained by chordal transfer or artificial chords rather than chordal shortening. Annuloplasty is routinely used with annular bands or flexible or rigid rings. Many additional technical procedures might be used at the surgeon's discretion to restore coaptation and valve competence. Conversely, in functional mitral regurgitation, valve repair is rather uniform with restrictive annuloplasty substantially reducing the anteroposterior annular diameter. New rings aimed at annular reshaping, specific to each cause of functional regurgitation (ischaemic disease or cardiomyopathy) are now available but their incremental value (compared with traditional rings) is not defined. Valve repair is done in about half of patients who undergo surgery for mitral regurgitation in the USA and Europe. In centres with surgeons proficient in valve repair, more than 80—90% repair rates are achieved. A failed repair is caused rarely by systolic anterior motion of the mitral valve due to excessively redundant tissue or by stenosis, but more often by insufficient correction of a prolapse, recurrence of ruptured chords, and excessive tissue retraction or resection. Overall, reoperation after 10 years is necessary in 5% of patients with repaired posterior leaflet prolapse and 10% of those with anterior leaflet interventions. 20—30% of patients with repaired functional mitral regurgitation are estimated to have recurrent regurgitation. Reoperation rate is not greater after valve repair than after replacement and because of the morbidity and mortality advantages, valve repair is the preferred method of surgical correction of mitral regurgitation.

Valve replacement involves insertion of a biological or mechanical prosthesis. Bioprosthetic valve replacement is associated with low embolic risk but shorter durability, whereas

mechanical valve replacement is associated with high risk of embolism and haemorrhagic complications (due to intensive warfarin treatment) but has potential for long-lasting durability. Results of randomised trials showed that within 10 years of surgery these risks are balanced. Older age determines the probability that bioprosthetic durability will be longer than life expectancy, and is the main bioprosthesis insertion indication (usually >65 years of age). Ability to achieve high-quality anticoagulation and patient's desire also affect the choice of prosthesis. Irrespective of the prosthesis selected, conservation of subvalvular apparatus is essential for preservation of ventricular function. The risk of prosthetic complications makes surgical indications more restrictive when valve replacement is likely.

Controversies and guidelines for treatment

In view of the experimental nature of medical and interventional treatments for mitral regurgitation, surgery is the only treatment recommended by management guidelines. Because surgery is associated with small but definite risks, those patients with a higher risk of spontaneous complications than of surgery-related complications are selected. Guidelines should, in our opinion, be interpreted as a minimum to be applied by all physicians but should not deter centres with better results than those of other centres from providing advanced care to patients with mitral regurgitation. Furthermore, the absence of clinical trials and few prospective studies create ample controversy, which should be addressed in future studies.

Although approaches to surgical indications are detailed in clinical guidelines, they are summarised here. Rescue surgical indications—class I by guidelines—are compulsory. Patients with organic mitral regurgitation who have developed severe symptoms (class III or IV), heart failure, or signs of overt left-ventricular dysfunction (ejection fraction <60% or end-systolic dimension ≥ 40 –45 mm) have an immediate high risk and therefore prompt surgery—repair (preferable) or replacement—is indicated. Even with advanced heart failure or ventricular dysfunction, contraindications to surgery are rare as long as mitral regurgitation remains severe, emphasising the importance of quantitative assessment of disease. Such rescue surgery is indispensable, but is not the preferred timing for surgery in organic disease. Indeed, patients who need to be operated on at such a late stage of their disease have increased mortality after surgery. This outcome emphasises the importance of early detection and assessment of mitral regurgitation. In functional regurgitation, rescue surgery is the most frequent surgical indication, but consideration should be given to surgery in symptomatic patients before heart failure becomes intractable.

Restorative surgical indications—class II by guidelines—are optional. Patients with no or minimum symptoms at baseline cannot expect substantial symptomatic improvement. Those with functional mitral regurgitation are rarely candidates for restorative surgery while asymptomatic but might be suitable for valve repair if coronary artery bypass grafting is necessary independently of the mitral regurgitation. In organic regurgitation, postoperative outcome studies in patients with no or minimum symptoms before surgery show restoration of life expectancy, emphasising the importance of this approach. Patients who are asymptomatic but had either reduced functional capacity by objective exercise testing, hormonal activation, or paroxysmal atrial fibrillation are specific but not exclusive candidates for restorative surgery.

Mitral stenosis

Etiology and Pathology

Rheumatic fever is the leading cause of mitral stenosis (MS) (Table). Other less common etiologies of obstruction to left atrial outflow include congenital mitral valve stenosis, cor triatriatum, mitral annular calcification with extension onto the leaflets, systemic lupus erythematosus, rheumatoid arthritis, left atrial myxoma, and infective endocarditis with large

vegetations.

Mitral Stenosis

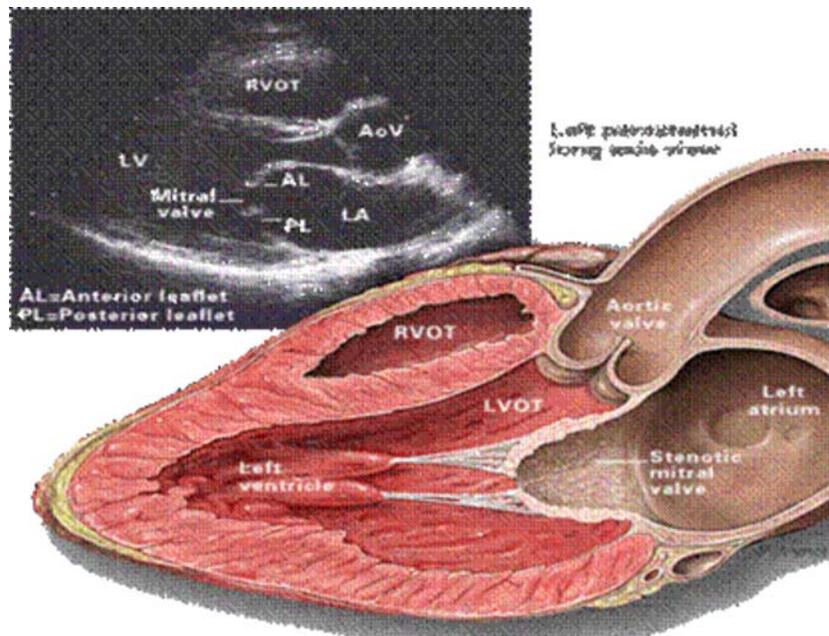

Etiologies

- **Rheumatic** – almost all cases in adults
- **Mitral Annular Ca+ - massive (rare)**
- **Congenital** – rare

60% of pts don't have a history of ARC
50% of pts who have ARC don't develop VHD

Pure or predominant MS occurs in approximately 40% of all patients with rheumatic heart disease and a history of rheumatic fever. In other patients with rheumatic heart disease, lesser degrees of MS may accompany mitral regurgitation (MR) and aortic valve disease. With reductions in the incidence of acute rheumatic fever, particularly in temperate climates and developed countries, the incidence of MS has declined considerably over the past few decades. However, it remains a major problem in developing nations, especially in tropical and

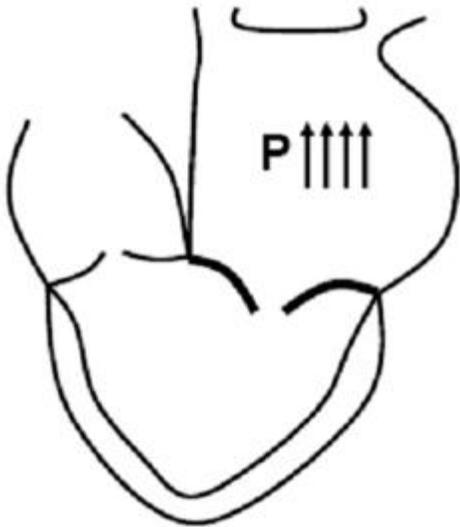

semiotropical climates.

In rheumatic MS, the valve leaflets are diffusely thickened by fibrous tissue and/or calcific deposits. The mitral commissures fuse, the chordae tendineae fuse and shorten, the valvular cusps become rigid, and these changes, in turn, lead to narrowing at the apex of the funnel-shaped ("fish-mouth") valve. Although the initial insult to the mitral valve is rheumatic, the later changes may be a nonspecific process resulting from trauma to the valve caused by altered flow patterns due to the initial deformity. Calcification of the stenotic mitral valve immobilizes the leaflets and narrows the orifice further. Thrombus formation and arterial embolization may arise from the calcific valve itself, but in patients with atrial fibrillation (AF), thrombi arise more frequently from the dilated left atrium (LA), particularly the left atrial appendage.

Pathophysiology

In normal adults, the area of the mitral valve orifice is 4–6 cm². In the presence of significant obstruction, i.e., when the orifice area is reduced to < ~2 cm², blood can flow from the LA to the left ventricle (LV) only if propelled by an abnormally elevated left atrioventricular pressure gradient, the hemodynamic hallmark of MS.

Normal MV area = 4-6cm²
Symptoms begin = < 2cm²
Critical MS = < 1cm²

When the mitral valve opening is reduced to $<1 \text{ cm}^2$, often referred to as "severe" MS, a LA pressure of $\sim 25 \text{ mmHg}$ is required to maintain a normal cardiac output (CO). The elevated pulmonary venous and pulmonary arterial (PA) wedge pressures reduce pulmonary compliance, contributing to exertional dyspnea. The first bouts of dyspnea are usually precipitated by clinical events that increase the rate of blood flow across the mitral orifice, resulting in further elevation of the LA pressure (see below).

Symptoms of Mitral Stenosis

- **Dyspnea**
 - Pulmonary venous congestion
- **Fatigue**
 - Diminished cardiac output
- **Inability to tolerate increased volume**
- **Inability to tolerate increased HR**
 - Decreased filling
 - Increased LA pressure/PV congestion
- **Hemoptysis**

Pulmonary Hypertension

The clinical and hemodynamic features of MS are influenced importantly by the level of the PAP. Pulmonary hypertension results from: (1) passive backward transmission of the elevated LA pressure; (2) pulmonary arteriolar constriction, which presumably is triggered by LA and pulmonary venous hypertension (reactive pulmonary hypertension); (3) interstitial edema in the walls of the small pulmonary vessels; and (4) organic obliterative changes in the pulmonary vascular bed. Severe pulmonary hypertension results in RV enlargement, secondary tricuspid regurgitation (TR) and pulmonic regurgitation (PR), as well as right-sided heart failure.

Symptoms

In temperate climates, the latent period between the initial attack of rheumatic carditis (in the increasingly rare circumstances in which a history of one can be elicited) and the development of symptoms due to MS is generally about two decades; most patients begin to experience disability in the fourth decade of life. Studies carried out before the development of mitral valvotomy revealed that once a patient with MS became seriously symptomatic, the disease progressed continuously to death within 2–5 years.

In patients whose mitral orifices are large enough to accommodate a normal blood flow with only mild elevations of LA pressure, marked elevations of this pressure leading to dyspnea and cough may be precipitated by sudden changes in the heart rate, volume status, or CO, as for

example with severe exertion, excitement, fever, severe anemia, paroxysmal AF and other tachycardias, sexual intercourse, pregnancy, and thyrotoxicosis. As MS progresses, lesser stresses precipitate dyspnea, and the patient becomes limited in daily activities, and orthopnea and paroxysmal nocturnal dyspnea develop. The development of permanent AF often marks a turning point in the patient's course and is generally associated with acceleration of the rate at which symptoms progress.

Pulmonary Changes

In addition to the aforementioned changes in the pulmonary vascular bed, fibrous thickening of the walls of the alveoli and pulmonary capillaries occurs commonly in MS. The vital capacity, total lung capacity, maximal breathing capacity, and [oxygen](#) uptake per unit of ventilation are reduced. Pulmonary compliance falls further as pulmonary capillary pressure rises during exercise.

Physical Findings

Inspection and Palpation

In patients with severe MS, there may be a malar flush with pinched and blue facies. In patients with sinus rhythm and severe pulmonary hypertension or associated tricuspid stenosis (TS), the jugular venous pulse reveals prominent *a* waves due to vigorous right atrial systole. The systemic arterial pressure is usually normal or slightly low. An RV tap along the left sternal border signifies an enlarged RV. A diastolic thrill may be present at the cardiac apex, with the patient in the left lateral recumbent position.

Auscultation

The first heart sound (S_1) is usually accentuated and slightly delayed. The pulmonic component of the second heart sound (P_2) also is often accentuated, and the two components of the second heart sound (S_2) are closely split. The opening snap (OS) of the mitral valve is most readily audible in expiration at, or just medial to the cardiac apex. This sound generally follows the sound of aortic valve closure (A_2) by 0.05–0.12 s. The time interval between A_2 and OS varies inversely with the severity of the MS. The OS is followed by a low-pitched, rumbling, diastolic murmur, heard best at the apex with the patient in the left lateral recumbent position. It is accentuated by mild exercise (e.g., a few rapid sit-ups) carried out just before auscultation. In general, the duration of this murmur correlates with the severity of the stenosis

in patients with preserved CO. In patients with sinus rhythm, the murmur often reappears or becomes louder during atrial systole (presystolic accentuation). Soft grade I or II/VI systolic murmurs are commonly heard at the apex or along the left sternal border in patients with pure MS and do not necessarily signify the presence of MR. Hepatomegaly, ankle edema, ascites, and pleural effusion, particularly in the right pleural cavity, may occur in patients with MS and RV failure.

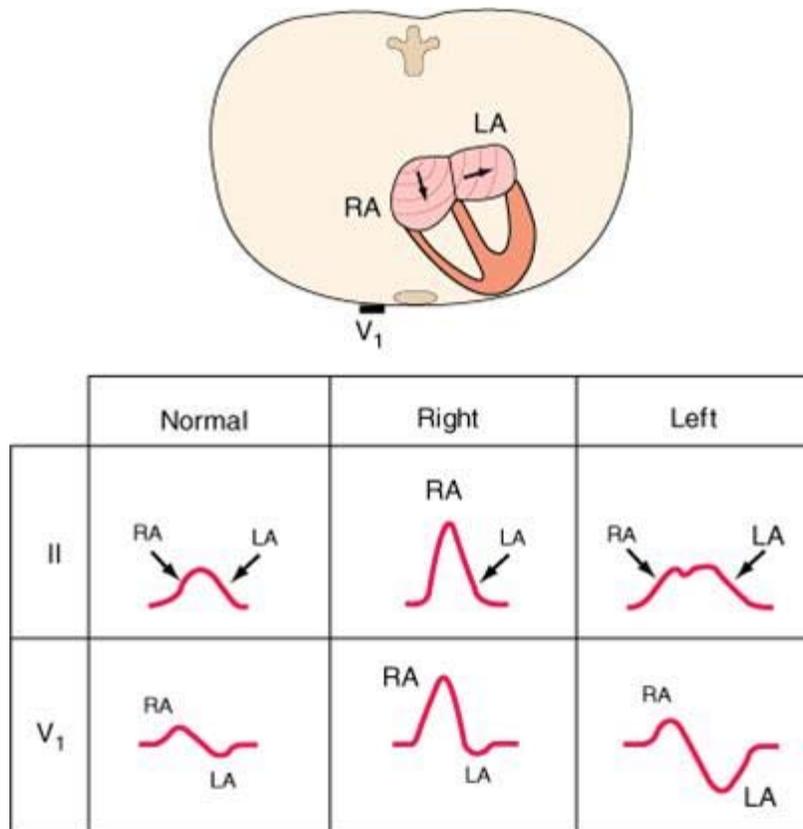

Associated Lesions

With severe pulmonary hypertension, a pansystolic murmur produced by functional TR may be audible along the left sternal border. This murmur is usually louder during inspiration and diminishes during forced expiration (Carvallo's sign). When the CO is markedly reduced in MS, the typical auscultatory findings, including the diastolic rumbling murmur, may not be detectable (silent MS), but they may reappear as compensation is restored. The *Graham Steell murmur* of PR, a high-pitched, diastolic, decrescendo blowing murmur along the left sternal border, results from dilatation of the pulmonary valve ring and occurs in patients with mitral valve disease and severe pulmonary hypertension. This murmur may be indistinguishable from the more common murmur produced by aortic regurgitation (AR), though it may increase in intensity with inspiration and is accompanied by a loud P2.

Laboratory Examination

ECG

In MS and sinus rhythm, the P wave usually suggests LA enlargement. It may become tall and peaked in lead II and upright in lead V₁ when severe pulmonary hypertension or TS complicates MS and right atrial (RA) enlargement occurs. The QRS complex is usually normal. However, with severe pulmonary hypertension, right axis deviation and RV hypertrophy are often present.

Source: Fauci AS, Kasper DL, Braunwald E, Hauser SL, Longo DL, Jameson JL, Loscalzo J. *Harrison's Principles of Internal Medicine*, 17th Edition: <http://www.accessmedicine.com>

Echocardiogram

Transthoracic two-dimensional echocardiography (TTE) with color flow Doppler imaging provides critical information, including an estimate of the transvalvular peak and mean gradients and of mitral orifice size, the presence and severity of accompanying MR, the extent of restriction of valve leaflets and their thickness, the degree of distortion of the subvalvular apparatus, and the anatomic suitability for percutaneous mitral balloon valvotomy (PMBV; see below). In addition, TTE provides an assessment of the size of the cardiac chambers, an estimation of LV function, an estimation of the pulmonary artery pressure (PAP), and an indication of the presence and severity of associated valvular lesions. Transesophageal echocardiography (TEE) provides superior images and should be employed when TTE is inadequate for guiding therapy. TEE is especially indicated to exclude the presence of left atrial thrombi prior to PMBV.

Chest X-Ray

The earliest changes are straightening of the upper left border of the cardiac silhouette,

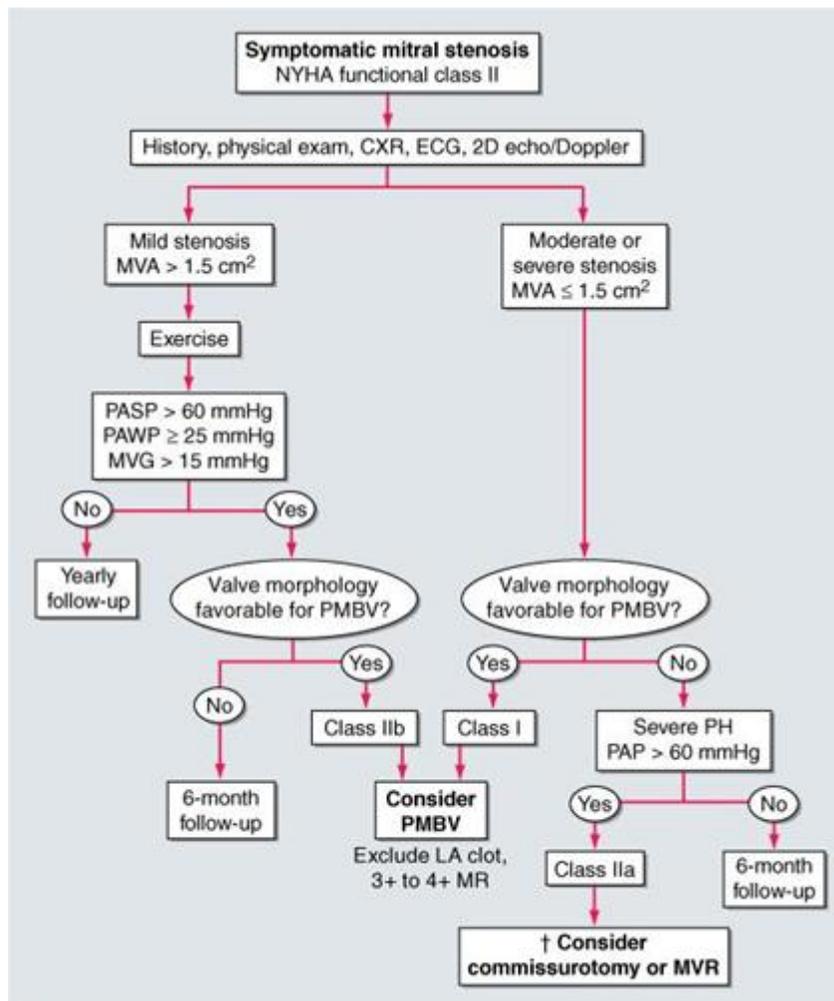

prominence of the main pulmonary arteries, dilatation of the upper lobe pulmonary veins, and posterior displacement of the esophagus by an enlarged LA. Kerley B lines are fine, dense, opaque, horizontal lines that are most prominent in the lower and mid-lung fields and that result from distention of interlobular septae and lymphatics with edema when the resting mean LA pressure exceeds approximately 20 mmHg.

Differential Diagnosis

Like MS, significant MR may also be associated with a prominent diastolic murmur at the apex due to increased flow, but in MR this diastolic murmur commences slightly later than in patients with MS, and there is often clear-cut evidence of LV enlargement. An apical pansystolic murmur of at least grade III/VI intensity as well as an S₃ suggests significant associated MR. Similarly, the apical mid-diastolic murmur associated with severe AR (*Austin Flint murmur*) may be mistaken for MS but can be differentiated from it because it is not intensified in presystole. TS, which occurs rarely in the absence of MS, may mask many of the clinical features of MS or be clinically silent.

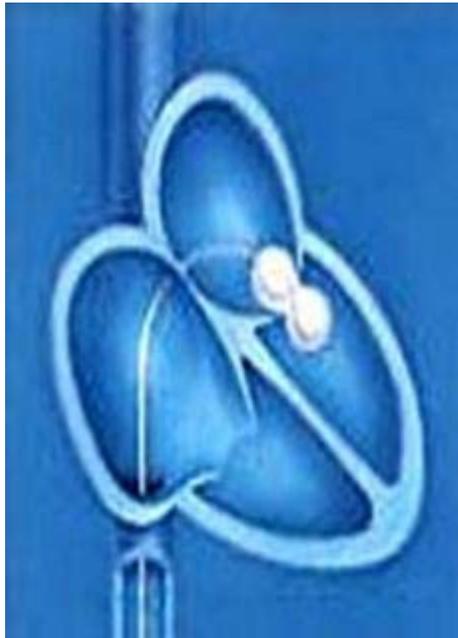

Treatment

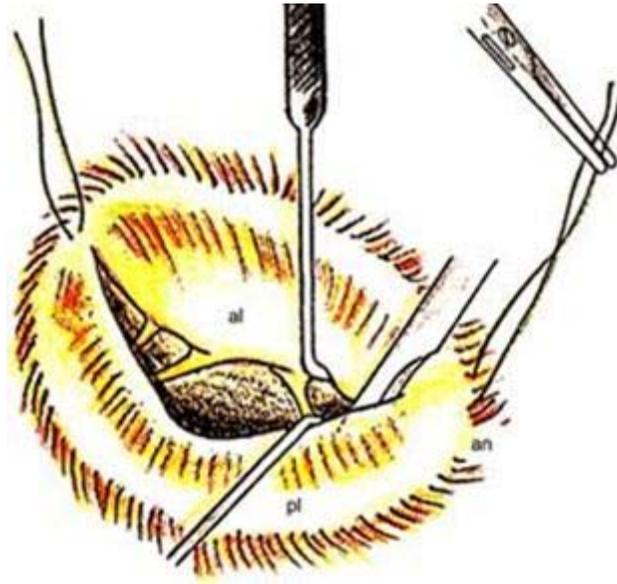

Penicillin prophylaxis of Group A β -hemolytic streptococcal infections to prevent rheumatic fever is important for at-risk patients with MS. Recommendations for infective endocarditis prophylaxis have recently changed. In symptomatic patients, some improvement usually occurs with restriction of sodium intake and maintenance doses of oral diuretics. Digitalis glycosides usually do not benefit patients with MS and sinus rhythm, but they are helpful in slowing the ventricular rate of patients with AF. Beta blockers and nondihydropyridine calcium channel blockers (e.g., [verapamil](#) or [diltiazem](#)) are also useful in this regard.

Source: Fauci AS, Kasper DL, Braunwald E, Hauser SL, Longo DL, Jameson JL, Loscalzo J: *Harrison's Principles of Internal Medicine*, 17th Edition: <http://www.accessmedicine.com>

[Warfarin](#) to an international normalized ration (INR) of 2–3 should be administered indefinitely to patients with MS who have AF or a history of thromboembolism. The routine use of warfarin in patients in sinus rhythm with LA enlargement (maximal dimension >5.5 cm) with or without spontaneous echo contrast is more controversial.

Management strategy for patients with mitral stenosis (MS) and mild symptoms. There is controversy as to whether patients with severe MS (MVA $<1.0 \text{ cm}^2$) and severe pulmonary hypertension (PH) (PASP $>60 \text{ mmHg}$) should undergo percutaneous mitral balloon valvotomy (PMBV) or mitral valve replacement (MVR) to prevent right ventricular failure. CXR, chest x-ray; ECG, electrocardiogram; echo, echocardiography; LA, left atrial; MR, mitral regurgitation; MVA, mitral valve area; MVG, mean mitral valve pressure gradient; NYHA, New York Heart Association; PASP, pulmonary artery systolic pressure; PAWP, pulmonary artery wedge pressure; 2D, 2-dimensional. Medical Therapy of Valvular Heart Disease

Lesion	Symptom Control	Natural History
Mitral stenosis	Beta blockers, nondihydropyridine calcium channel blockers, or <u>digoxin</u> for rate control of AF; cardioversion for new-onset AF and HF; diuretics for HF	Warfarin for AF or thromboembolism; PCN for RF prophylaxis
Mitral regurgitation	Diuretics for HF Vasodilators for acute MR	<u>Warfarin</u> for AF or thromboembolism Vasodilators for HTN
Aortic stenosis	Diuretics for HF	No proven therapy
Aortic regurgitation	Diuretics and vasodilators for HF	Vasodilators for HTN

Note: Antibiotic prophylaxis is recommended according to current American Heart Association guidelines. For patients with these forms of valvular heart disease, prophylaxis is indicated for a prior history of endocarditis. HF is an indication for surgical or percutaneous treatment, and the recommendations here pertain to short-term therapy prior to definitive correction of the valve lesion. For patients whose comorbidities prohibit surgery, the medical therapies listed can be continued according to available guidelines for the management of HF. See text.

Abbreviations: AF, atrial fibrillation; HF, heart failure; HTN, systemic hypertension; PCN, penicillin; RF, rheumatic fever.

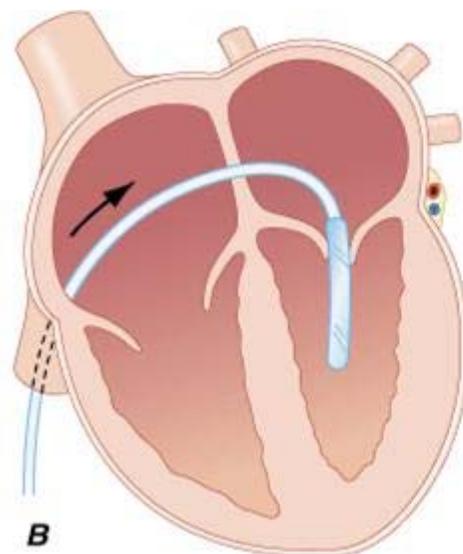

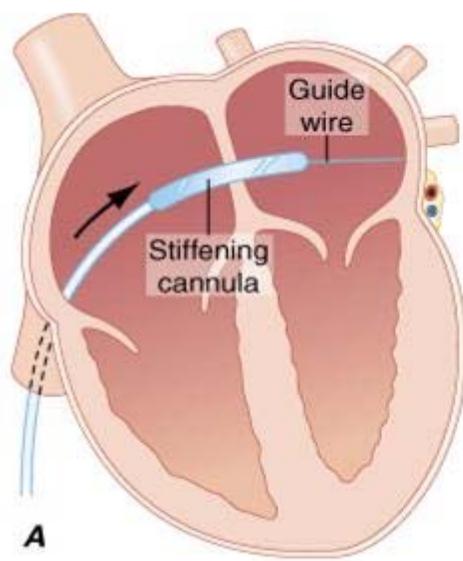

Source: Adapted from NA Boon, P Bloomfield: The medical management of valvular heart disease. Heart 87:395, 2002

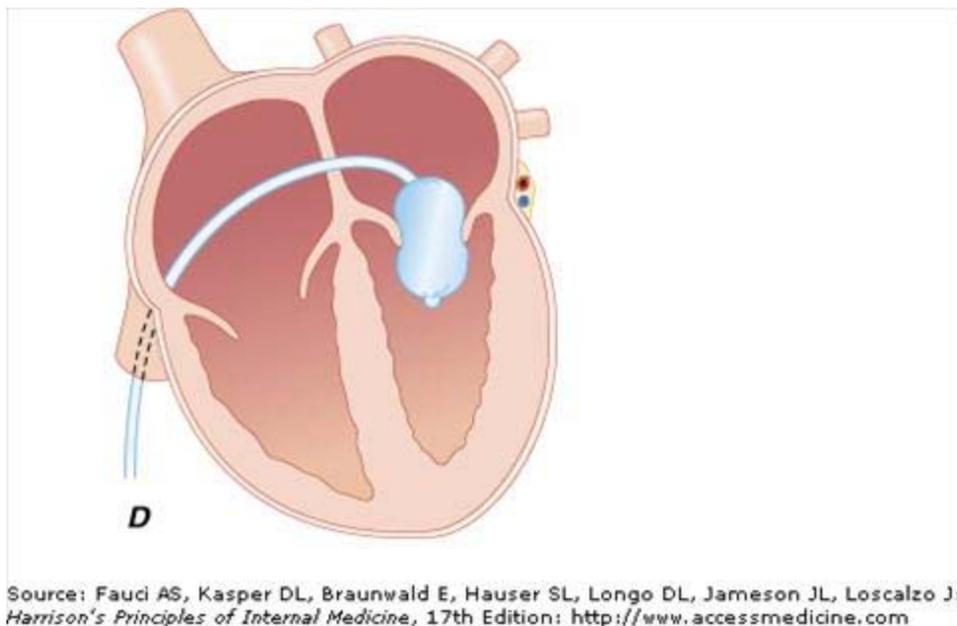

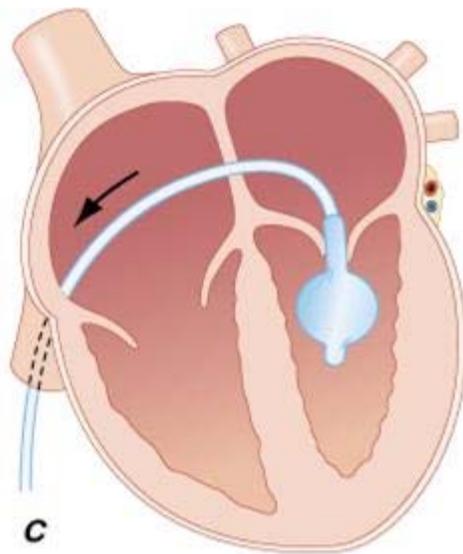

If AF is of relatively recent onset in a patient whose MS is not severe enough to warrant PMBV or surgical commissurotomy, reversion to sinus rhythm pharmacologically or by means of electrical countershock is indicated. Usually, cardioversion should be undertaken after the patient has had at least 3 consecutive weeks of [anticoagulant](#) treatment to a therapeutic INR. If cardioversion is indicated more urgently, then intravenous [heparin](#) should be provided and a TEE performed to exclude the presence of left atrial thrombus before the procedure. Conversion to sinus rhythm is rarely successful or sustained in patients with severe MS, particularly those in whom the LA is especially enlarged or in whom AF has been present for more than 1 year.

Mitral Valvotomy

Unless there is a contraindication, mitral valvotomy is indicated in symptomatic [New York Heart Association (NYHA) Functional Class II–IV] patients with isolated MS whose effective orifice (valve area) is $< \sim 1.0 \text{ cm}^2/\text{m}^2$ body surface area, or $< 1.5 \text{ cm}^2$ in normal-sized adults. Mitral valvotomy can be carried out by two techniques: PMBV and surgical valvotomy. In PMBV a catheter is directed into the LA after transseptal puncture, and a single balloon is directed across the valve and inflated in the valvular orifice. Ideal patients have relatively pliable leaflets with little or no commissural calcium. In addition, the subvalvular structures should not be significantly scarred or thickened and there should be no left atrial thrombus. The short- and long-term results of this procedure in appropriate patients are similar to those of surgical valvotomy, but with less morbidity and a lower periprocedural mortality rate. Event-free survival in younger (< 45 years) patients with pliable valves is excellent, with rates

as high as 80–90% over 3–7 years. Therefore, PMBV has become the procedure of choice for such patients when it can be performed by a skilled operator in a high-volume center.

Inoue balloon technique for mitral balloon valvotomy. **A.** After transseptal puncture, the deflated balloon catheter is advanced across the inter-atrial septum, then across the mitral valve and into the left ventricle. **B-D.** The balloon is then inflated stepwise within the mitral orifice.

Successful valvotomy is defined by a 50% reduction in the mean mitral valve gradient and a doubling of the mitral valve area. Successful valvotomy, whether balloon or surgical, usually results in striking symptomatic and hemodynamic improvement and prolongs survival. However, there is no evidence that the procedure improves the prognosis of patients with slight

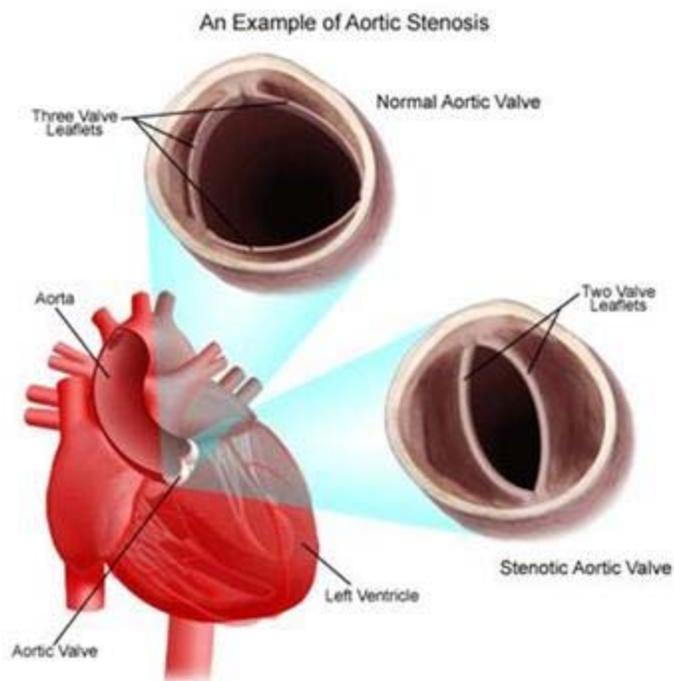

or no functional impairment. Therefore, unless recurrent systemic embolization or severe pulmonary hypertension has occurred (PA systolic pressures >50 mmHg at rest or >60 mmHg with exercise), valvotomy is *not* recommended for patients who are entirely asymptomatic and/or who have mild stenosis (mitral valve area $>1/5$ cm²). When there is little symptomatic improvement after valvotomy, it is likely that the procedure was ineffective, that it induced MR, or that associated valvular or myocardial disease was present. About half of all patients undergoing surgical mitral valvotomy require reoperation by 10 years. In the pregnant patient with MS, valvotomy should be carried out if pulmonary congestion occurs despite intensive medical treatment. PMBV is the preferred strategy in this setting and is performed with TEE and no or minimal x-ray exposure.

Mitral valve replacement (MVR) is necessary in patients with MS and significant associated MR, those in whom the valve has been severely distorted by previous transcatheter or operative manipulation, or those in whom the surgeon does not find it possible to improve valve function significantly. MVR is now routinely performed with preservation of the chordal attachments to optimize LV functional recovery. Perioperative mortality rates with MVR vary with age, LV function, the presence of CAD, and associated comorbidities. They average 5% overall but are lower in young patients and may be twice as high in older patients with comorbidities. Since there are also long-term complications of valve replacement, patients in whom preoperative evaluation suggests the possibility that MVR may be required should be operated on only if they have severe MS—i.e., an orifice area <1 cm²—and are in NYHA Class III, i.e., symptomatic with ordinary activity despite optimal medical therapy. The overall 10-year survival of surgical survivors is $\sim 70\%$. Long-term prognosis is worse in older patients and those with marked disability and marked depression of the CO preoperatively. Pulmonary hypertension and RV dysfunction are additional risk factors for poor outcome.

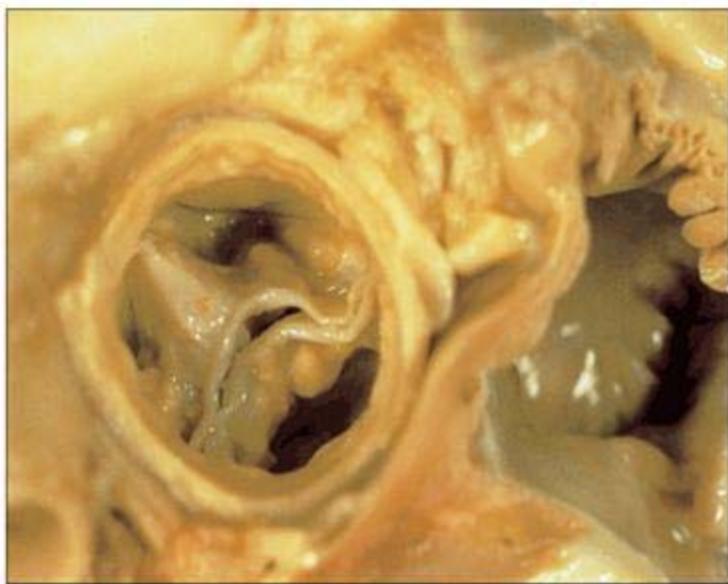

Aortic stenosis

Aortic stenosis (AS) most often is due to calcification of a congenitally bicuspid or normal trileaflet valve. Calcific changes are due to an active disease process characterized by lipid accumulation, inflammation, and calcification. Once initiated, progressive leaflet calcification and fibrosis eventually result in reduced leaflet motion with obstruction to left ventricular (LV) outflow. **Aortic stenosis** often is first diagnosed by the finding of a murmur on auscultation.

However, while a soft murmur with a physiologic split S2 reliably excludes severe **stenosis** and a grade 4 murmur with diminished carotid upstrokes confirms severe obstruction, between these extremes physical examination is not accurate for evaluation of disease severity.

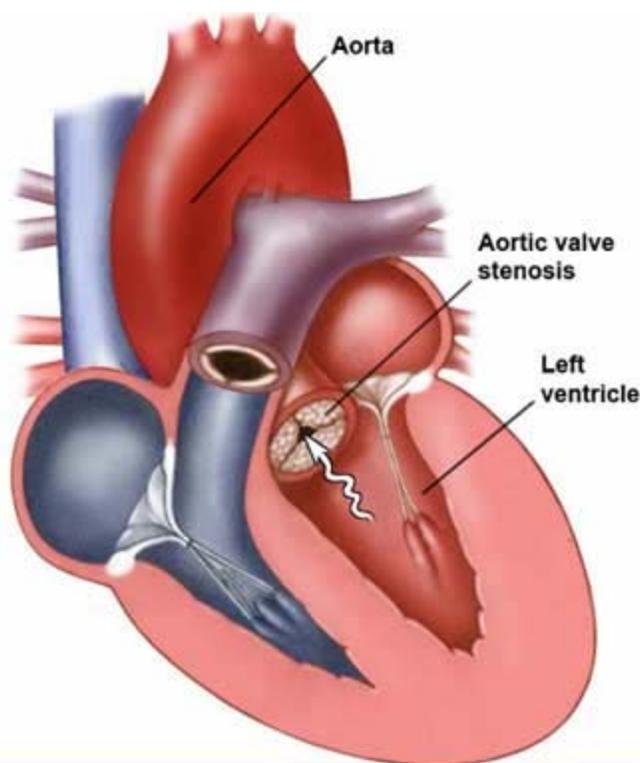

Bicuspid Aortic Valve Stenosis

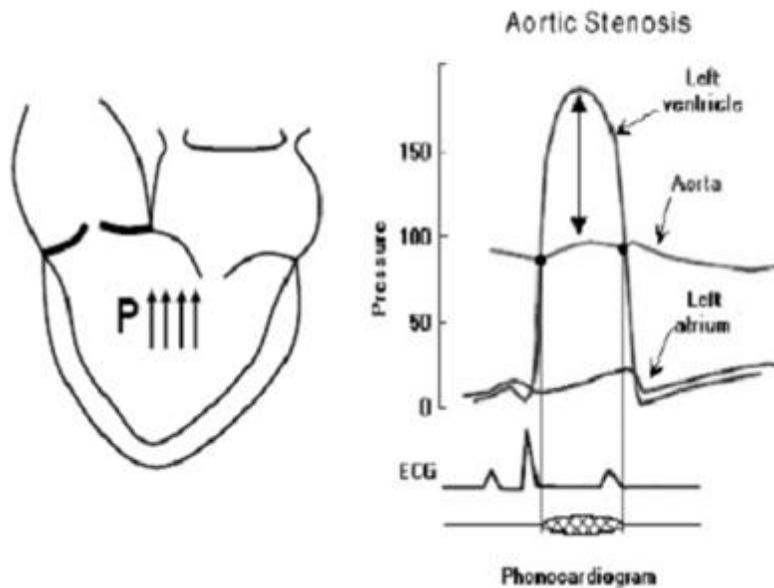

AS occurs in about one-fourth of all patients with chronic valvular heart disease; approximately 80% of adult patients with symptomatic valvular AS are male.

AS in adults may be due to degenerative calcification of the aortic cusps. It may be congenital in origin or it may be secondary to rheumatic inflammation. *Age-related degenerative calcific AS* (also known as senile or sclerocalcific AS) is now the most common cause of AS in adults in North America and Western Europe. About 30% of persons >65 years exhibit aortic valve sclerosis; many of these have a systolic murmur of AS but without obstruction, while 2% exhibit frank stenosis. Aortic sclerosis is defined echocardiographically as focal thickening or calcification of the valve cusps with a peak Doppler transaortic velocity of 2.5 m/s. Aortic sclerosis appears to be a marker for an increased risk of coronary heart disease events. On histologic examination these valves frequently exhibit changes similar to those seen with atherosclerosis and vascular inflammation. Interestingly, risk factors for atherosclerosis, such as age, male sex, smoking, diabetes mellitus, hypertension, chronic kidney disease, increased LDL, reduced HDL cholesterol, and elevated C-reactive protein are all risk factors for aortic valve calcification.

Pathophysiology

Ventricular Compensation

- **Concentric hypertrophy**
 - Reduces wall stress
 - Reduces ventricular compliance
 - LVEDp increases
 - LAp increases

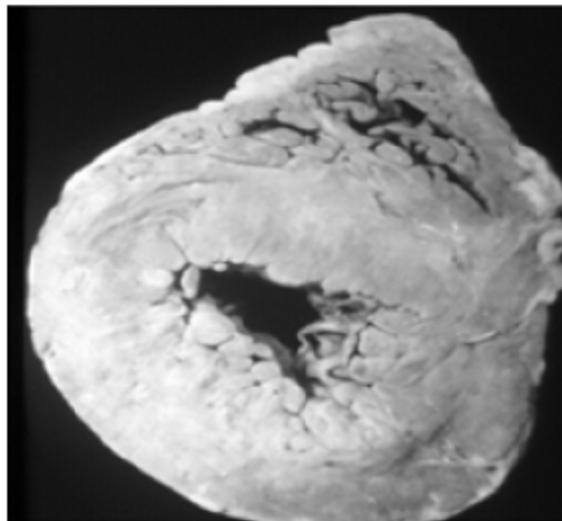

Fig. Aortic stenosis

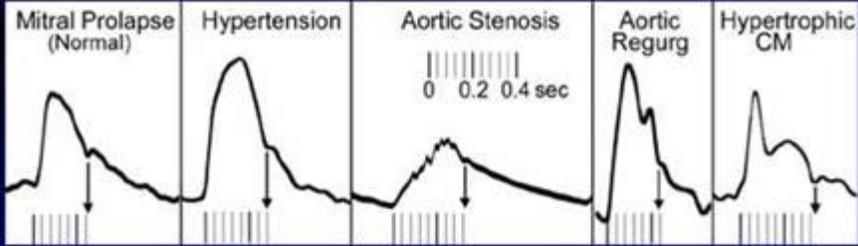

The *congenitally affected valve* may be stenotic at birth and may become progressively more fibrotic, calcified, and stenotic. In other cases the valve may be congenitally deformed, usually bicuspid [bicuspid aortic valve (BAV)], without serious narrowing of the aortic orifice during childhood; its abnormal architecture makes its leaflets susceptible to otherwise ordinary

hemodynamic stresses, which ultimately lead to valvular thickening, calcification, increased rigidity, and narrowing of the aortic orifice.

Aortic Stenosis

Physical Exam

- **Harsh Systolic Ejection Murmur – late peaking**
- **S4 gallop (from LVH)**
- **Sustained Bifid LV impulse (from LVH)**
- **Pulsus Parvus et Tardus (Carotid Impulse)**

The diagram shows five panels of pulse waveforms: Mitral Prolapse (Normal), Hypertension, Aortic Stenosis, Aortic Regurg, and Hypertrophic CM. A scale bar indicates 0, 0.2, and 0.4 seconds. The Aortic Stenosis waveform shows a low-amplitude, late-peaking systolic pulse.

Rheumatic disease of the aortic leaflets produces commissural fusion, sometimes resulting in a bicuspid-appearing valve. This condition in turn makes the leaflets more susceptible to trauma and ultimately leads to fibrosis, calcification, and further narrowing. By the time the obstruction to LV outflow causes serious clinical disability, the valve is usually a rigid calcified mass, and careful examination may make it difficult or even impossible to determine the etiology of the underlying process. Rheumatic AS is almost always associated with involvement of the mitral valve and with AR.

Pathophysiology

The obstruction to LV outflow produces a systolic pressure gradient between the LV and aorta. When severe obstruction is suddenly produced experimentally, the LV responds by dilatation and reduction of stroke volume. However, in some patients the obstruction may be present at birth and/or increase gradually over the course of many years, and LV output is maintained by the presence of concentric LV hypertrophy. Initially, this serves as an adaptive mechanism because it reduces toward normal the systolic stress developed by the myocardium, as predicted by the Laplace relation ($S = Pr/h$, where S = systolic wall stress, P = pressure, r = radius, and h = wall thickness). A large transaortic valvular pressure gradient may exist for many years

without a reduction in CO or LV dilatation; ultimately, however, excessive hypertrophy becomes maladaptive, and LV function declines.

A mean systolic pressure gradient >40 mmHg with a normal CO or an effective aortic orifice area $< \sim 1.0 \text{ cm}^2$ (or $\sim < 0.6 \text{ cm}^2/\text{m}^2$ body surface area in a normal-sized adult)—i.e., less than approximately one-third of the normal orifice—is generally considered to represent severe obstruction to LV outflow. The elevated LV end-diastolic pressure observed in many patients with severe AS signifies the presence of LV dilatation and/or diminished compliance of the hypertrophied LV wall. Although the CO at rest is within normal limits in most patients with severe AS, it usually fails to rise normally during exercise. Loss of an appropriately timed, vigorous atrial contraction, as occurs in AF or atrioventricular dissociation, may cause rapid progression of symptoms. Late in the course, the CO and LV–aortic pressure gradient decline, and the mean LA, PA, and RV pressures rise.

The hypertrophied LV elevates myocardial [oxygen](#) requirements. In addition, even in the absence of obstructive CAD, there may be interference with coronary blood flow. This is because the pressure compressing the coronary arteries exceeds the coronary perfusion pressure, often causing ischemia (especially in the subendocardium), both in the presence and in the absence of coronary arterial narrowing.

Symptoms

AS is rarely of clinical importance until the valve orifice has narrowed to approximately 1.0 cm^2 . Even severe AS may exist for many years without producing any symptoms because of the ability of the hypertrophied LV to generate the elevated intraventricular pressures required for a normal stroke volume.

Most patients with pure or predominant AS have gradually increasing obstruction for years but do not become symptomatic until the sixth to eighth decades. Exertional dyspnea, angina pectoris, and syncope are the three cardinal symptoms. Often there is a history of insidious progression of fatigue and dyspnea associated with gradual curtailment of activities. *Dyspnea* results primarily from elevation of the pulmonary capillary pressure caused by elevations of LV diastolic pressures secondary to reduced left ventricular compliance. *Angina pectoris* usually develops somewhat later and reflects an imbalance between the augmented myocardial [oxygen](#) requirements and reduced oxygen availability; the former results from the increased myocardial mass and intraventricular pressure, while the latter may result from accompanying CAD, which

is not uncommon in patients with AS, as well as from compression of the coronary vessels by the hypertrophied myocardium. Therefore, angina may occur in severe AS even without obstructive epicardial CAD. *Exertional syncope* may result from a decline in arterial pressure caused by vasodilatation in the exercising muscles and inadequate vasoconstriction in nonexercising muscles in the face of a fixed CO, or from a sudden fall in CO produced by an arrhythmia.

Since the CO at rest is usually well maintained until late in the course, marked fatigability, weakness, peripheral cyanosis, cachexia, and other clinical manifestations of a low CO are usually not prominent until this stage is reached. Orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema, i.e., symptoms of LV failure, also occur only in the advanced stages of the disease. Severe pulmonary hypertension leading to RV failure and systemic venous hypertension, hepatomegaly, AF, and TR are usually late findings in patients with isolated severe AS.

When AS and MS coexist, the reduction in CO induced by MS lowers the pressure gradient across the aortic valve and thereby masks many of the clinical findings produced by AS.

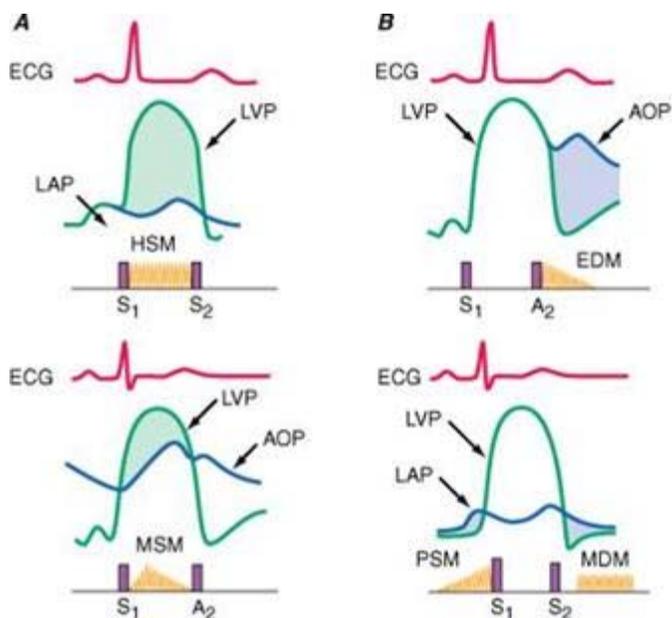

Physical Findings

The rhythm is generally regular until late in the course; at other times, AF should suggest the possibility of associated mitral valve disease. The systemic arterial pressure is usually within normal limits. In the late stages, however, when stroke volume declines, the systolic pressure may fall and the pulse pressure narrow. The peripheral arterial pulse rises slowly to a delayed sustained peak (*pulsus parvus et tardus*). In the elderly, the stiffening of the arterial wall may mask this important physical sign. In many patients the *a* wave in the jugular venous pulse is accentuated. This results from the diminished distensibility of the RV cavity caused by the bulging, hypertrophied interventricular septum.

Auscultation

An early systolic ejection sound is frequently audible in children and adolescents with congenital noncalcific valvular AS. This sound usually disappears when the valve becomes calcified and rigid. As AS increases in severity, LV systole may become prolonged so that the aortic valve closure sound no longer precedes the pulmonic valve closure sound, and the two components may become synchronous, or aortic valve closure may even follow pulmonic valve

closure, causing paradoxical splitting of S₂. The sound of aortic valve closure can be heard most frequently in patients with AS who have pliable valves, and calcification diminishes the intensity of this sound. Frequently, an S₄ is audible at the apex and reflects the presence of LV hypertrophy and an elevated LV end-diastolic pressure; an S₃ generally occurs late in the course, when the LV dilates.

A. Schematic representation of ECG, aortic pressure (AOP), left ventricular pressure (LVP), and left atrial pressure (LAP). The shaded areas indicate a transvalvular pressure difference during systole. HSM, holosystolic murmur; MSM, midsystolic murmur. **B.** Graphic representation of ECG, aortic pressure (AOP), left ventricular pressure (LVP), and left atrial pressure (LAP) with shaded areas indicating transvalvular diastolic pressure difference. EDM, early diastolic murmur; PSM, presystolic murmur; MDM, middiastolic murmur.

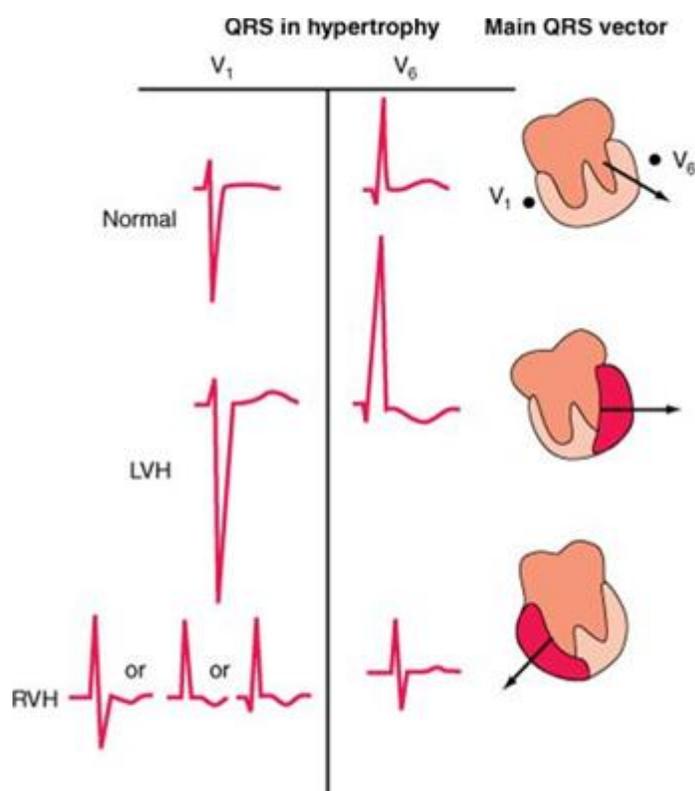

The murmur of AS is characteristically an ejection (mid) systolic murmur that commences shortly after the S₁, increases in intensity to reach a peak toward the middle of ejection, and ends just before aortic valve closure. It is characteristically low-pitched, rough and rasping in character, and loudest at the base of the heart, most commonly in the second right intercostal space. It is transmitted upward along the carotid arteries. Occasionally it is transmitted downward and to the apex, where it may be confused with the systolic murmur of MR (Gallavardin effect). In almost all patients with severe obstruction and preserved CO, the murmur is at least grade III/VI. In patients with mild degrees of obstruction or in those with

severe stenosis with heart failure in whom the stroke volume and therefore the transvalvular flow rate are reduced, the murmur may be relatively soft and brief.

Laboratory Examination

ECG

In most patients with severe AS there is LV hypertrophy.

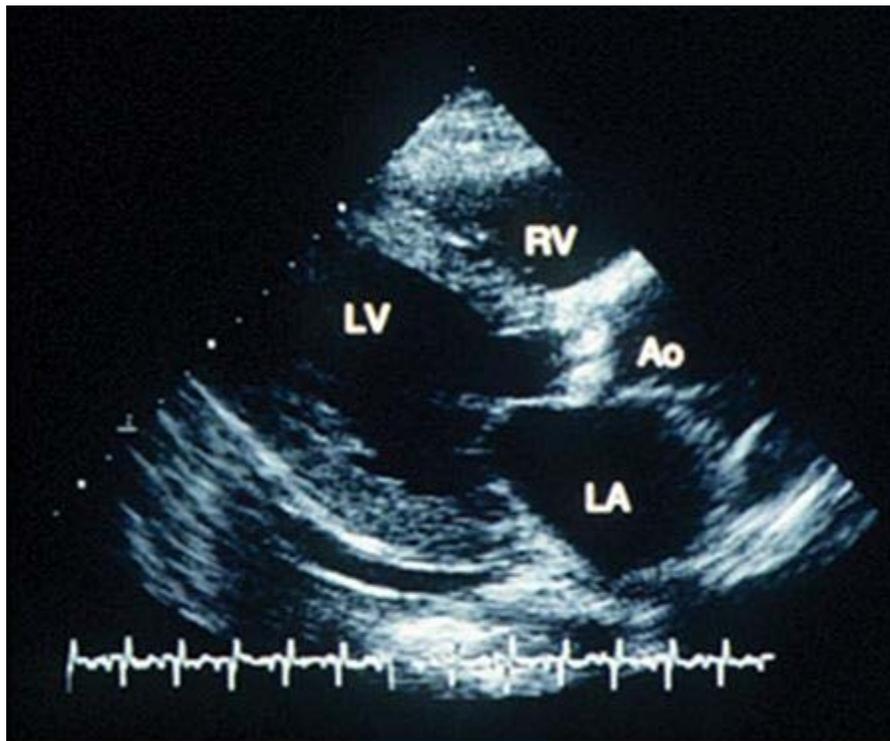

Left ventricular hypertrophy (LVH) increases the amplitude of electrical forces directed to the left and posteriorly.

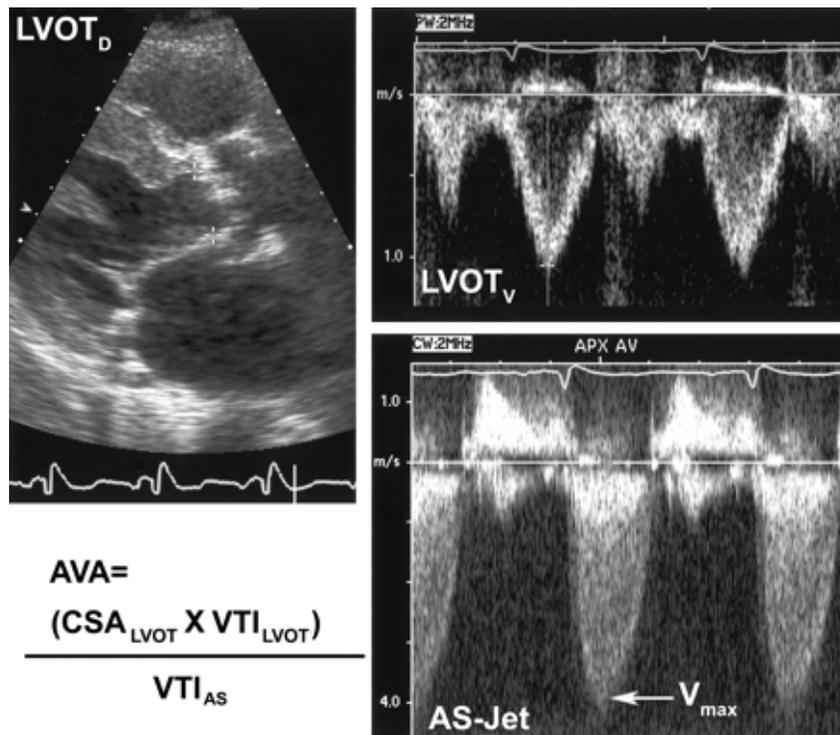

In advanced cases, ST-segment depression and T-wave inversion (LV "strain") in standard leads I and aVL and in the left precordial leads are evident. However, there is no close correlation between the ECG and the hemodynamic severity of obstruction, and the absence of ECG signs of LV hypertrophy does not exclude severe obstruction.

Echocardiogram

The key findings are LV hypertrophy and, in patients with valvular calcification (i.e., most adult patients with symptomatic AS), multiple, bright, thick, echoes from the valve.

Still frame two-dimensional echocardiographic image from the parasternal long axis view of a patient with aortic stenosis. The aortic valve is calcified with restricted opening during systole. Ao, aorta; RV, right ventricle; LA, left atrium; LV, left ventricle.

Standard evaluation of aortic stenosis (AS) severity is based on measurement of left ventricular outflow tract (LVOT) diameter (D) in a parasternal long-axis view for calculation of a circular cross-sectional area (CSA), outflow tract velocity (V) from an apical approach using pulsed Doppler, and the maximum aortic jet (AS-Jet, V_{\max}) from the continuous-wave Doppler recording. Either velocity-time integrals (VTIs) or maximum velocities can be used in the continuity equation for aortic valve area (AVA).

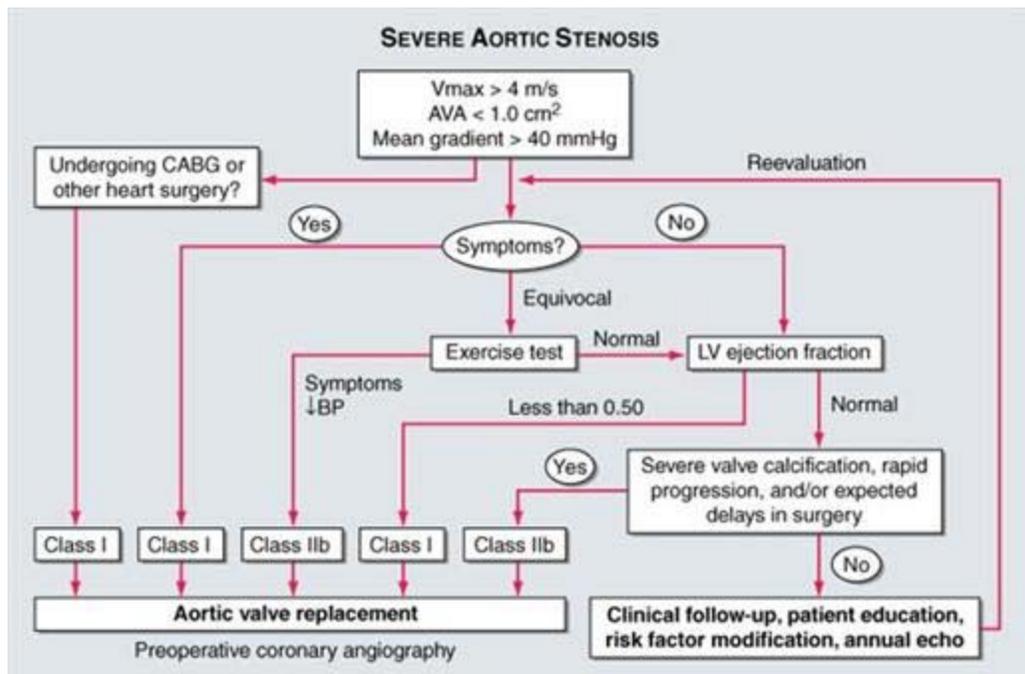

. The valve gradient and aortic valve area can be estimated by Doppler measurement of the transaortic velocity. Severe AS is defined by a valve area $<1.0 \text{ cm}^2$, whereas moderate AS is defined by a valve area of $1.0\text{--}1.5 \text{ cm}^2$ and mild AS by a valve area of $1.5\text{--}2.0 \text{ cm}^2$. LV dilatation and reduced systolic shortening reflect impairment of LV function.

Echocardiography is useful for identifying coexisting valvular abnormalities such as MS and AR, which sometimes accompany AS; for differentiating valvular AS from other forms of outflow obstruction; and for measurement of the aortic root. Aneurysmal enlargement (maximal dimension $>4.5 \text{ cm}$) of the root or ascending aorta can occur in up to 20% of patients with bicuspid aortic valve disease, independent of the severity of the valve lesion. [Dobutamine](#) stress echocardiography is useful for the evaluation of patients with severe AS and severe LV systolic dysfunction (EF <0.35).

Chest X-Ray

The chest x-ray may show no or little overall cardiac enlargement for many years. Hypertrophy without dilatation may produce some rounding of the cardiac apex in the frontal projection and slight backward displacement in the lateral view; severe AS is often associated with poststenotic dilatation of the ascending aorta. As noted above, however, aortic enlargement may be an independent process and mediated by the same type of structural changes that occur in patients with Marfan syndrome. Aortic calcification is usually readily apparent on fluoroscopic examination or by echocardiography; the absence of valvular calcification in an adult suggests that severe valvular AS is *not* present. In later stages of the disease, as the LV dilates there is increasing roentgenographic evidence of LV enlargement, pulmonary congestion, and enlargement of the LA, PA, and right side of the heart.

Medical Treatment

Management strategy for patients with severe aortic stenosis. Preoperative coronary angiography should be performed routinely as determined by age, symptoms, and coronary risk factors. Cardiac catheterization and angiography may also be helpful when there is discordance between clinical findings and echocardiography. *AVA*, aortic valve area; *BP*, blood pressure; *CABG*, coronary artery bypass graft surgery; *echo*, echocardiography; *LV*, left ventricle; *Vmax*, maximal velocity across aortic valve by Doppler echocardiography. (From Bonow et al. Modified from CM Otto: *J Am Coll Cardiol* 47:2141, 2006.)

In patients with severe AS ($<1.0 \text{ cm}^2$), strenuous physical activity should be avoided, even in the asymptomatic stage. Care must be taken to avoid dehydration and hypovolemia to protect against a significant reduction in CO. Medications used for the treatment of hypertension or CAD, including beta blockers and ACE inhibitors, are generally safe for asymptomatic patients with preserved left ventricular systolic function. [Nitroglycerin](#) is helpful in relieving angina pectoris. Retrospective studies have shown that patients with degenerative calcific AS who receive [HMG-CoA reductase inhibitors](#) ("statins") exhibit slower progression of leaflet calcification and aortic valve area reduction than those who do not. One prospective randomized clinical trial using high-dose [atorvastatin](#) failed to show a measurable benefit, although a more recent trial using [rosuvastatin](#) did show a beneficial effect. The role of [statin](#) medications may be more clearly defined with further study.

Surgical Treatment

Asymptomatic patients with calcific AS and severe obstruction should be followed carefully for the development of symptoms and by serial echocardiograms for evidence of deteriorating

LV function. Operation is indicated in patients with severe AS (valve area $<1.0 \text{ cm}^2$ or $0.6 \text{ cm}^2/\text{m}^2$ body surface area) who are symptomatic, those who exhibit LV dysfunction (EF $<50\%$), as well as those with an aneurysmal or expanding aortic root (maximal dimension $>4.5 \text{ cm}$ or annual increase in size $>0.5 \text{ cm/year}$), even if they are asymptomatic. In patients without heart failure, the operative risk of AVR is approximately 3%. It is prudent to postpone operation in patients with severe calcific AS who are truly asymptomatic and who exhibit normal LV function, i.e., EF $>50\%$, since they may continue to do well for years. However, some advocate AVR in patients with severe valve calcification and rapid progression of obstruction. The risk of surgical mortality exceeds that of sudden death in asymptomatic patients. Exercise testing is employed in many centers to assess objectively the functional capacity of asymptomatic patients for whom the history is ambiguous. As many as one-third of patients will show signs of functional impairment during exercise for which AVR should be considered. AVR is carried out in asymptomatic patients with severe or moderately severe stenosis who undergo coronary artery bypass grafting. AVR is also routinely performed in patients with moderate AS who are undergoing coronary bypass grafting or aortic root reconstruction.

Operation should, if possible, be carried out before frank LV failure develops; at this late stage, the aortic valve pressure gradient declines as the CO, stroke volume, and EF decline (low gradient, low output AS). In such patients the perioperative risk is high (15–20%), and evidence of myocardial disease may persist even when the operation is technically successful. Furthermore, long-term postoperative survival also correlates inversely with preoperative LV dysfunction. Nonetheless, in view of the even worse prognosis of such patients when they are treated medically, there is usually little choice but to advise surgical treatment, especially in patients in whom contractile reserve can be demonstrated by [dobutamine](#) echocardiography (defined by a 20% increase in stroke volume after dobutamine challenge). In patients in whom severe AS and CAD coexist, relief of the AS and revascularization of the myocardium by means of aortocoronary bypass grafting may result in striking clinical and hemodynamic improvement.

Because many patients with calcific AS are elderly, particular attention must be directed to the adequacy of hepatic, renal, and pulmonary function before AVR is recommended. Age alone is not a contraindication to AVR for AS. The mortality rate depends to a substantial extent on the patient's preoperative clinical and hemodynamic state. The 10-year survival rate of patients with AVR is approximately 60%. Approximately 30% of bioprosthetic valves evidence primary valve

failure in 10 years, requiring re-replacement, and an approximately equal percentage of patients with mechanical prostheses develop significant hemorrhagic complications as a consequence of treatment with anticoagulants.

Percutaneous Balloon Aortic Valvuloplasty

This procedure is preferable to operation in children and young adults with congenital, noncalcific AS. It is not commonly used in adults with severe calcific AS because of a very high restenosis rate and the risk of procedural complications, but on occasion it has been used successfully as a "bridge to operation" in patients with severe LV dysfunction and shock who are too ill to tolerate surgery.

Aortic Regurgitation

In approximately two-thirds of patients with valvular AR, the disease is rheumatic in origin, resulting in thickening, deformity, and shortening of the individual aortic valve cusps, changes that prevent their proper opening during systole and closure during diastole. A rheumatic origin is much less common in patients with isolated AR who do not have associated mitral valve disease. Patients with congenital BAV disease may develop predominant AR. Congenital fenestrations of the aortic valve occasionally produce mild AR. Membranous subaortic stenosis often leads to thickening and scarring of the aortic valve leaflets with secondary AR. Prolapse of an aortic cusp, resulting in progressive chronic AR, occurs in approximately 15% of patients with ventricular septal defect but may also occur as an isolated phenomenon or as a consequence of myxomatous degeneration sometimes associated with mitral and/or tricuspid valve involvement.

AR may result from infective endocarditis, which can develop on a valve previously affected by rheumatic disease, a congenitally deformed valve, or, rarely, on a normal aortic valve, and may lead to perforation or erosion of one or more leaflets. The aortic valve leaflets may become scarred and retracted during the course of syphilis or ankylosing spondylitis and contribute further to the AR that derives primarily from the associated root disease. Although traumatic rupture or avulsion of the aortic valve is an uncommon cause of acute AR, it does represent the most frequent serious lesion in patients surviving nonpenetrating cardiac injuries. The coexistence of hemodynamically significant AS with AR usually excludes all the rarer forms of AR because it occurs almost exclusively in patients with rheumatic or congenital AR. In patients with AR due to primary valvular disease, dilatation of the aortic annulus may occur

secondarily and intensify the regurgitation.

Pathophysiology

The total stroke volume ejected by the LV (i.e., the sum of the effective forward stroke volume and the volume of blood that regurgitates back into the LV) is increased in patients with AR. In patients with wide-open (free) AR, the volume of regurgitant flow may equal the effective forward stroke volume. In contrast to MR, in which a fraction of the LV stroke volume is delivered into the low-pressure LA, in AR the entire LV stroke volume is ejected into a high-pressure zone, the aorta. An increase in the LV end-diastolic volume (increased preload) constitutes the major hemodynamic compensation for AR. The dilatation and eccentric hypertrophy of the LV allow this chamber to eject a larger stroke volume without requiring any increase in the relative shortening of each myofibril. Therefore, severe AR may occur with a normal effective forward stroke volume and a normal left ventricular EF [total (forward plus regurgitant) stroke volume/end-diastolic volume], together with an elevated LV end-diastolic pressure and volume. However, through the operation of Laplace's law, LV dilatation increases the LV systolic tension required to develop any given level of systolic pressure. Chronic AR is thus a state in which LV preload and afterload are both increased. Ultimately, these adaptive measures fail. As LV function deteriorates, the end-diastolic volume rises further and the forward stroke volume and EF decline. Deterioration of LV function often precedes the development of symptoms. Considerable thickening of the LV wall also occurs with chronic AR, and at autopsy the hearts of these patients may be among the largest encountered, sometimes weighing >1000 g.

The reverse pressure gradient from aorta to LV, which drives the AR flow, falls progressively during diastole, accounting for the decrescendo nature of the diastolic murmur. Equilibration between aortic and LV pressures may occur toward the end of diastole in patients with chronic severe AR, particularly when the heart rate is slow. In patients with acute severe AR, the LV is unprepared for the regurgitant volume load. LV compliance is normal or reduced, and LV diastolic pressures rise rapidly, occasionally to levels >40 mmHg. The LV pressure may exceed the LA pressure toward the end of diastole, and this reversed pressure gradient closes the mitral valve prematurely.

In patients with chronic severe AR, the effective forward CO usually is normal or only slightly reduced at rest, but often it fails to rise normally during exertion. Early signs of LV dysfunction include reduction in the EF. In advanced stages there may be considerable

elevation of the LA, PA wedge, PA, and RV pressures and lowering of the forward CO at rest.

Physical Findings

In chronic severe AR, the jarring of the entire body and the bobbing motion of the head with each systole can be appreciated, and the abrupt distention and collapse of the larger arteries are easily visible. The examination should be directed toward the detection of conditions predisposing to AR, such as Marfan syndrome, ankylosing spondylitis, and ventricular septal defect.

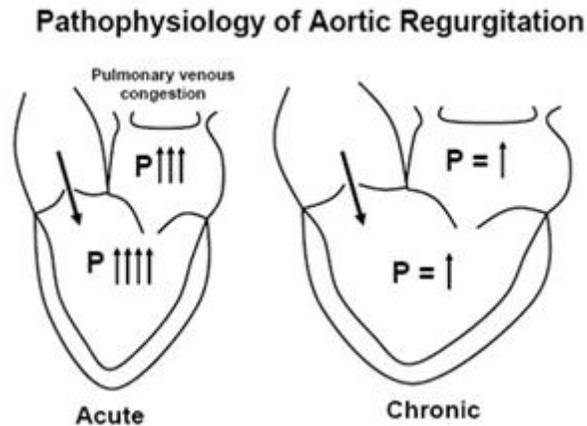

Arterial Pulse

A rapidly rising "water-hammer" pulse, which collapses suddenly as arterial pressure falls rapidly during late systole and diastole (Corrigan's pulse), and capillary pulsations, an alternate flushing and paling of the skin at the root of the nail while pressure is applied to the tip of the nail (Quincke's pulse), are characteristic of free AR. A booming "pistol-shot" sound can be heard over the femoral arteries (Traube's sign), and a to-and-fro murmur (Duroziez's sign) is audible if the femoral artery is lightly compressed with a stethoscope.

The arterial pulse pressure is widened, and there is an elevation of the systolic pressure, sometimes to as high as 300 mmHg, and a depression of the diastolic pressure. The measurement of arterial diastolic pressure with a sphygmomanometer may be complicated by the fact that systolic sounds are frequently heard with the cuff completely deflated. However, the level of cuff pressure at the time of muffling of the Korotkoff sounds (Phase IV) generally corresponds fairly closely to the true intraarterial diastolic pressure. As the disease progresses and the LV end-diastolic pressure rises, the arterial diastolic pressure may actually rise as well, since the aortic diastolic pressure cannot fall below the LV end-diastolic pressure. For the same reason, acute severe AR may also be accompanied by only a slight widening of the pulse pressure. Such patients are invariably tachycardic as the heart rate increases in an attempt to preserve the CO.

Auscultation

In patients with severe AR, the aortic valve closure sound (A_2) is usually absent. An S_3 and systolic ejection sound are frequently audible, and occasionally an S_4 also may be heard. The murmur of chronic AR is typically a high-pitched, blowing, decrescendo diastolic murmur, heard best in the third intercostal space along the left sternal border.

A. Schematic representation of ECG, aortic pressure (AOP), left ventricular pressure (LVP), and left atrial pressure (LAP). The shaded areas indicate a transvalvular pressure difference during systole. HSM, holosystolic murmur; MSM, midsystolic murmur. **B.** Graphic representation of ECG, aortic pressure (AOP), left ventricular pressure (LVP), and left atrial pressure (LAP) with shaded areas indicating transvalvular diastolic pressure difference. EDM, early diastolic murmur; PSM, presystolic murmur; MDM, middiastolic murmur.

In patients with mild AR, this murmur is brief but, as the severity increases, generally becomes louder and longer, indeed holodiastolic. When the murmur is soft, it can be heard best with the diaphragm of the stethoscope and with the patient sitting up, leaning forward, and with the breath held in forced expiration. In patients in whom the AR is caused by primary valvular disease, the diastolic murmur is usually louder along the left than the right sternal border. However, when the murmur is heard best along the right sternal border, it suggests that the AR is caused by aneurysmal dilatation of the aortic root. "Cooing" or musical diastolic murmurs suggest eversion of an aortic cusp vibrating in the regurgitant stream.

A mid-systolic ejection murmur is frequently audible in isolated AR. It is generally heard best at the base of the heart and is transmitted along the carotid vessels. This murmur may be quite loud without signifying aortic obstruction. A third murmur frequently heard in patients with severe AR is the *Austin Flint murmur*, a soft, low-pitched, rumbling mid-diastolic murmur. It is probably produced by the diastolic displacement of the anterior leaflet of the mitral valve by the AR stream but does not appear to be associated with hemodynamically significant mitral obstruction. The auscultatory features of AR are intensified by strenuous handgrip, which augments systemic resistance.

In acute severe AR, the elevation of LV end-diastolic pressure may lead to early closure of the mitral valve, an associated mid-diastolic sound, a soft or absent S₁, a pulse pressure that is not particularly wide, and a soft, short diastolic murmur of AR.

Laboratory Examination

ECG

In patients with chronic severe AR, the ECG signs of LV hypertrophy become manifest. In addition, these patients frequently exhibit ST-segment depression and T-wave inversion in leads I, aVL, V₅, and V₆ ("LV strain"). Left axis deviation and/or QRS prolongation denote diffuse myocardial disease, generally associated with patchy fibrosis, and usually signify a poor prognosis.

Echocardiogram

The extent and velocity of wall motion are normal or even supernormal, until myocardial contractility declines. A rapid, high-frequency fluttering of the anterior mitral leaflet produced by the impact of the regurgitant jet is a characteristic finding. The echocardiogram is also useful in determining the cause of AR, by detecting dilatation of the aortic annulus and root or aortic dissection. Thickening and failure of coaptation of the leaflets also may be noted. Color flow Doppler echocardiographic imaging is very sensitive in the detection of AR, and Doppler echocardiography is helpful in assessing its severity. With severe AR, the central jet width exceeds 65% of the left ventricular outflow tract, the regurgitant volume is 60 ml/beat, the regurgitant fraction is 50%, and there is diastolic flow reversal in the proximal descending thoracic aorta. The continuous wave Doppler profile shows a rapid deceleration time in patients with acute severe AR, due to the rapid increase in LV diastolic pressure. Serial two-dimensional echocardiography is valuable in assessing LV performance and in detecting progressive myocardial dysfunction.

Chest X-Ray

In chronic severe AR, the apex is displaced downward and to the left in the frontal projection. In the left anterior oblique and lateral projections, the LV is displaced posteriorly and encroaches on the spine. When AR is caused by primary disease of the aortic root, aneurysmal dilatation of the aorta may be noted, and the aorta may fill the retrosternal space in the lateral view. Echocardiography and CT angiography are more sensitive than the chest x-ray for the

detection of aortic root enlargement.

Table 1. Classification of the Severity of Aortic Regurgitation.*				
Variable	Aortic Regurgitation			
	Mild	Moderate‡		Severe
Width of vena contracta (mm)†	<3.0	3.0–5.9		≥6.0
Ratio of width of aortic regurgitant jet to left ventricular outflow (%)	<25	25–44	45–64	≥65
Regurgitant volume (ml per beat)	<30	30–44	45–59	≥60
Regurgitant fraction (%)	<30	30–39	40–49	≥50
Effective regurgitant orifice (mm ²)	<10	10–19	20–29	≥30

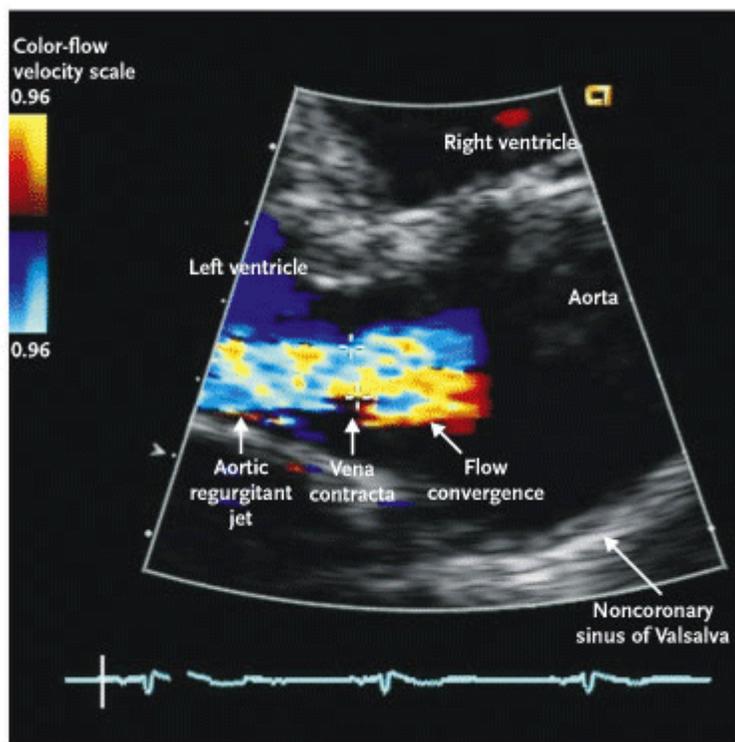

* The classification is from the American Society of Echocardiography.¹¹

† The vena contracta is the regurgitant flow at the orifice on color-flow imaging.

‡ The subdivisions of the moderate class correspond to the subcategories of “mild to moderate” and “moderately severe.”

Clinically, bounding arterial pulses, a widened pulse pressure, a loud diastolic murmur, and a third heart sound are signs of severe regurgitation but are not always specific. Doppler echocardiography has become the mainstay of the assessment of the severity of aortic regurgitation. Suggestive of severe regurgitation are signs of a broad jet width on color-flow imaging, steep jet velocity deceleration (reflecting equalization of aortic and ventricular pressure), and prolonged diastolic flow reversal in the aorta. The use of Doppler echocardiography makes it possible to quantify the effective regurgitant orifice (severe if 0.30 cm^2) and regurgitant volume (severe if 60 ml per beat)

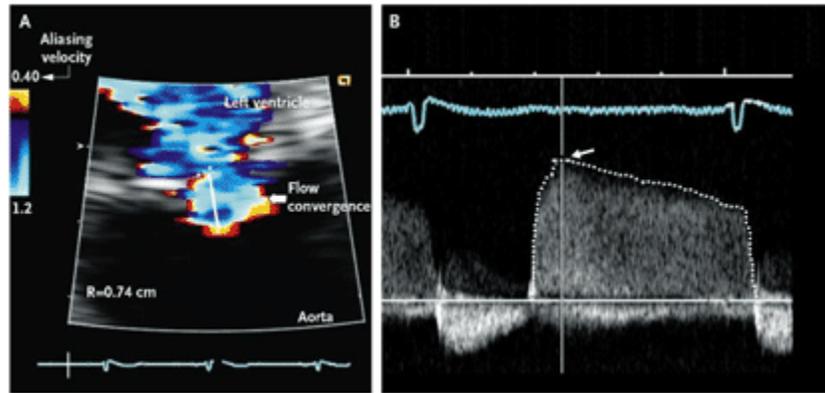

[Echo-Doppler imaging of aortic regurgitation \(video\)](#)

Example of a Jet of Aortic Regurgitation, as Shown by Color-Flow Imaging.

The three components of the regurgitant flow (flow convergence above the orifice, vena contracta through the orifice, and the jet below the orifice) are shown. The width of the vena contracta (as indicated by crosses) can be measured as a surrogate for the regurgitant orifice.

A simple, reliable measurement is the "vena contracta" — that is, the width of the regurgitant flow at the orifice, a surrogate measurement for the size of the orifice. Measurements that are 0.5 cm or more have a high sensitivity for the diagnosis of severe regurgitation, and measurements that are 0.7 cm or more have a high specificity for the diagnosis. On rare occasions, this approach is inconclusive, and either transesophageal echocardiography or angiography of the aortic root is necessary to determine the severity of aortic regurgitation. Left ventricular size and function (particularly, the end-systolic diameter and ejection fraction) should be routinely assessed, as should dilatation of the ascending aorta. If transthoracic imaging is suboptimal for the latter, transesophageal echocardiography, computed tomography, or magnetic resonance imaging can be used. Exercise testing may be warranted in asymptomatic patients with limited physical activity to evaluate functional limitations and may also provide information about changes of left ventricular function with stress.

Example of Quantitation of Aortic Regurgitation by the Convergence of the Proximal Flow. Panel A is a color-flow image of the aortic valve; the measured radius of the proximal flow convergence (R) is 0.74 cm, and the regurgitant flow is calculated as 138 ml per second. The "aliasing" velocity of 0.40 m per second (modified by baseline displacement) is the blood velocity at the junction of the orange and blue flows. Panel B shows a continuous-wave Doppler measurement of regurgitant blood velocity, at 455 cm per second (arrow). The effective regurgitant orifice area is determined by dividing the flow by the velocity, which in this case is 0.30 cm^2 .

Treatment

Acute Aortic Regurgitation

Patients with acute severe AR may respond to intravenous diuretics and vasodilators (such as [sodium nitroprusside](#)), but stabilization is usually short-lived and operation is indicated urgently. Intraaortic balloon counterpulsation is contraindicated. Beta-blockers are also best avoided so as not to reduce the CO further or slow the heart rate, which might allow proportionately more time in diastole for regurgitation to occur. Surgery is the treatment of choice.

Chronic Aortic Regurgitation

Early symptoms of dyspnea and effort intolerance respond to treatment with diuretics and vasodilators (ACE inhibitors, dihydropyridine calcium channel blockers, or [hydralazine](#)) may be useful as well. Surgery can then be performed in more controlled circumstances. The use of vasodilators to extend the compensated phase of chronic severe AR before the onset of symptoms or the development of LV dysfunction is more controversial. Expert consensus is strong regarding the need to control systolic blood pressure (goal $<140 \text{ mmHg}$) in patients with

chronic AR, and vasodilators are an excellent first choice as antihypertensive agents. It is often difficult to achieve adequate control in such patients because of the increased stroke volume. Cardiac arrhythmias and systemic infections are poorly tolerated in patients with severe AR and must be treated promptly and vigorously. Although [nitroglycerin](#) and long-acting nitrates are not as helpful in relieving anginal pain as they are in patients with ischemic heart disease, they are worth a trial. Patients with syphilitic aortitis should receive a full course of penicillin therapy. Beta blockers may be useful to retard the rate of aortic root enlargement in young patients with Marfan syndrome and aortic root dilatation with no or only mild AR. Patients with severe AR should avoid isometric exercises.

Surgical Treatment

In deciding on the advisability and proper timing of surgical treatment, two points should be kept in mind: (1) patients with chronic severe AR usually do not become symptomatic until *after* the development of myocardial dysfunction; and (2) when delayed too long (defined as >1 year from onset of symptoms or LV dysfunction), surgical treatment often does not restore normal LV function. Therefore, in patients with chronic severe AR, careful clinical follow-up and noninvasive testing with echocardiography at approximately 6-month intervals are necessary if operation is to be undertaken at the optimal time, i.e., *after* the onset of LV dysfunction but *prior* to the development of severe symptoms. Operation can be deferred as long as the patient both remains asymptomatic and retains normal LV function.

AVR is indicated for the treatment of severe AR in symptomatic patients irrespective of LV function. In general, operation should be carried out in asymptomatic patients with severe AR and progressive LV dysfunction defined by an LVEF <50%, an LV end-systolic dimension >55mm or end-systolic volume >55 mL/m², or an LV diastolic dimension >75 mm. Smaller dimensions may be appropriate thresholds in individuals of smaller stature. Patients with severe AR without indications for operation should be followed by clinical and echocardiographic examination every 3–12 months.

Surgical options for management of aortic valve and root disease have expanded considerably over the past decade. AVR with a suitable mechanical or tissue prosthesis is generally necessary in patients with rheumatic AR and in many patients with other forms of regurgitation. Rarely, when a leaflet has been perforated during infective endocarditis or torn from its attachments to the aortic annulus by thoracic trauma, primary surgical repair may be

possible. When AR is due to aneurysmal dilatation of the annulus and ascending aorta rather than to primary valvular involvement, it may be possible to reduce the regurgitation by narrowing the annulus or by excising a portion of the aortic root without replacing the valve. Resuspension of the native aortic valve leaflets is possible in approximately 50% of patients with acute AR in the setting of Type A aortic dissection. In other conditions, however, regurgitation can be eliminated only by replacing the aortic valve, excising the dilated or aneurysmal ascending aorta responsible for the regurgitation, and replacing it with a graft. This formidable procedure entails a higher risk than isolated AVR.

As in patients with other valvular abnormalities, both the operative risk and the late mortality are largely dependent on the stage of the disease and on myocardial function at the time of operation. The overall operative mortality for isolated AVR is about 3%. However, patients with marked cardiac enlargement and prolonged LV dysfunction experience an operative mortality rate of approximately 10% and a late mortality rate of approximately 5% per year due to LV failure despite a technically satisfactory operation. Nonetheless, because of the very poor prognosis with medical management, even patients with LV failure should be considered for operation.

Patients with acute severe AR require prompt surgical treatment, which may be lifesaving.

Tricuspid stenosis

TS, much less prevalent than MS in North America and Western Europe, is generally rheumatic in origin and is more common in females than in males. It does not occur as an isolated lesion and is usually associated with MS. Hemodynamically significant TS occurs in 5–10% of patients with severe MS; rheumatic TS is commonly associated with some degree of TR. Nonrheumatic causes of TS are rare.

Pathophysiology

A diastolic pressure gradient between the RA and RV defines TS. It is augmented when the transvalvular blood flow increases during inspiration and declines during expiration. A mean diastolic pressure gradient of 4 mmHg is usually sufficient to elevate the mean RA pressure to levels that result in systemic venous congestion. Unless sodium intake has been restricted and diuretics administered, this venous congestion is associated with hepatomegaly, ascites, and edema, sometimes severe. In patients with sinus rhythm, the RA *a* wave may be extremely tall

and may even approach the level of the RV systolic pressure. The y descent is prolonged. The CO at rest is usually depressed, and it fails to rise during exercise. The low CO is responsible for the normal or only slightly elevated LA, PA, and RV systolic pressures despite the presence of MS. Thus, the presence of TS can mask the hemodynamic and clinical features of the MS, which usually accompanies it.

Symptoms

Since the development of MS generally precedes that of TS, many patients initially have symptoms of pulmonary congestion. Spontaneous improvement of these symptoms should raise the possibility that TS may be developing. Characteristically, patients complain of relatively little dyspnea for the degree of hepatomegaly, ascites, and edema that they have. However, fatigue secondary to a low CO and discomfort due to refractory edema, ascites, and marked hepatomegaly are common in patients with TS and/or TR. In some patients, TS may be suspected for the first time when symptoms of right-sided failure persist after an adequate mitral valvotomy.

Physical Findings

Severe TS is associated with marked hepatic congestion, often resulting in cirrhosis, jaundice, serious malnutrition, anasarca, and ascites. Congestive hepatomegaly and, in cases of severe tricuspid valve disease, splenomegaly are present.

On auscultation, an OS of the tricuspid valve may occasionally be heard approximately 0.06 s after pulmonic valve closure. The diastolic murmur of TS has many of the qualities of the diastolic murmur of MS, and since TS almost always occurs in the presence of MS, the less-common valvular lesion may be missed. However, the tricuspid murmur is generally heard best along the left lower sternal margin and over the xiphoid process, and it is most prominent during presystole in patients with sinus rhythm. The murmur of TS is augmented during inspiration, and it is reduced during expiration and particularly during the strain phase of the Valsalva maneuver, when tricuspid blood flow is reduced.

Laboratory Examination

The ECG features of RA enlargement include tall, peaked P waves in lead II, as well as prominent, upright P waves in lead V₁. The *absence* of ECG evidence of right ventricular hypertrophy (RVH) in a patient with right-sided heart failure who is believed to have MS

should suggest associated tricuspid valve disease. The chest x-ray in patients with combined TS and MS shows particular prominence of the RA and superior vena cava without much enlargement of the PA and with less evidence of pulmonary vascular congestion than occurs in patients with isolated MS. On echocardiographic examination, the tricuspid valve is usually thickened and domes in diastole; the transvalvular gradient can be estimated by Doppler echocardiography. TTE provides additional information regarding mitral valve structure and function, LV and RV size and function, and PA pressure.

Tricuspid Stenosis: Treatment

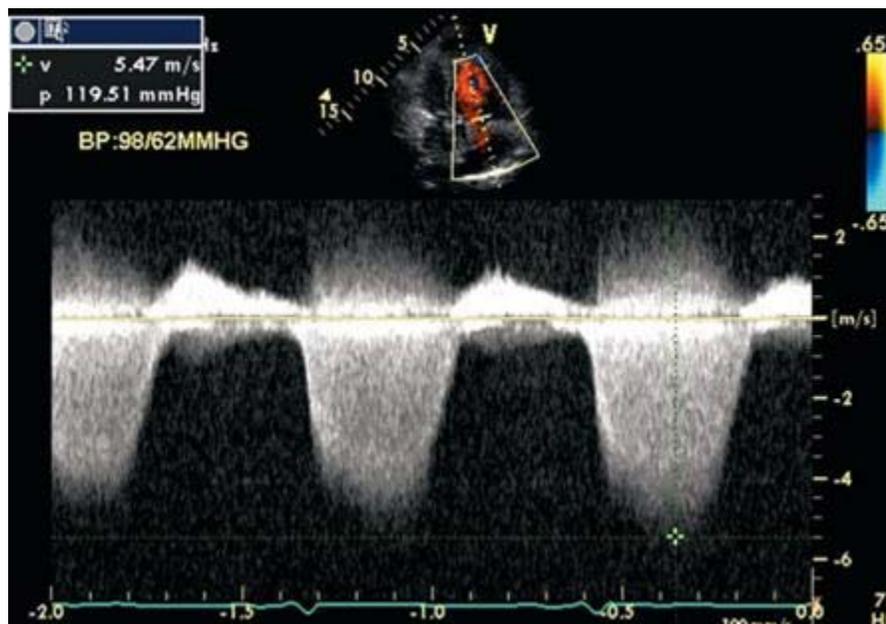

Patients with TS generally exhibit marked systemic venous congestion; intensive salt restriction, bed rest, and diuretic therapy are required during the preoperative period. Such a preparatory period may diminish hepatic congestion and thereby improve hepatic function sufficiently so that the risks of operation, particularly bleeding, are diminished. Surgical relief of the TS should be carried out, preferably at the time of surgical mitral valvotomy or MVR, in patients with moderate or severe TS who have mean diastolic pressure gradients exceeding ~ 4 mmHg and tricuspid orifice areas $< 1.5\text{--}2.0\text{ cm}^2$. TS is almost always accompanied by significant TR. Operative repair may permit substantial improvement of tricuspid valve function. If repair cannot be accomplished, the tricuspid valve may have to be replaced with a prosthesis, preferably a large bioprosthetic valve. Mechanical valves in the tricuspid position are more prone to thromboembolic complications than in other positions.

Tricuspid regurgitation

Most commonly, TR is functional and secondary to marked dilatation of the tricuspid annulus. Functional TR may complicate RV enlargement of any cause, including inferior wall infarcts that involve the RV. It is commonly seen in the late stages of heart failure due to rheumatic or congenital heart disease with severe pulmonary hypertension (pulmonary artery systolic pressure > 55 mmHg), as well as in ischemic heart disease and dilated cardiomyopathy. It is reversible in part if pulmonary hypertension is relieved. Rheumatic fever may produce organic (primary) TR, often associated with TS. Infarction of RV papillary muscles, tricuspid valve prolapse, carcinoid heart disease, endomyocardial fibrosis, infective endocarditis, and trauma all may produce TR. Less commonly, TR results from congenitally deformed tricuspid valves, and it occurs with defects of the atrioventricular canal, as well as with Ebstein's malformation of the tricuspid valve. TR also develops eventually in patients with chronic RV apical pacing.

As is the case for TS, the clinical features of TR result primarily from systemic venous congestion and reduction of CO. With the onset of TR in patients with pulmonary hypertension, symptoms of pulmonary congestion diminish, but the clinical manifestations of right-sided heart failure become intensified. The neck veins are distended with prominent *v* waves and rapid *y* descents, marked hepatomegaly, ascites, pleural effusions, edema, systolic pulsations of the liver, and a positive hepatojugular reflux. A prominent RV pulsation along the left parasternal region and a blowing holosystolic murmur along the lower left sternal margin, which may be intensified during inspiration and reduced during expiration or the strain of the Valsalva maneuver (Carvalho's sign), are characteristic findings; AF is usually present.

The ECG usually shows changes characteristic of the lesion responsible for the enlargement of the RV that leads to TR, e.g., inferior wall myocardial infarction or severe RVH. Echocardiography may be helpful by demonstrating RV dilatation and prolapsing, flail, scarred, or displaced tricuspid leaflets; the diagnosis of TR can be made by color flow Doppler echocardiography, and its severity can be estimated by Doppler examination.

Continuous-wave Doppler of tricuspid regurgitation in a patient with pulmonary hypertension. There is an increase in the velocity of flow from the right ventricle into the right atrium to 5.4 m/s. Using the modified Bernoulli equation, the peak pressure gradient between the right ventricle and right atrium during systole is 120 mmHg. Assuming a right atrial pressure of 10 mmHg, the right ventricular systolic pressure is 130 mmHg. In the absence of right ventricular outflow tract obstruction, this indicates there is severe pulmonary hypertension with a pulmonary artery systolic pressure of 130 mmHg.

Severe TR is accompanied by hepatic vein systolic flow reversal. Continuous wave Doppler is also useful in estimating PA pressure. Roentgenographic examination usually reveals enlargement of both the RA and RV.

In patients with severe TR, the CO is usually markedly reduced, and the RA pressure pulse may exhibit no *x* descent during early systole but a prominent *c-v* wave with a rapid *y* descent. The mean RA and the RV end-diastolic pressures are often elevated.

Tricuspid Regurgitation: Treatment

Isolated TR, in the absence of pulmonary hypertension, such as that occurring as a consequence of infective endocarditis or trauma, is usually well tolerated and does not require operation. Indeed, even total excision of an infected tricuspid valve may be well tolerated for several years if the PA pressure is normal. Treatment of the underlying cause of heart failure usually reduces the severity of functional TR, by reducing the size of the tricuspid annulus. In patients with mitral valve disease and TR secondary to pulmonary hypertension and massive RV enlargement, effective surgical correction of the mitral valvular abnormality results in lowering of the PA pressures and gradual reduction or disappearance of the TR without direct treatment of the tricuspid valve. However, recovery may be much more rapid in patients with severe secondary TR if, at the time of mitral valve surgery, and especially when there is measurable enlargement of the tricuspid valve annulus, tricuspid annuloplasty (generally with the insertion of a plastic ring), open tricuspid valve repair, or, in the rare instance of severe organic tricuspid valve disease, tricuspid valve replacement is performed. Tricuspid annuloplasty or replacement may be required for severe TR with primary involvement of the valve.

Ebstein's Anomaly

Ebstein's anomaly is an abnormality of the tricuspid valve in which the septal leaflets and often the posterior leaflets are displaced into the right ventricle and the anterior leaflet is usually malformed, excessively large, and abnormally attached or adherent to the right ventricular free wall. Thus, a portion of the right ventricle is "atrialized" in that it is located on the atrial side of the tricuspid valve, and the remaining functional right ventricle is small (Figure 6). The tricuspid valve is usually regurgitant but may be stenotic. Eighty percent of patients with

Ebstein's anomaly have an interatrial communication (atrial septal defect or patent foramen ovale) through which right-to-left shunting of blood may occur.

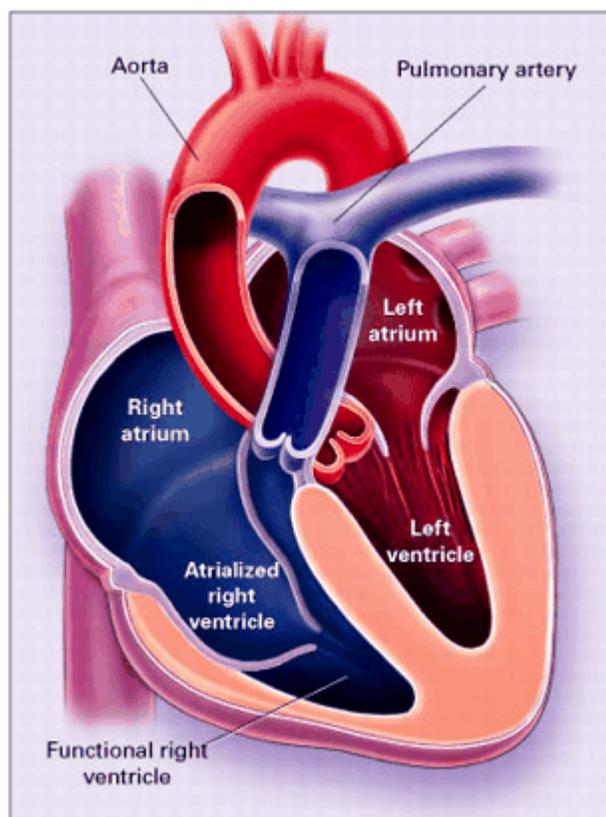

Figure Ebstein's Anomaly.

In patients with Ebstein's anomaly, a portion of the right ventricle is atrialized (i.e., located on the atrial side of the tricuspid valve), and as a result, the functional right ventricle is small. In addition, most patients have an interatrial communication (atrial septal defect or patent foramen ovale), through which right-to-left shunting may occur.

The severity of the hemodynamic derangements in patients with Ebstein's anomaly depends on the degree of displacement and the functional status of the tricuspid-valve leaflets. Patients with mild apical displacement of the tricuspid leaflets have normal valvular function, whereas those with severe tricuspid-leaflet displacement or abnormal anterior leaflet attachment, with valvular dysfunction, have elevated right atrial pressure and right-to-left interatrial shunting. Similarly, the clinical presentation of Ebstein's anomaly varies from severe heart failure in a fetus or neonate to the absence of symptoms in an adult in whom it is discovered incidentally.

When Ebstein's anomaly is discovered during fetal life, the rate of intrauterine mortality is

high. Neonates with severe disease have cyanosis, with heart failure and a murmur noted in the first days of life. Transient improvement may occur as pulmonary vascular resistance falls, but the condition worsens after the ductus arteriosus closes, thereby decreasing pulmonary blood flow. Older children with Ebstein's anomaly often come to medical attention because of an incidental murmur, whereas adolescents and adults present with a supraventricular arrhythmia. In adults with Ebstein's anomaly, the most important predictors of outcome are the New York Heart Association (NYHA) functional class, the heart size, the presence or absence of cyanosis, and the presence or absence of paroxysmal atrial tachycardias. Such tachycardias may lead to cardiac failure, worsening cyanosis, and even syncope. Patients with Ebstein's anomaly and an interatrial communication are at risk for paradoxical embolization, brain abscess, and sudden death.

On physical examination, the severity of cyanosis depends on the magnitude of right-to-left shunting. The first and second heart sounds are widely split, and a third or fourth heart sound is often present, resulting in a "triple" or "quadruple" rhythm. A systolic murmur caused by tricuspid regurgitation is usually present at the left lower sternal border. Hepatomegaly (resulting from passive hepatic congestion due to elevated right atrial pressure) may be present.

Tall and broad P waves are common on the electrocardiogram, as is right bundle-branch block. First-degree atrioventricular block occurs frequently. Since about 20 percent of patients with Ebstein's anomaly have ventricular preexcitation by way of an accessory electrical pathway between the atrium and ventricle (Wolff–Parkinson–White syndrome), a delta wave may be present. The radiographic findings depend on the severity of the anatomical abnormality. In mild cases, the heart size and pulmonary vasculature are normal. In more severe cases, marked cardiomegaly, which is largely due to right atrial enlargement, is present. In severe cases (with little functional right ventricle and marked right-to-left shunting), pulmonary vascular markings are decreased. Echocardiography is used to assess right atrial dilatation, anatomical displacement and distortion of the tricuspid-valve leaflets, and the severity of tricuspid regurgitation or stenosis; in addition, the presence and magnitude of interatrial shunting can be determined (by color Doppler imaging or bubble study), as can the presence of associated cardiac abnormalities. Electrophysiologic evaluation is warranted in patients with atrial tachyarrhythmias.

The management of Ebstein's anomaly centers on the prevention and treatment of complications. Prophylaxis against infective endocarditis is recommended. Patients with symptomatic heart failure are given diuretic agents and digoxin. Those with atrial arrhythmias may be treated pharmacologically or with catheter ablation (if an accessory pathway is present). Ablation of accessory pathways has a lower rate of success in patients with Ebstein's anomaly than in those with structurally normal hearts, and the risk of recurrence of arrhythmia is higher. In severely ill infants with Ebstein's anomaly, an arterial shunt from the systemic circulation to the pulmonary circulation is created to increase pulmonary blood flow, thereby decreasing cyanosis. Further surgery to create a univentricular heart (i.e., by the Fontan procedure) may also be considered in neonates.

Repair or replacement of the tricuspid valve in conjunction with closure of the interatrial communication is recommended for older patients who have severe symptoms despite medical therapy. When possible, valve repair is preferable to valve replacement, because it is associated with lower mortality and has fewer long-term complications. The complications of surgery to correct Ebstein's anomaly include complete heart block, persistence of supraventricular arrhythmias, residual tricuspid regurgitation after valve repair, and prosthetic-valve dysfunction.

Ebstein's Anomaly

Ebstein's anomaly is an abnormality of the tricuspid valve in which the septal leaflets and often the posterior leaflets are displaced into the right ventricle and the anterior leaflet is usually malformed, excessively large, and abnormally attached or adherent to the right ventricular free wall. Thus, a portion of the right ventricle is "atrialized" in that it is located on the atrial side of the tricuspid valve, and the remaining functional right ventricle is small (Figure 6). The tricuspid valve is usually regurgitant but may be stenotic. Eighty percent of patients with Ebstein's anomaly have an interatrial communication (atrial septal defect or patent foramen ovale) through which right-to-left shunting of blood may occur.

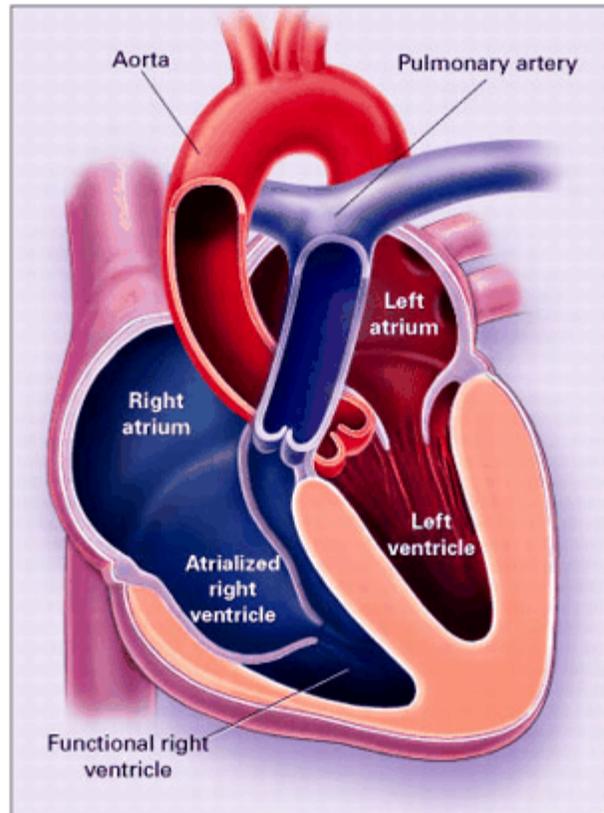

Figure 6. Ebstein's Anomaly.

In patients with Ebstein's anomaly, a portion of the right ventricle is atrialized (i.e., located on the atrial side of the tricuspid valve), and as a result, the functional right ventricle is small. In addition, most patients have an interatrial communication (atrial septal defect or patent foramen ovale), through which right-to-left shunting may occur.

The severity of the hemodynamic derangements in patients with Ebstein's anomaly depends on the degree of displacement and the functional status of the tricuspid-valve leaflets. Patients with mild apical displacement of the tricuspid leaflets have normal valvular function, whereas those with severe tricuspid-leaflet displacement or abnormal anterior leaflet attachment, with valvular dysfunction, have elevated right atrial pressure and right-to-left interatrial shunting. Similarly, the clinical presentation of Ebstein's anomaly varies from severe heart failure in a fetus or neonate to the absence of symptoms in an adult in whom it is discovered incidentally.

When Ebstein's anomaly is discovered during fetal life, the rate of intrauterine mortality is high. Neonates with severe disease have cyanosis, with heart failure and a murmur noted in the first days of life. Transient improvement may occur as pulmonary vascular resistance falls, but

the condition worsens after the ductus arteriosus closes, thereby decreasing pulmonary blood flow. Older children with Ebstein's anomaly often come to medical attention because of an incidental murmur, whereas adolescents and adults present with a supraventricular arrhythmia. In adults with Ebstein's anomaly, the most important predictors of outcome are the New York Heart Association (NYHA) functional class, the heart size, the presence or absence of cyanosis, and the presence or absence of paroxysmal atrial tachycardias. Such tachycardias may lead to cardiac failure, worsening cyanosis, and even syncope. Patients with Ebstein's anomaly and an interatrial communication are at risk for paradoxical embolization, brain abscess, and sudden death.

On physical examination, the severity of cyanosis depends on the magnitude of right-to-left shunting. The first and second heart sounds are widely split, and a third or fourth heart sound is often present, resulting in a "triple" or "quadruple" rhythm. A systolic murmur caused by tricuspid regurgitation is usually present at the left lower sternal border. Hepatomegaly (resulting from passive hepatic congestion due to elevated right atrial pressure) may be present.

Tall and broad P waves are common on the electrocardiogram, as is right bundle-branch block. First-degree atrioventricular block occurs frequently. Since about 20 percent of patients with Ebstein's anomaly have ventricular preexcitation by way of an accessory electrical pathway between the atrium and ventricle (Wolff–Parkinson–White syndrome), a delta wave may be present. The radiographic findings depend on the severity of the anatomical abnormality. In mild cases, the heart size and pulmonary vasculature are normal. In more severe cases, marked cardiomegaly, which is largely due to right atrial enlargement, is present. In severe cases (with little functional right ventricle and marked right-to-left shunting), pulmonary vascular markings are decreased. Echocardiography is used to assess right atrial dilatation, anatomical displacement and distortion of the tricuspid-valve leaflets, and the severity of tricuspid regurgitation or stenosis; in addition, the presence and magnitude of interatrial shunting can be determined (by color Doppler imaging or bubble study), as can the presence of associated cardiac abnormalities. Electrophysiologic evaluation is warranted in patients with atrial tachyarrhythmias.

The management of Ebstein's anomaly centers on the prevention and treatment of

complications. Prophylaxis against infective endocarditis is recommended. Patients with symptomatic heart failure are given diuretic agents and digoxin. Those with atrial arrhythmias may be treated pharmacologically or with catheter ablation (if an accessory pathway is present). Ablation of accessory pathways has a lower rate of success in patients with Ebstein's anomaly than in those with structurally normal hearts, and the risk of recurrence of arrhythmia is higher. In severely ill infants with Ebstein's anomaly, an arterial shunt from the systemic circulation to the pulmonary circulation is created to increase pulmonary blood flow, thereby decreasing cyanosis. Further surgery to create a univentricular heart (i.e., by the Fontan procedure) may also be considered in neonates.

Repair or replacement of the tricuspid valve in conjunction with closure of the interatrial communication is recommended for older patients who have severe symptoms despite medical therapy. In addition, repair or replacement should be considered for patients with less severe symptoms who have cardiac enlargement, since this condition has a poor prognosis. When possible, valve repair is preferable to valve replacement, because it is associated with lower mortality and has fewer long-term complications. However, when valve replacement is required, a bioprosthesis is preferable to a mechanical prosthesis. The complications of surgery to correct Ebstein's anomaly include complete heart block, persistence of supraventricular arrhythmias, residual tricuspid regurgitation after valve repair, and prosthetic-valve dysfunction.

Transposition of the Great Arteries

With d-transposition of the great arteries (also known as complete transposition), the aorta arises in an anterior position from the right ventricle and the pulmonary artery arises from the left ventricle (Figure 7A). Therefore, there is complete separation of the pulmonary and systemic circulations: systemic venous blood traverses the right atrium, right ventricle, aorta, and systemic circulation, whereas pulmonary venous blood traverses the left atrium, left ventricle, pulmonary artery, and pulmonary circulation. In order for an infant with this condition to survive, there must be a communication between the two circuits. In about two thirds of patients, no other associated cardiac defect is present, so that the ductus arteriosus and foramen ovale allow communication between the two circuits. Infants with this condition have severe cyanosis. The one third of patients with other associated defects that permit

intracardiac mixing (e.g., atrial septal defect, ventricular septal defect, or patent ductus arteriosus) are less critically ill, since they have less severe cyanosis. However, they are at risk for left ventricular failure due to volume overload caused by left-to-right shunting.

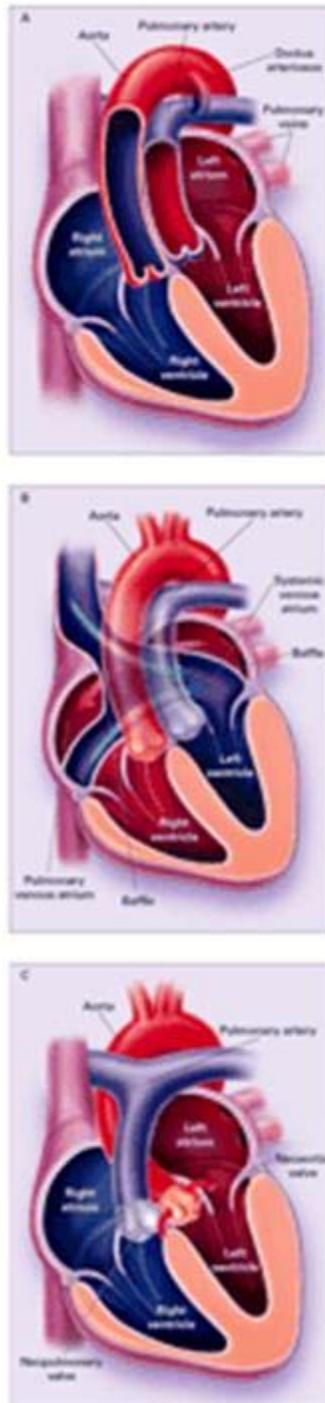

Figure 7. Transposition and Switching of the Great Arteries.

In d-transposition of the great arteries (complete transposition) (Panel A), systemic venous blood returns to the right atrium, from which it goes to the right ventricle and then to the aorta. Pulmonary venous blood returns to the left atrium, from which it goes to the left ventricle and then to the pulmonary artery. Survival is possible only if there is a communication between the two circuits, such as a patent ductus arteriosus. With the "atrial switch" operation (Panel B), a pericardial baffle is created in the atria, so that blood returning from the systemic venous circulation is directed into the left ventricle and then the pulmonary artery (blue arrows), whereas blood returning from the pulmonary venous circulation is directed into the right ventricle and then the aorta (red arrow). With the "arterial switch" operation (Panel C), the pulmonary artery and ascending aorta are transected above the semilunar valves and coronary arteries, then switched (neoaortic and neopulmonary valves).

Patients with complete transposition have cyanosis from birth and often have heart failure in the newborn period. The findings on physical examination are nonspecific. Infants have cyanosis and tachypnea. The second heart sound is single and loud (due to the anterior position of the aorta). In patients with mild cyanosis, a holosystolic murmur caused by a ventricular septal defect may be heard. Likewise, a soft systolic ejection murmur (due to pulmonary stenosis, ejection into the anteriorly located aorta, or both) may be audible. The electrocardiogram shows right-axis deviation and right ventricular hypertrophy (since the right ventricle is the systemic ventricle). Patients with a large ventricular septal defect or patent ductus arteriosus, as well as those with pulmonary stenosis, have left ventricular hypertrophy. The chest radiograph shows cardiomegaly with increased pulmonary vascularity. Classically, the cardiac silhouette is described as being egg-shaped, with a narrow "stalk."

Without intervention, patients with complete transposition have a poor prognosis. Unless intracardiac mixing is improved, progressive hypoxemia and acidosis develop; the mortality rate is 90 percent by six months of age. Infants who have less severe cyanosis (because of a sizable ventricular septal defect or patent ductus arteriosus) fare better in the neonatal period, but pulmonary vascular obstructive disease (due to increased pulmonary blood flow) is more likely to develop than in infants with more severe cyanosis; infants with less severe cyanosis are also more likely to have higher operative mortality and are less likely to have complete repair of their defect.

The immediate management of complete transposition involves creating intracardiac mixing or increasing its extent. This can be accomplished with an infusion of prostaglandin E (to maintain or restore patency of the ductus arteriosus), the creation of an atrial septal defect by means of balloon atrial septostomy (the Rashkind procedure), or both. In addition, oxygen is given to most patients (to decrease pulmonary vascular resistance and to increase pulmonary blood flow), as are digoxin and diuretic drugs (to treat heart failure).

Two surgical procedures have been used in patients with complete transposition of the great arteries. With the initial approach, known as the "atrial switch" operation (the Mustard or Senning operation), the atrial septum was excised, then a "baffle" within the atria was constructed to direct systemic venous blood across the mitral valve into the left ventricle and pulmonary venous blood across the tricuspid valve into the right ventricle (Figure 7B). Thus, physiologic circulation was restored; however, after this procedure was performed, the right ventricle continued to function as the "systemic ventricle." This operation corrected cyanosis and improved survival. The complications associated with it were leakage of the atrial baffle (often clinically inconsequential); obstruction of the baffle (often insidious and frequently asymptomatic); sinus-node dysfunction and atrial arrhythmias, particularly atrial flutter; right (systemic) ventricular dysfunction; and an increased risk of sudden death.

The atrial-switch operation has been replaced by the arterial-switch operation, in which the pulmonary artery and ascending aorta are transected above the semilunar valves and coronary arteries and then switched, so that the aorta is connected to the neo-aortic valve (formerly the pulmonary valve) arising from the left ventricle, and the pulmonary artery is connected to the neopulmonary valve (formerly the aortic valve) arising from the right ventricle (Figure 7C). The coronary arteries are relocated to the neo-aorta to restore normal coronary circulation. This operation can be performed in neonates and is associated with a low operative mortality and an excellent long-term outcome.

Eisenmenger's Syndrome

A patient with Eisenmenger's syndrome has a large left-to-right shunt that causes severe pulmonary vascular disease and pulmonary hypertension, with resultant reversal of the direction of shunting (Figure 8). With substantial left-to-right shunting, the exposure of the

pulmonary vasculature to increased blood flow as well as increased pressure often results in pulmonary vascular obstructive disease. The initial morphologic alterations (medial hypertrophy of the pulmonary arterioles, intimal proliferation and fibrosis, and occlusion of capillaries and small arterioles) are potentially reversible. However, as the disease progresses, the more advanced morphologic changes (plexiform lesions and necrotizing arteritis) are irreversible. The result is obliteration of much of the pulmonary vascular bed, leading to increased pulmonary vascular resistance. As the pulmonary vascular resistance approaches or exceeds systemic resistance, the shunt is reversed.

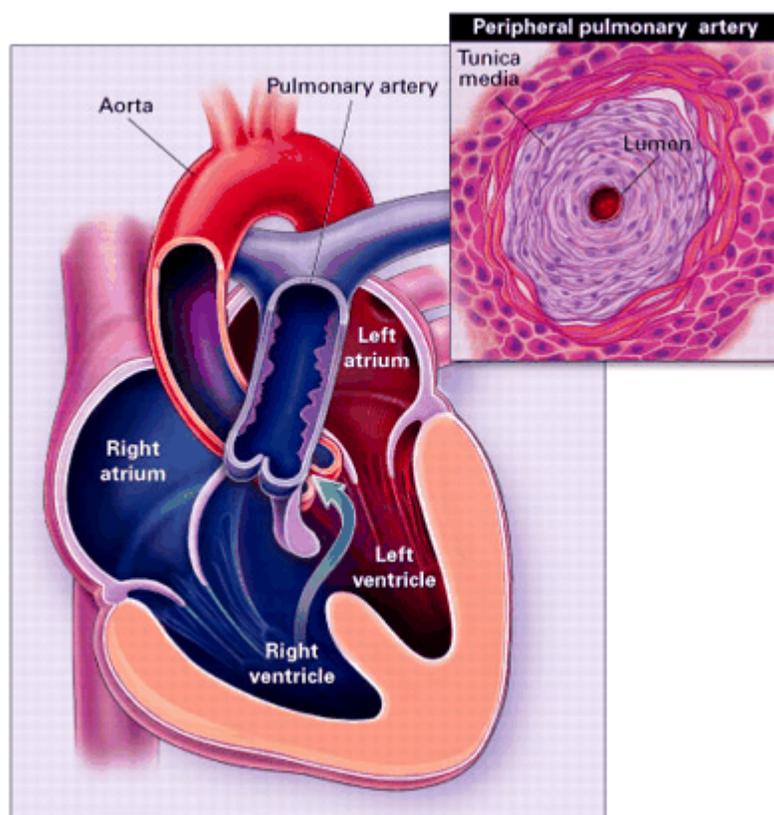

Figure 8. Eisenmenger's Syndrome.

In patients with Eisenmenger's syndrome, in response to substantial left-to-right shunting, morphologic alterations occur in the small pulmonary arteries and arterioles (inset), leading to pulmonary hypertension and the resultant reversal of the intracardiac shunt (arrow). In the small pulmonary arteries and arterioles, medial hypertrophy, intimal cellular proliferation, and fibrosis lead to narrowing or closure of the vessel lumen. With sustained pulmonary hypertension, extensive atherosclerosis and calcification often develop in the large pulmonary arteries. Eisenmenger's syndrome may occur in association with a ventricular septal defect (as

shown), but it also may occur in association with an atrial septal defect or patent ductus arteriosus.

The morphologic changes in the pulmonary vasculature that occur with Eisenmenger's syndrome usually begin in childhood, but symptoms may not appear until late childhood or early adulthood. In many patients, pulmonary congestion in early infancy (a result of the large left-to-right shunt) resolves in later infancy or early childhood as pulmonary vascular resistance increases and the magnitude of shunting decreases. Likewise, the patient may have a murmur in early childhood that disappears (as the pulmonary disease progresses and the magnitude of shunting decreases), leading to the mistaken assumption that the intracardiac communication has closed. Occasionally, patients have no history of pulmonary congestion or a murmur in childhood.

As right-to-left shunting develops, cyanosis appears. Most patients will have impaired exercise tolerance and exertional dyspnea, but these symptoms may be well compensated for years. Palpitations are common and are most often due to atrial fibrillation or flutter. As erythrocytosis due to arterial desaturation develops in patients with Eisenmenger's syndrome, symptoms of hyperviscosity (visual disturbances, fatigue, headache, dizziness, and paresthesias) may appear. Hemoptysis may occur, as a result of pulmonary infarction or rupture of dilated pulmonary arteries, arterioles, or aortopulmonary collateral vessels. Since patients with arterial desaturation have abnormal hemostasis, they are at risk for both bleeding and thrombosis. Cerebrovascular accidents may occur as a result of paradoxical embolization, venous thrombosis of cerebral vessels, or intracranial hemorrhage. In addition, patients with this condition are at risk for brain abscess. Patients with Eisenmenger's syndrome may have syncope owing to inadequate cardiac output or, less commonly, an arrhythmia. Symptoms of heart failure, which are uncommon until the disease is far advanced, portend a poor prognosis. Finally, these patients are at risk for sudden death.

On physical examination, patients have digital clubbing and cyanosis, the severity of which depends on the magnitude of right-to-left shunting. The jugular venous pressure may be normal or elevated, and prominent V waves are seen if tricuspid regurgitation is present. Arterial pulses are small in volume. A right parasternal heave (due to right ventricular hypertrophy) is present,

and the pulmonary component of the second heart sound is loud (and often palpable). The murmur caused by a ventricular septal defect, patent ductus arteriosus, or atrial septal defect disappears when Eisenmenger's syndrome develops. Many patients have a decrescendo diastolic murmur caused by pulmonary regurgitation or a holosystolic murmur caused by tricuspid regurgitation. A right-sided fourth heart sound is usually present. The lungs are clear. Peripheral edema and hepatic congestion are absent unless there is substantial right ventricular dysfunction.

The electrocardiogram shows right ventricular hypertrophy. Atrial arrhythmias may be present, particularly in patients with atrial septal defect. The chest film reveals prominent central pulmonary arteries and decreased vascular markings ("pruning") of the peripheral vessels. The size of the heart is normal in patients with a ventricular septal defect or patent ductus arteriosus, but cardiomegaly (due to right ventricular enlargement) is usually seen in those with atrial septal defect. On transthoracic echocardiography, there is evidence of right ventricular pressure overload and pulmonary hypertension. The underlying cardiac defect can usually be visualized, although shunting across the defect may be difficult to demonstrate by color Doppler imaging because of the low velocity of the jet. Contrast echocardiography permits the location of the shunt to be determined. Catheterization should be performed in any patient with suspected Eisenmenger's syndrome in order to assess the severity of pulmonary vascular disease and to quantify the magnitude of intracardiac shunting. Pulmonary vasodilators — such as oxygen, inhaled nitrous oxide, or intravenous adenosine or epoprostenol — should be administered to permit assessment of the reversibility of pulmonary hypertension.

The rate of survival among patients with Eisenmenger's syndrome is 80 percent 10 years after diagnosis, 77 percent at 15 years, and 42 percent at 25 years. Death is usually sudden, presumably caused by arrhythmias, but some patients die of heart failure, hemoptysis, brain abscess, or stroke. A history of syncope, clinically evident right ventricular systolic dysfunction, low cardiac output, and severe hypoxemia portend a poor outcome.

Patients with Eisenmenger's syndrome should avoid intravascular volume depletion, heavy exertion, high altitude, and the use of vasodilators. Because of high maternal and fetal morbidity and mortality, pregnancy should be avoided. Although no therapy has been proved to

reduce pulmonary vascular resistance, intravenous epoprostenol may be beneficial. Phlebotomy with isovolumic replacement should be performed in patients with moderate or severe symptoms of hyperviscosity; it should not be performed in asymptomatic or mildly symptomatic patients (regardless of the hematocrit). Repeated phlebotomy may result in iron deficiency, which may worsen symptoms of hyperviscosity, since iron-deficient erythrocytes are less deformable than iron-replete erythrocytes.

Patients with Eisenmenger's syndrome who are undergoing noncardiac surgery require meticulous management of anesthesia, with attention to the maintenance of systemic vascular resistance, the minimization of blood loss and intravascular volume depletion, and the prevention of iatrogenic paradoxical embolization. In preparation for noncardiac surgery, prophylactic phlebotomy (usually of 1 to 2 units of blood, with isovolumic replacement) is recommended for patients with a hematocrit above 65 percent in order to reduce the likelihood of perioperative hemorrhagic and thrombotic complications. In general, anticoagulants and antiplatelet agents should be avoided, since they exacerbate the hemorrhagic diathesis.

Lung transplantation with repair of the cardiac defect or combined heart–lung transplantation is an option for patients with Eisenmenger's syndrome who have markers of a poor prognosis (syncope, refractory right-sided heart failure, a high NYHA functional class, or severe hypoxemia). Because of the somewhat limited success of transplantation and the reasonably good survival among patients treated medically, careful selection of patients for transplantation is imperative.

Atrial septal defect: case 1

A 43-year-old businessman presents to the accident and emergency department having had palpitations for 12 h. He admits to having increasing shortness of breath over the past two years, and having to rest after climbing three flights of stairs. On examination, his pulse was irregular at a rate of 110 beats per minute, and his jugular venous pulsation (JVP) 6 cm over the sternal angle. He also had a mild right ventricular impulse, a fixed split of S2 (second heart sound) and an ejection murmur 2/6 best heard at the second left intercostal space. Chest radiography showed a dilated right ventricle and increased pulmonary blood flow. The electrocardiogram showed atrial fibrillation. Transthoracic echocardiography confirmed the

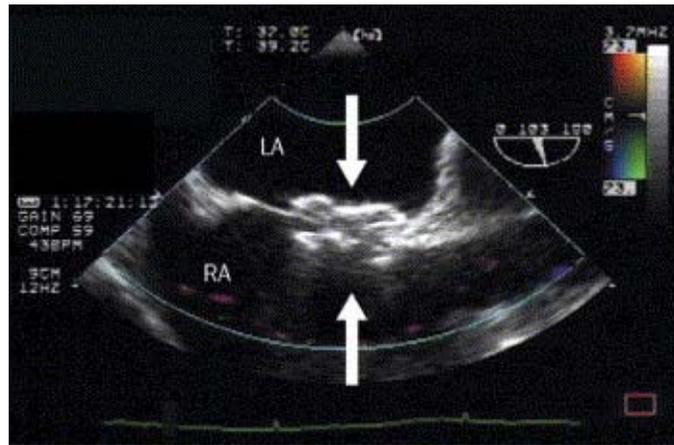

presence of a secundum atrial septal defect with moderate right ventricular dilation.

Atrial septal defects are some of the most common congenital cardiac malformations in adults, representing up to 40% of acyanotic shunt lesions in patients older than 40 years. They arise from either excessive resorption of the septum primum or from deficient growth of the septum secundum, and are occasionally associated with anomalous pulmonary venous connection (about 10%). The degree of left-to-right atrial shunting depends on the size of the defect and the diastolic filling properties of the two ventricles. A substantial shunt ($Q_p/Q_s > 1.5/1.0$) will probably cause symptoms over time, and the movement of such patients will become progressively more restricted with age. Effort dyspnoea is seen in about 30% of patients by their third decade whereas supraventricular arrhythmias (atrial fibrillation or flutter) and right heart failure develop in about 10% of patients by age 40 years.

Treatment

Haemodynamically unimportant atrial septal defects ($Q_p/Q_s < 1.5$) do not need closure, except for the prevention of paradoxical emboli in patients who have had cryptogenic stroke. In the absence of clinically significant pulmonary hypertension, closure is recommended for severe defects ($Q_p/Q_s > 1.5$, or those associated with right ventricular volume overload). In patients without symptoms, indications for closure are somewhat controversial. In those younger than 40 years, severe defects should probably be closed. The appropriate treatment for patients who are older than 40 years is in some dispute, although results of one randomised clinical trial which showed an overall survival benefit among surgical patients would suggest that closure is advisable.

Surgical closure of these defects can be done by primary suture closure or by an autologous pericardial or synthetic patch. Surgical mortality in adults with no pulmonary hypertension should be less than 1%, with a low morbidity related mainly to the development of perioperative arrhythmias (atrial flutter or fibrillation, or junctional rhythm). The use of devices to close defects percutaneously under fluoroscopy and transoesophageal echocardiographic guidance is gaining popularity.

Transoesophageal echocardiographical image of a secundum atrial septal defect after closure with Amplatzer device

LA=left atrium. RA=right atrium. Arrows point at both sides of the Amplatzer device after insertion.

Indications for closure by devices are the same as for surgical closure but selection criteria are stricter than for surgery. Devices are available only for patients with one secundum atrial septal defect and with an adequate septal margin for proper device support. Anomalous pulmonary venous connection precludes the use of this technique. This procedure is safe and effective when done by a skilled cardiologist, and major complications (eg, device embolisation, atrial perforation) arise in less than 1% of patients. Complete closure is achieved in 80% or more of patients. Long-term follow-up data, however, are not available. Notwithstanding, closure by device can be appealing to a patient wishing to avoid the consequences of surgery (general anaesthesia, cardiopulmonary bypass, pain, scar, and time for convalescence), or to a patient believed to be at high surgical risk.

Patent ductus arteriosus: case 2

A 72-year-old woman is referred by her family doctor for atypical chest pain. Risk factors for coronary artery disease are few. Physical examination revealed a grade 1/6 continuous murmur in the left subclavian area. Transthoracic echo confirmed a small colour flow jet area seen between the aorta and the pulmonary artery in the suprasternal view, suggestive of a small patent ductus arteriosus. Left-heart chambers are of normal size and function.

The incidence of isolated persistent patency of the ductus arteriosus is estimated at one in 2000 to one in 5000 births. The ductus arteriosus derives from the left sixth primitive aortic arch and

connects the proximal left pulmonary artery to the descending aorta, distal to the left subclavian artery. Occasionally, the ductus fails to close at birth and presents as a potential clinical problem.

Physiological consequences of a patent ductus arteriosus depend on the degree of left-to-right shunting, which is determined by both the size of the duct and the difference between systemic and pulmonary vascular resistances. A small ductus accompanied by a small shunt does not cause significant haemodynamic disruption but might predispose to endarteritis, especially if accompanied by an audible murmur. A moderate sized duct and shunt put a volume load on the left atrium and ventricle that results in dilation and often dysfunction of the left ventricle, and development of a trial fibrillation, or both. A large duct results initially in left-ventricular volume overload (which disappears after pulmonary hypertension develops), with a progressive rise in pulmonary artery pressure. This rise in pressure leads to high pulmonary vascular resistance and eventually, irreversible pulmonary vascular changes and systemic pulmonary pressures.

Treatment

Closure of a clinically detectable patent ductus arteriosus, in the absence of irreversible pulmonary hypertension, is usually recommended, although controversial, to avoid infective endarteritis. The risk of endarteritis in a patient with a small silent patent ductus arteriosus is regarded as negligible, and closure of such small ducts is therefore not recommended. Over the past 20 years, the effectiveness and safety of transcatheter device closure for ducts smaller than 8 mm has been established. Complete ductal closure is achieved in more than 85% of patients, 1 year after device placement, with a mortality rate of less than 1%. Patients who undergo transcatheter closure avoid general anaesthesia, thoracotomy, postoperative pain, and long convalescence, which makes this procedure very appealing. In centres with appropriate resources and experience, transcatheter device occlusion should be the method of choice for ductal closure.

Surgical closure, by ductal ligation or division, or both, has been done for over 50 years with a slightly better closure rate, but greater morbidity and mortality, than that for closure with device. Surgical closure of a duct should be reserved for patients with ducts larger than 8 mm in diameter or done in centres with no cardiologists specialising in such interventional techniques. Patients who undergo duct closure by device or surgery should be examined periodically and have an echocardiogram to assess possible recanalisation. The risk of late endarteritis from a clinically silent residual shunt, after device implantation or surgical closure,

is unknown,²⁴ and appropriate clinical management of such patients is unclear. Some would recommend closure by device in this patient to eliminate the risk of endarteritis. In our view however, there is no evidence for that approach. Others might choose a non-interventional approach with the use of prophylactic treatment for subacute bacterial endocarditis when needed.

Bicuspid aortic valve: case 3

A 25-year-old woman (Gravida one, pregnancy none, abortion none) is referred at 18 weeks' pregnancy for a heart murmur. The patient is asymptomatic. Her blood pressure is 90/60 mm Hg. On examination she had an ejection click best heard at the apex, a grade 3/6 systolic ejection murmur best heard at the second right intercostal space, with radiation to the carotids with a soft diastolic murmur grade 2/6 heard clearest along the left sternal border. A transthoracic echocardiogram confirmed the presence of a bicuspid aortic valve with moderate aortic stenosis (aortic valve area 1.0 cm^2), and mild-to-moderate aortic regurgitation. Cardiac MRI showed a dilated ascending aorta measuring 50 mm and no evidence of coarctation.

MRI of a dilated ascending aorta in a patient with a bicuspid aortic valve

Arrows indicate the sides of the dilated ascending aorta.

Bicuspid aortic valve has a male preponderance of 4 to 1. This lesion accounts for about half the cases of surgically important isolated aortic stenosis in adults. A bicuspid aortic valve consists of two cusps, often of unequal size, the larger usually containing a false raphe. This lesion generally arises in isolation but is associated with other abnormalities in 20% of patients, the most common of which is coarctation of the aorta and patent ductus arteriosus.

At least half the patients with a bicuspid aortic valve have no complications, although there is always the risk of endocarditis. Mild aortic stenosis or regurgitation from bicuspid aortic valve generally progresses as the patient ages, but the rate is variable. Enlargement of the aortic root resulting from cystic medial changes in patients with bicuspid aortic valve has a high prevalence, and occurs irrespective of altered haemodynamics or age. Aortic dissection is rare.

Treatment

Bicuspid aortic valves need intervention for stenosis when symptoms (exertional dyspnoea, angina, pre-syncope, or syncope) are present and should be considered before pregnancy when the stenosis is severe. Intervention for asymptomatic severe aortic stenosis to allow safe pregnancy is controversial, but severe aortic stenosis has proved to be a risk factor for cardiac decompensation during pregnancy.³⁰ Bicuspid aortic stenosis can be treated with balloon valvuloplasty if the patient is younger than 30 years and if the valve is not calcified. Other treatment options include open aortic valvotomy, or valve replacement with a mechanical valve, a biological valve, or a pulmonary autograft (Ross procedure).

Prophylactic surgery for proximal aortic dilation (>55 mm), in the context of bicuspid aortopathy, seems better than waiting for the aorta to dissect or rupture, although there is no agreement about the diameter at which referral for surgery is appropriate. With the added haemodynamic load of pregnancy (50% increase in cardiac output) and the high oestrogen concentrations that tend to lessen the strength of the aortic wall, any patient with a dilated ascending aorta should be closely monitored during their pregnancy.

This patient would be best treated with close medical follow-up and echocardiography every 3 months or so, to look for signs of progressive aortic root dilation. Treatment with β blockers (if blood pressure is normal) and bedrest, with or without early delivery, should be considered when rapid progression of the ascending aortopathy is seen or the ascending aorta reaches more than 55 mm. Vaginal delivery at term with a rapid (forceps-assisted) second stage labour would

be acceptable if her ascending aortopathy remained stable during pregnancy. Prophylactic replacement of the ascending aortic root with a bioprosthetic aortic valve should be considered before other pregnancies in this patient if her ascending aorta is 55 mm or more or if she has severe aortic stenosis, or both.

Coarctation of aorta: case 4

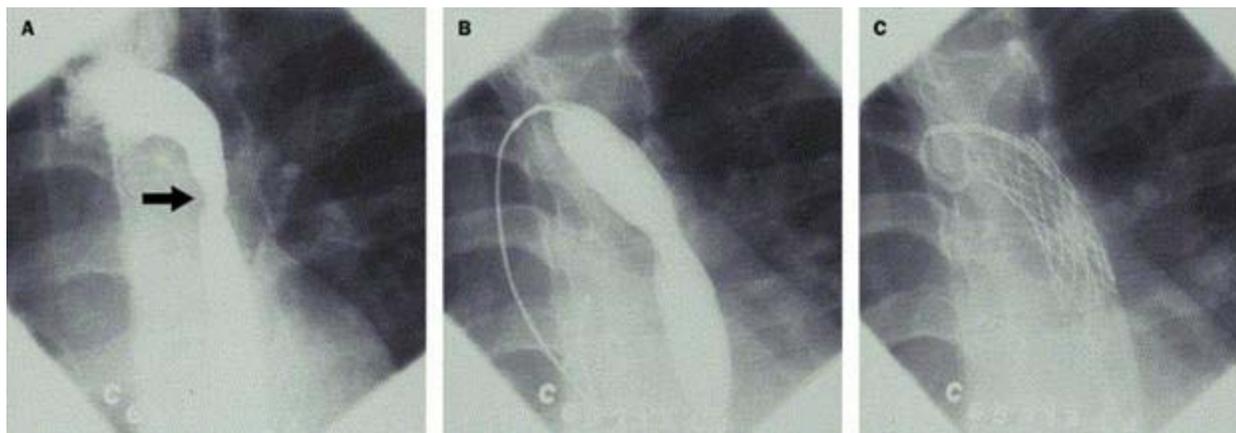

A 44-year-old man with a history of coarctation repair in his childhood is referred for persistent mild systolic hypertension. The patient is otherwise asymptomatic. The blood pressure is 145/80 mm Hg on the right arm, 120/80 mm Hg on the left arm, 120/80 mm Hg on the right leg with a mild radiofemoral delay. MRI confirms the presence of a mild discrete narrowing at the site of previous coarctation repair and cardiac catheter shows a withdrawal gradient of 20 mm Hg between the proximal and distal descending aorta.

Coarctation of the aorta is seen most frequently in men with a ratio of almost 3 to 1. It usually resides in the region of the ligamentum arteriosum. It might be discrete or associated with hypoplasia of the aortic arch and isthmus. Related abnormalities include bicuspid aortic valve in 50-85% of cases. Despite initial successful correction of coarctation, the risk of late systemic hypertension (due to residual or recurrent coarctation, or merely to abnormal aortic wall compliance) in these patients is fairly high. If inadequately controlled, hypertension leads to an increased risk of premature death from late heart failure. Other causes of premature death might be coronary artery disease with or without aortic rupture or dissection. Careful long-term follow-up and aggressive management of patients with hypertension is therefore recommended. Local complications such as re-coarctation and aneurysm formation at the site of previous transcatheter or surgical correction should be identified through periodic chest radiography, echocardiogram, MRI, or spiral CT examinations.

Treatment

All patients with serious coarctation or recoarctation having proximal hypertension, a withdrawal gradient greater than 20 mm Hg at angiography or an echo peak gradient of more than 20 mm Hg in the absence of extensive collaterals or less than 20 mm Hg in their presence, warrant treatment to eliminate the gradient and reduce the risk of long-term complications. Balloon dilatation with stent insertion in patients with native coarctation and recoarctation can be done with good immediate and medium-term results in adolescents and adults and should probably be the procedure of choice when the anatomy is suitable and expert skills are

available. If the anatomy is not suitable (ie, long tunnel-like stenosis) surgery might be needed. After surgical repair of isolated aortic coarctation, the obstruction is usually relieved with minimum mortality (<2%). However, mortality is increased for reoperation (5-15%).

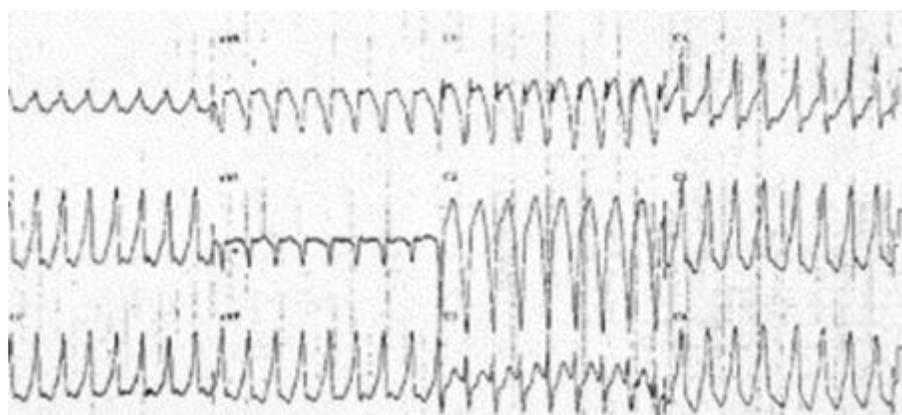

Angiograms of mild re-coarctation of the aorta (A); balloon dilatation and stenting of the re-coarctation segment of the descending aorta (B); and stented descending aorta (C)
Arrow in (A) indicates re-coarctation segment.

This patient has mild re-coarctation of the aorta (peak gradient >20 mm Hg) at the site of previous surgical repair with superimposed mild systolic hypertension. Balloon dilatation and stenting of the re-coarctation segment (if the anatomy is suitable) should be done to reduce proximal systolic blood pressure. The procedure should only be done, however, by experienced cardiologists. Surgical revision or antihypertensive medication, or both, might also be appropriate.

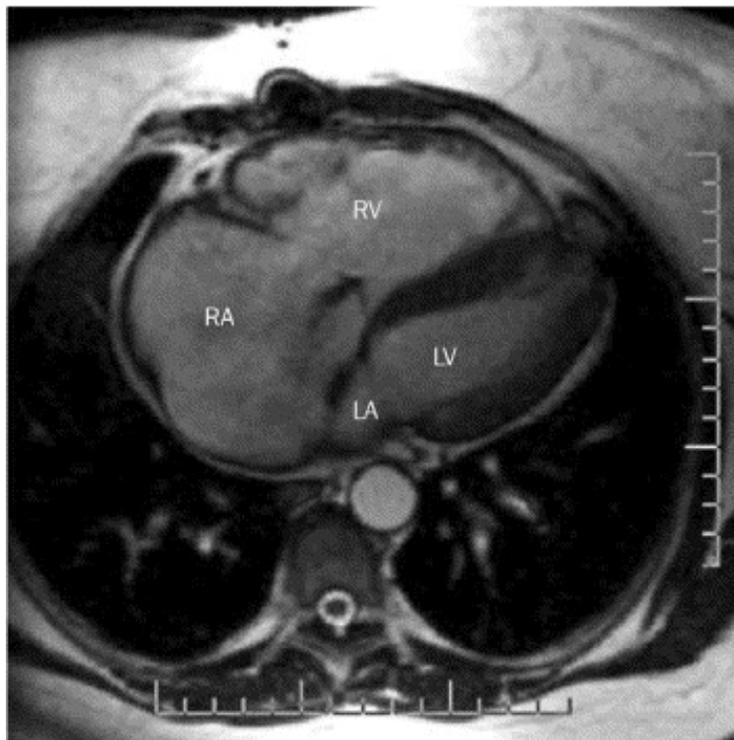

Tetralogy of Fallot: case 5

A 46-year-old woman is brought to the emergency room by ambulance after a witnessed collapse. Sustained ventricular tachycardia was ended and the patient successfully revived.

Electrocardiogram showing ventricular tachycardia in a patient after repair of tetralogy of Fallot

The patient has a history of repaired tetralogy of Fallot in childhood. She was lost to follow-up. Physical examination showed a right ventricular impulse and a low-pitched diastolic murmur grade 3/6 best heard along the left sternal border. Transthoracic echo showed a dilated right ventricle and severe pulmonary regurgitation. Cardiac MRI confirmed a severely dilated right ventricle (right ventricular end-diastolic volume 350 mL—normal range up to 108 mL/m²), severe pulmonary regurgitation, and fairly normal right ventricular systolic function.

MRI showing right right ventricular dilation in a patient after repair of tetralogy of Fallot
LA=left atrium. LV=left ventricle. RA=right atrium. RV=right ventricle.

Electrophysiological studies confirmed the presence of easily inducible ventricular tachycardia from the right ventricular outflow tract, and angiography shows normal pulmonary and coronary arteries.

Tetralogy of Fallot is the most common form of cyanotic congenital heart disease after 1 year of age, with a frequency of almost 10% of all congenital heart disease. The defect is caused by anterocephalad deviation of the outlet septum resulting in four features: (1) a non-restrictive

ventricular septal defect; (2) an overriding aorta (<50% override); (3) obstruction of the right ventricular outflow tract which may be infundibular, valvar, or (usually) both, with or without supra-valvar or branch pulmonary artery stenosis; and (4) consequent right ventricular hypertrophy.

Reparative surgery is usually done early in infancy, by closure of the ventricular septal defect with a Dacron patch and relief of the right ventricular outflow tract obstruction. Obstruction relief might include resection of infundibular muscle and insertion of a right ventricular outflow tract or transannular patch—a patch across the pulmonary valve annulus that disrupts the integrity of the pulmonary valve and causes important pulmonary regurgitation. Significant pulmonary regurgitation is almost always encountered when the transannular patch repair technique is used. Pulmonary regurgitation is usually well-tolerated indefinitely, if mild to moderate. Severe chronic pulmonary regurgitation might be well tolerated for 20 years or more, but could then lead to symptomatic right ventricular dysfunction, and increase the susceptibility to ventricular tachycardia and sudden cardiac death.

Residual obstruction of the right ventricular outflow tract can arise in the infundibulum, the pulmonary valve, and the main pulmonary trunk or branches of the left and right pulmonary arteries, or both branches. Right ventricular dilation in this setting is usually due to longstanding free pulmonary regurgitation, but might result from operative injury. Substantial tricuspid regurgitation might occur because of right ventricular dilation, which then leads to further dilation of the right ventricle.

Atrial tachyarrhythmia arises in about a third of adults and contributes to late morbidity and even mortality. It usually takes the form of atrial flutter or intra-atrial re-entrant tachycardia. Often indicative of haemodynamic trouble (significant right ventricular dilation and dysfunction, increased tricuspid regurgitation), the substrate is most likely a surgical scar in the atria and the trigger, atrial dilation.

Sustained monomorphic ventricular tachycardia is rare, compared with other types, and is highly associated with pronounced right ventricular dilation. The QRS duration from the standard surface ECG has been shown to correlate well with right ventricle size in these patients. A maximum QRS duration of 180 ms or more is a highly sensitive marker for sustained ventricular tachycardia and sudden cardiac death in adults with previous tetralogy repair, although its positive predictive value is low. Dilation of the right ventricle is thought to trigger ventricular tachycardia, whereas surgical scars (near the right ventricular outflow tract or ventricular septal defect patch) form the arrhythmia substrate. The reported frequency of

sudden death, presumably due to arrhythmia, in late follow-up series is 0.5—6% over 30 years, accounting for about a third to a half of late deaths. Older age at repair, severe left ventricular dysfunction, postoperative right ventricular hypertension, transannular patching (causing free pulmonary regurgitation), and an accelerated rate of QRS prolongation are all predictors of sudden death in these patients.

Treatment of complications

Replacement of the pulmonary valve (with either a homograft or porcine bioprosthesis) might be necessary for severe pulmonary regurgitation leading to right ventricular dilation, sustained arrhythmias or symptoms, or both. Such replacement might also be needed for a grossly calcified pulmonary valve. It has a low operative risk and leads to symptomatic improvement. Timely pulmonary valve replacement, before irreversible severe right ventricular dilation and systolic right ventricular dysfunction begins, is a major clinical goal. Concomitant tricuspid valve annuloplasty might also be necessary when at least moderate tricuspid regurgitation is present.

Patients presenting with sustained atrial flutter, atrial fibrillation, or ventricular tachycardia, should undergo a thorough assessment of their haemodynamics and should have residual haemodynamic lesions repaired—eg, significant right ventricular dilation from pulmonary regurgitation with resulting tricuspid regurgitation that needs pulmonary valve replacement and tricuspid valve annuloplasty^{50, 51}. Radiofrequency ablation, after mapping for atrial re-entry tachycardia, now yields better results than before for classic atrial flutter or incisional atrial reentrant tachycardia, or both, and should be done either percutaneously (if there is no need for concomitant surgery) or intraoperatively at the time of surgical repair of underlying haemodynamic lesions. For atrial fibrillation, a biatrial maze procedure should also be considered, and ideally done at reoperation. Likewise, transcatheter (when surgery is unnecessary) or concomitant intraoperative ablative procedures of the ventricular tachycardial pathway should be done when appropriate. Antiarrhythmic medications and the new generation of atrial antitachycardia pacemakers (for supraventricular tachycardia) can be used as adjunct treatments. Patients who were resuscitated after sudden cardiac death and are in need of surgery without a haemodynamic substrate should probably receive an automated implantable cardioverter defibrillator (AICD).

This patient should probably have pulmonary valve replacement since the right ventricle is severely dilated, with repair of the ventricular septal defect patch as well as cryoablation of the ventricular tachycardia focus at the time of surgery. Pulmonary valve replacement will lead to a smaller right ventricle and cryoablation of the ventricular tachycardia focus would eliminate the

arrhythmia substrate and probably prevent a further episode of sudden cardiac death.

Transposition of the great arteries: case 6

A 32-year-old man who had the Mustard procedure for D-transposition of the great arteries presents with increasing exertional dyspnoea and fatigue. Cardiac examination revealed a right ventricular impulse, a loud single S2 (second heart sound) and a holosystolic murmur best heard at the left sternal border. Transthoracic echo confirmed the presence of severe systemic tricuspid regurgitation and severe systemic right ventricular systolic dysfunction (ejection fraction 15%).

In patients with complete transposition of the great arteries, the connections between the atria and ventricles are concordant (normal), and the connections between ventricles and great arteries are discordant. Thus, the pulmonary and systemic circulations are connected in parallel rather than the normal in-series connection. In one circuit, systemic venous blood passes to the right atrium, the right ventricle, and then to the aorta. In the other, pulmonary venous blood passes through the left atrium and ventricle to the pulmonary artery. This situation is fatal unless the two circuits mix. About half of patients with transposition of the great arteries have additional abnormalities, most often a ventricular septal defect.

The most common previously done surgical procedure seen in adults is the atrial switch operation. Patients will have had either a Mustard or a Senning procedure. Blood is redirected at atrial level with a baffle made of Dacron or pericardium (Mustard operation) or with atrial flaps (Senning operation), to achieve physiological correction. Systemic venous return is diverted through the mitral valve into the subpulmonary morphological left ventricle and the pulmonary venous return is rerouted via the tricuspid valve into the subaortic morphological right ventricle. This repair, however, leaves the morphological right ventricle to support the systemic circulation.

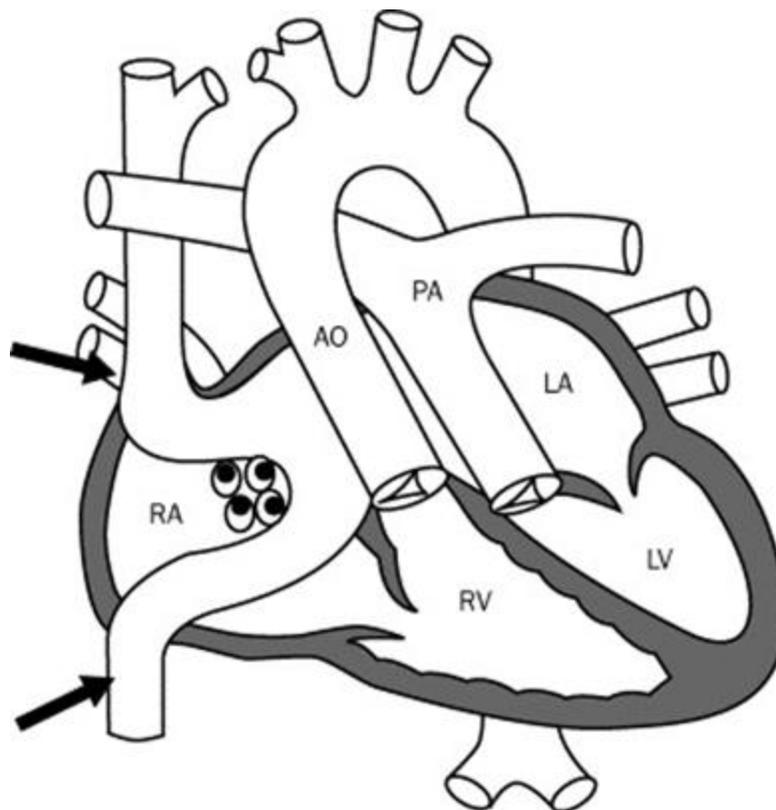

Diagram showing atrial baffle in a patient with D-transposition of the great arteries

RA=right atrium. RV=right ventricle. LA=left atrium. LV=left ventricle. PA=pulmonary artery, AO=aorta. Arrows indicate systemic venous baffle, and black dots pulmonary venous baffle.

After atrial baffle surgery, most patients reaching adulthood will be in New York Heart Association class I—II. During 25 years of follow-up, about half these patients will have moderate systemic dysfunction of the right ventricle with only a few presenting with symptoms of congestive heart failure. Severe systemic tricuspid regurgitation is present in about a third, which exacerbates right ventricular dysfunction. Atrial flutter arises in 20% of patients by age 20 and progressive sinus node dysfunction is seen in half the patients by that time. These rhythm disturbances are thought to be a result of atrial and sinus node damage at the time of atrial baffle surgery. Baffle leak or obstruction can also occur.

The atrial switch operation was gradually replaced by the arterial switch operation (Jatene) in the 1980s, but few of these patients have yet become adults. Blood is redirected at the great artery level by switching the aorta and pulmonary arteries such that the morphological left ventricle becomes the subaortic ventricle and the morphological right ventricle becomes the

subpulmonary ventricle. Reliable data for the clinical outcome in adults after the arterial switch procedure should be available over the next decade. Clinical arrhythmia promises to be less of a problem in this group of patients, but concerns about the development of supra neopulmonary artery stenosis, ostial coronary artery disease, and progressive neoaortic valve regurgitation warrant serial follow-up

Treatment

The benefits of angiotensin-converting enzyme inhibitors in patients with systemic right ventricular dysfunction after an atrial switch have not been established, and are being investigated in a double-blind multicentre randomised trial of ramipril. Occasionally, patients with a failed Mustard or Senning operation might need heart transplantation. Alternatively, a conversion procedure to an arterial switch, after re-training of the left ventricle with a pulmonary artery band, could be considered, but few data for the outcome of such a procedure are available in adults.

The degree of right ventricular dilation and systolic dysfunction should be confirmed by MRI or multiple gated acquisition examinations. An angiotensin-converting enzyme inhibitor with or without other heart failure therapies could be tried in this patient. If no clinical improvement is noted, however, a switch conversion procedure (pulmonary artery banding with left ventricular training followed by pulmonary artery debanding, and arterial switch with take down of the atrial baffle) should be used. Tricuspid valve replacement in this patient would probably lead to worsening of right ventricular function and is not recommended. Cardiac transplantation could also be considered at an appropriate time.

Fontan procedure: case 7

A 26-year-old college student with a diagnosis of tricuspid atresia palliated by the Fontan procedure goes to her local emergency room because of 6 h of continuous rapid palpitations. The patient is haemodynamically stable, and a cardiac monitor reveals atrial fibrillation with a ventricular response of ten beats per minute.

The Fontan procedure is the palliative, non-curative, surgical treatment for patients with univentricular hearts. The principle is diversion of the systemic venous return directly to the pulmonary arteries without the need for a subpulmonary ventricle. Many modifications of this procedure have been described, eg—direct atrio-pulmonary connection, total cavopulmonary connection, and extracardiac conduit. Progressive deterioration of functional status with time is

the rule, with survival at 10 years after the procedure reported to be 60—71%. The most common complications after a Fontan procedure include atrial flutter or fibrillation, right atrial thrombus formation, obstruction of the Fontan circuit, and ventricular dysfunction.

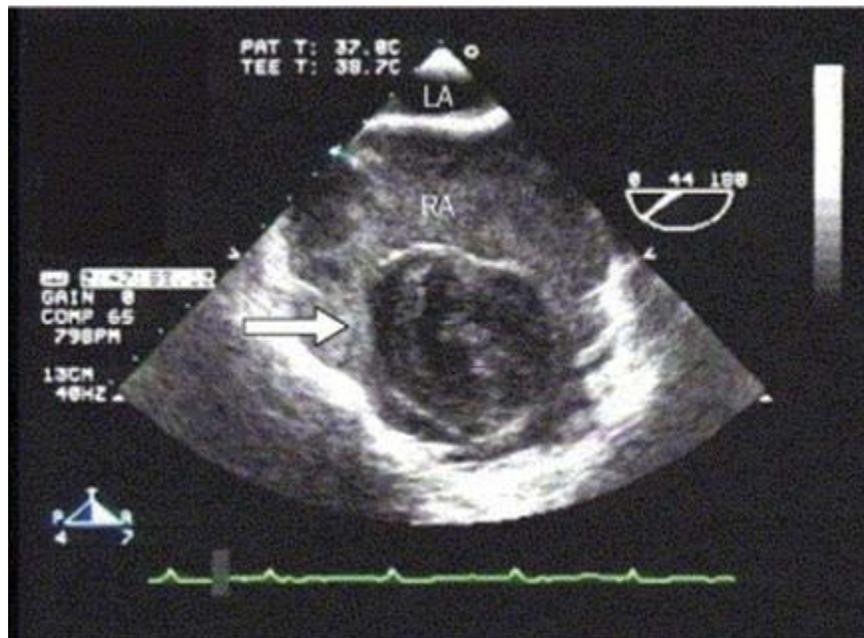

Atrial flutter or fibrillation are common (15—20% at 5-year follow-up), and increases with duration of follow-up. They are associated with serious morbidity (especially the development of atrial thrombi within hours), and can lead to profound haemodynamic deterioration. Such patients need prompt and expert medical attention. The combination of atrial incisions and multiple suture lines at the time of Fontan surgery with increased right atrial pressure and size probably accounts for the high frequency of atrial arrhythmias in these patients. Obstruction of the Fontan connection should be ruled out in all patients presenting with new onset atrial arrhythmias.

The reported frequency of thromboembolic complications in the Fontan circuit varies from 6% to 33%, dependent on the diagnostic method used and the length of follow-up. Right atrial thrombus formation relates to the presence of atrial flutter or fibrillation, right atrial dilation, right atrial smoke (spontaneous echo contrast), and the presence of artificial material used to construct the Fontan circuit.

Part obstruction of the Fontan connection leads to exercise intolerance, atrial tachyarrhythmias, and right-sided heart failure. Sudden total obstruction presents as sudden death. Protein-losing enteropathy is seen in about 2—3% of patients after the Fontan procedure. Patients present with generalised oedema, ascites, pleural effusion, or chronic diarrhoea. The diagnosis is confirmed by low serum albumin and protein and high α 1-antitrypsin stool clearance. The prognosis is poor, with a 5-year survival of 46—59%.

Treatment of complications

In patients with atrial fibrillation or flutter, prompt anticoagulation and transoesophageal echo assessment to rule out atrial thrombi before cardioversion is recommended. Long-term management with antiarrhythmic therapy is successful in less than 50%. Transcatheter atrial ablation can be done in specialised centres, with a 50% success rate. For recalcitrant cases, surgical revision with antiarrhythmic surgery is recommended.

Transoesophageal echocardiogram showing a right atrial clot
 LA=left atrium. RA=right atrium. Arrow indicates right atrial clot.

For established thrombus, thrombolytic therapy or surgical removal of the clot and conversion of the Fontan circuit have been described. Long-term anticoagulation is recommended for patients with known thrombi. Some centres anticoagulate all Fontan circuits for the rest of the patient's life. For patients with Fontan obstruction, surgical revision of the Fontan connection is usually needed. Alternatively, balloon angioplasty with or without stenting can be used when appropriate. Patients with protein-losing enteropathy might be candidates for creation of a fenestration in the atrial septum or revision of the Fontan. Alternatively, subcutaneous heparin, octreotide treatment, and prednisone treatment have also been tried with variable success. No particular treatment seems more successful than any other.

In this patient, who is haemodynamically stable, ventricular rate should be controlled with digoxin or other agents, and prompt anticoagulation with heparin should be started. The patient should be transferred to a highly specialised hospital for transoesophageal echo to rule out right atrial clot before cardioversion. Fontan obstruction as the cause of atrial fibrillation (conduit obstruction with secondary right atrial stretch) should be ruled out either at the time of transoesophageal echo or by cardiac catheterisation. Long-term coumadin is recommended for all patients with Fontan obstruction who have a history of atrial fibrillation. Maintenance of sinus rhythm after cardioversion is probably best achieved with amiodarone, although the success rate is low at 50%. Antitachycardia pacing, catheter ablation or surgical revision, or both, with concomitant biatrial maze procedure are used as second-line treatment in patients

with Fontan obstruction and chronic or paroxysmal atrial fibrillation that is unresponsive to medical management. Other causes of atrial fibrillation such as ethanol binge or hyperthyroidism should also be ruled out.

DISEASE OF ESOPHAGUS

ESOPHAGEAL DIVERTICULA

The esophageal diverticula are the sacciform outpouchings of the esophageal wall, which filled with mucus and undigested food.

Etiology and pathogenesis

The conducting pathogenic moment in occurrence of esophageal diverticula is the increase of intraesophageal pressure proximal to muscle sphincters, which gradually results in herniation in weak sites of the esophageal wall. Such mechanism of formation is characteristic for pulsion diverticula. Traction diverticula are formed as a result of paraesophageal inflammatory and sclerotic processes, which tract esophagus to other organs, more often - with the right bronchus. During their motions owing to a traction esophageal diverticula also are gained.

Zenker's diverticula in advanced cases are great in size. There are three stages in their development:

- 1) outpouching of mucosa;
- 2) formation of a globular sack;
- 3) enlargement of diverticulum with further descending in mediastinum.

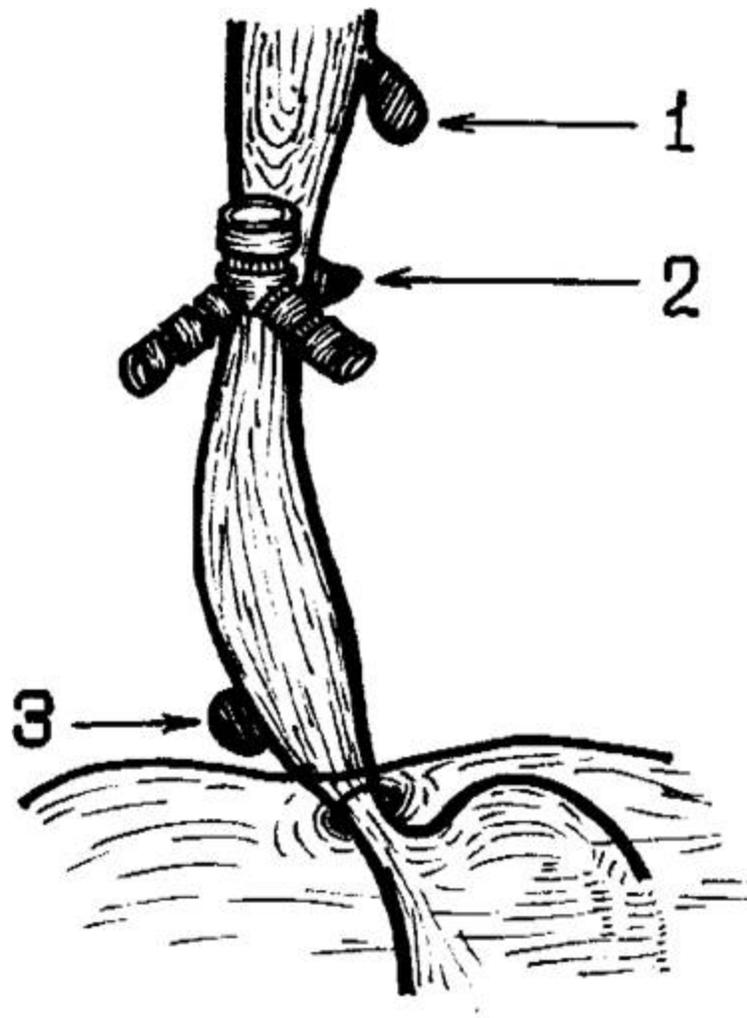

Pathology

The restricted blind herniation of the wall of esophagus could be single or multiple, ring-shaped, cylindrical, oval or sacciform-shaped. The muscle coat atrophies, that makes difficult differentiation between true and false diverticula. The latter caused by inflammatory processes. In such cases the paraesophageal scarring resulting from extrapharyngeal abscesses, mediastinitis, specific and nonspecific inflammatory processes of bifurcational lymph nodes (traction diverticula) are revealed.

The small size of the opening of pouch, for example, in globular diverticula, leads to congestion of contents with the further development of inflammation (diverticulitis erosive, catarrhal, gangrenous, purulent).

Classification

1. According to the origin:
 - a) congenital;
 - b) acquired.
2. According to number:
 - a) single;
 - b) multiple.
3. According to histological structure:
 - a) true (have all layers of esophageal wall);
 - b) false (absent muscular layer of esophageal wall).
4. According to localization:
 - a) pharyngoesophageal (Zenker's);
 - b) bifurcational;
 - c) epiphrenic.
5. According to the clinical course:
 - a) complicated;
 - b) uncomplicated.

Types of diverticula:

- 1 – pharyngoesophageal (Zenker's)
- 2 – bifurcational
- 3 – epiphrenic

Symptomatology and clinical course

Clinical manifestation of the esophageal diverticula, as a rule, connected with the occurrence of complications.

The symptomatology of Zenker's diverticula depends on the stage of development and their size.

A Zenker diverticulum, which is seen in the images below, is formed by the herniation of mucosa through an area of weakness in the posterior wall of the hypopharynx (the Killian triangle).

Sometimes Zenker diverticula are called pharyngoesophageal diverticula because of their close proximity to the cervical esophagus; however, this is somewhat of a misnomer because the diverticula actually arise from the hypopharynx rather than from the esophagus.

Of the diverticula discussed in this article, Zenker diverticula are the most common type to cause symptoms.

Zenker diverticula are an acquired pulsion-type of diverticula that probably develop because of the aging process. They form in the posterior hypopharynx at a point where a defect in the muscular wall, between the inferior pharyngeal constrictor muscle and the cricopharyngeal sphincter (Killian triangle), usually exists.

Zenker diverticula are believed to occur because of an outflow obstruction caused when loss of coordination of the buccal squirt (ie, swallowing movement of the tongue posteriorly with contraction of the oropharyngeal muscles) and opening of the cricopharyngeus (ie, the upper esophageal sphincter) occurs. The noncompliant cricopharyngeus muscle becomes

fibrotic over time.

Oropharyngeal dysphagia, usually to solids and to liquids, is the most common symptom. Retention of food material and secretions in the diverticulum, particularly when diverticula are large, can result in regurgitation of undigested food, halitosis, cough, and even aspiration pneumonia. The patient may note food on the pillow upon awakening in the morning. With very large diverticula, a mass in the neck occasionally can be detected. Cancer rarely has been reported in association with Zenker diverticula.

Salivation, cervical dysphagia, difficult swallowing and cough usually occur in advanced stages of the diverticulum.

The dysphagia is frequently caused by congestion of food in diverticulum. Also a compressible mass in the neck usually on the left side is frequently revealed. The patients should press this mass to swallow the food and sometimes make unusual movements by neck in order to empty the diverticulum. The gurgling sound when the patient is eating and foul-smell from the mouth resulting from decay of undigested food in diverticulum cause the patient to alter social activities.

The sign "of a wet pillow" results from increased salivation and nocturnal discharge of saliva and mucus from the mouth.

Diverticula of the esophageal body are relatively rare. They primarily occur in the middle and distal esophagus (see the image below).

Bifurcational diverticula are usually less 2 cm in size and therefrom rarely complicated and clinically manifested. At its greater size the complications can arise rather frequently and determine the course and manifestations of the disease.

Diverticula that occur in the distal esophagus, in the lower 6-10 cm, are termed epiphrenic diverticula (see the image below).

The epiphrenic diverticula can achieve considerably size, and more frequently complicated by diverticulitis. Being filled with food, such diverticulum can compress cervical organs, and sometimes is complicated with achalasia.

Diverticula of the mid and distal esophagus may have various etiologies. For instance, some diverticula in the mid esophagus are congenital in origin; others are of the traction variety. With the latter, diverticula develop by traction from contiguous mediastinal inflammation and adenopathy, eg, pulmonary tuberculosis and histoplasmosis. The diverticula that develop by traction and adenopathy usually are asymptomatic.

Retention of undigested food in large diverticula occasionally results in regurgitation, nocturnal cough, and aspiration pneumonia.

Occasional epiphrenic diverticula occur in the setting of long-standing peptic esophagitis and strictures, and they rarely are symptomatic. Other rare causes of diverticula of the mid and distal esophagus include iatrogenic surgical injury to the esophagus and Ehlers-Danlos syndrome (weakness of collagen). Perhaps the most common causes of mid esophageal and epiphrenic diverticula are motility disorders of the esophageal body, including achalasia, diffuse esophageal spasm, and hypertensive lower esophageal sphincter.

Dysphagia is the most common symptom associated with mid esophageal and epiphrenic diverticula, although it usually is related more to the underlying motility disturbance than to

the diverticulum per se. However, on occasion, the diverticulum may be responsible for the dysphagia, particularly if it is very large and filled with food or a bezoar. Regurgitation and aspiration may be related to large mid esophageal and epiphrenic diverticula; however, in patients with achalasia, regurgitation and aspiration are more likely to be related to poor esophageal emptying from the underlying motility disturbance (eg, hypertensive lower esophageal sphincter that fails to relax, absence of esophageal body peristalsis).

The diagnosis is confirmed by the findings of barium swallow, and also esophagoscopy.

Pharyngoesophageal (Zenker's) diverticulum)

Variants of clinical course and complications

Diverticulitis. The anginal pain, or the pain in epigastric region, which can resemble stenocardia or gastric disorders, belching, are the chief manifestations. Sometimes observed nausea and vomiting.

The perforation of diverticulum can be directed into pleural space, trachea, bronchus or pericardium. The clinical picture depends on the place of perforation. In part the perforation in trachea or bronchus results in occurrence of esophago-bronchial fistula. Clinically such complication is commonly shown by cough during meal. An everlasting esophago-bronchial fistula can cause the aspiration pneumonia with the further abscessing.

Bleeding from diverticula frequently results from erosion of esophageal mucosa on the

background of diverticulitis. Nevertheless such bleedings, as a rule, are not profuse and rather easily stopped by conservative treatment.

Malignancy rarely occurs and most often as the outcome of recurrent diverticulites.

The diagnostic program

1. Anamnesis and objective examination.
2. General blood and urine analyses.
3. Coagulogram.
4. Chest X-radiography.
5. Roentgenoscopy of esophagus and gastrointestinal tract.

Radiographic studies and upper GI endoscopy detect many esophageal diverticula incidentally because esophageal diverticula often are asymptomatic.

On standard chest radiographs and CT scans, large diverticula of the esophagus and hypopharynx also may manifest as air-filled and/or fluid-filled structures communicating with the esophagus.

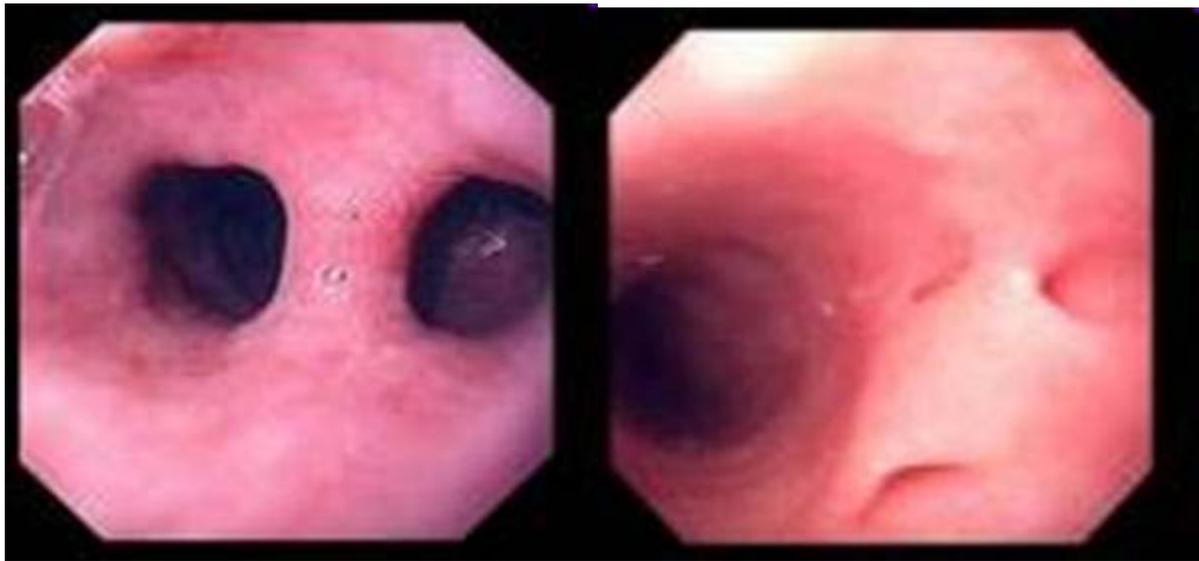

Barium radiography (ie, barium esophagography, barium swallow) generally is the diagnostic procedure of choice. In addition to being excellent at defining the structural appearance of diverticula, barium swallow also may provide clues to underlying motility disturbances that may be involved in diverticular formation. However, if the patient has dysphagia or odynophagia or has alarm symptoms, then upper endoscopy is indicated.

Barium swallow is a useful study in patients who are symptomatic and have mid esophageal and epiphrenic diverticula.

Diagnosis of esophageal intramural pseudodiverticulosis is made best using barium radiography.

Diagnosis of Zenker diverticulum is made best using barium swallow, which should include lateral views of the pharyngoesophageal junction. It also can be made using careful upper endoscopy by an experienced endoscopist.

6. Fibrogastroduodenoscopy.

Esophageal diverticula Fibrogastroduodenoscopy

Differential diagnostics

Functional diverticula (pseudodiverticula). Their clinical manifestations resemble a diffuse idiopathic esophagospasm. Intermittent dysphagia, which usually arises after meal or strong excitements, are the sings of pseudodiverticula. A retrosternal pain, which accompanied them, can result in misdiagnosis of stenocardia.

Stenocardia. It is characterized by pain attacks with irradiation in the left arm and left scapula, feeling of fear. After taking of nitroglycerin the pain, and fear, as a rule, disappear. In contrast with stenocardia, the retrosternal pain caused by a spastic stricture or diverticulum of esophagus, is characterized by feeling of compression deeply inside, which usually more expressed in the back. There is no obvious sensation of fear, irradiation of pain in arm and relief after nitroglycerin. Usually it is accompanied by disturbances of swallowing, sometimes vomiting, after that the pain frequently disappears.

Tactics and choice of treatment

The treatment of pharyngoesophageal diverticula is surgical. Conservative therapy is indicated in case of severe concomitant pathology, the patient's refusal of operation or there are no conditions for its performance. In such cases mechanically sparing diet with washing down of solid food.

Asymptomatic and minimally symptomatic esophageal body diverticula do not require treatment.

In many patients with mid esophageal and epiphrenic diverticula, dysphagia is related to underlying dysmotility; thus, treatment should be directed to the motility disorder when feasible. For instance, achalasia can be treated with pneumatic dilation, botulinum toxin injection into the lower esophageal sphincter, or surgical Heller esophagomyotomy.

Treatment of esophageal intramural pseudodiverticulosis is directed toward underlying strictures or dysmotility.

The bifurcational diverticula require operative treatment only in one patient in ten. The indications for such operation are frequently recurrent diverticulites, bleeding, perforation, esophago-bronchial fistula or suspicion on malignancy.

Treatment of Zenker diverticulum traditionally has been surgical, although the specific operation used still is controversial. Surgical options include diverticulectomy with cricopharyngeal myotomy, diverticular suspension (diverticulopexy) with cricopharyngeal myotomy, and cricopharyngeal myotomy alone.

Consider diverticulectomy when esophageal body diverticula are believed to be the cause of aspiration. An abdominal laparoscopic approach may be feasible for some patients with epiphrenic diverticula. Case reports of endoscopic treatment of giant midesophageal diverticula have been reported. However, patients who are being considered for diverticulectomy should first undergo careful study with barium swallow, flexible endoscopy, and esophageal manometry. Treatment directed at an underlying esophageal motility disorder, such as achalasia, cannot be ignored.

Diverticulectomy usually is not performed by itself because it does not correct the defect in cricopharyngeal function that usually contributes to the formation of a Zenker diverticulum.

While the transcervical approach has been used traditionally, the transoral route using a rigid esophagoscope also may be used.

Good results have been obtained by performing a diverticulotomy using a flexible endoscope and needle-knife papillotome to cut the common wall between the diverticulum and the oropharynx as well as the cricopharyngeus while the patient is consciously sedated. Data suggest that this technique offers good results with a relatively high success rate, but it should be performed in large centers with surgeons who are experienced with this technique. In some variations of this technique, the diverticulum is stapled.

Other novel techniques are being developed. Flexible endoscopic diverticulotomy approaches have been explored using various techniques, including argon plasma coagulation, monopolar coagulation forceps, and needle-knife incision. These techniques typically use a cap or hood attached to the endoscope. The goal of these techniques is the division of the septum

between the diverticulum and the esophagus, thus performing a cricopharyngeal myotomy.

Increased efforts to a laparoscopic approach to repair both epiphrenic diverticula and Zenker diverticula have been explored. The literature supports open surgery and a laparoscopic approach as appropriate methods of repair. The laparoscopic technique uses stapler closure, and multiple case reports cite wound leakage from stapler failure as a complication. With complication rates as high as 20%, a skilled surgeon with experience in this procedure is beneficial. Benefits of the laparoscopic approach include decreased morbidity because of no thoracotomy wounds and chest tubes and a less invasive approach.

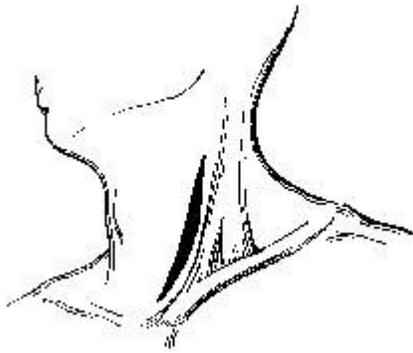

A study of 229 endoscopic diverticulotomies (in 189 patients), conducted by Kos et al, indicated that better results can be achieved using a combination of CO₂ laser and Acuspot in the endoscopic procedure than by employing endoscopic diverticulotomy with electrocautery or with a carbon dioxide (CO₂) laser alone. The investigators reported the following postsurgical results:

- Endoscopy with CO₂ laser
- Dysphagia - Absent following 78.4% of procedures
- Repeat surgery - Required following 19.6% of procedures
- Endoscopy with electrocautery
- Dysphagia - Absent following 72% of procedures
- Repeat surgery - Required following 24.3% of procedures
- Endoscopy with CO₂ laser and Acuspot
- Dysphagia - Absent following 84.6% of procedures
- Repeat surgery - Required following 13% of procedures

Accesses. In order to expose pharyngoesophageal diverticula the cervical access along the anterior border of the sternocleidomastoid muscle is applied; in case of bifurcational diverticula right-sided posterolateral thoracotomy in IV intercostal space is performed; in epiphrenal diverticula – left-sided posterolateral thoracotomy in VII intercostal space .

The essence of the operation consists of the following: the esophagus mobilized proximal and distal to diverticulum; after the exposure the latter is sutured or stapled near its basis and cut off. The line of suturing is covered by muscular layer of esophageal wall.

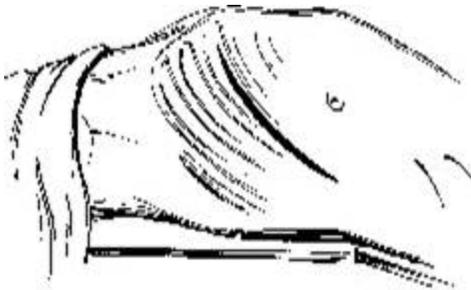

Accesses for diverticula

Cervical

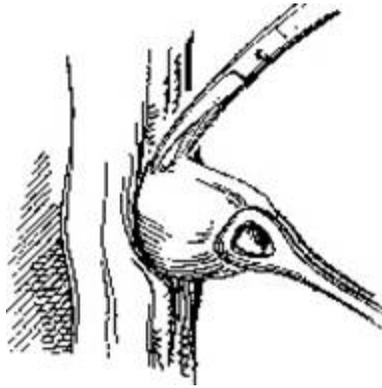

Right-sided posterolateral thoracotomy in IV intercostal space

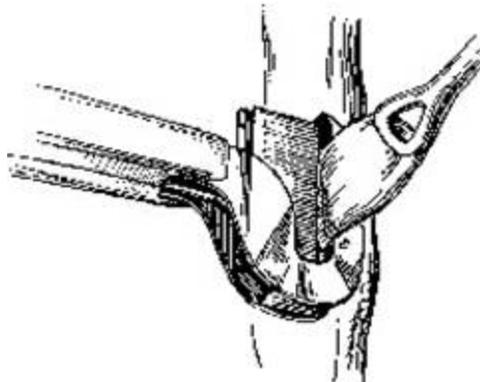

Left-sided posterolateral thoracotomy in VII intercostal space

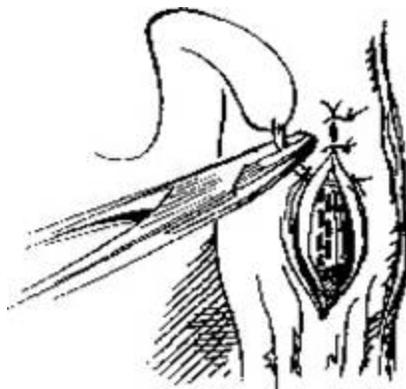

Steps of operation for esophageal diverticulum:

Mobilization of esophageal diverticulum

Suturing of diverticulum base

Suturing of esophageal muscles over the site of diverticulum

ACHALASIA OF THE CARDIA

Achalasia of the cardia is the disease, which is characterized by failure of the lower esophageal sphincter to relax with swallowing.

Etiology

The cause of this disease is still unknown. Among the underlying mechanisms are the psycho-emotional trauma, disturbance of parasympathetic and sympathetic innervation and influence of vegetotrophic substances on muscular fibers.

Pathology

Morphological changes depend on the stage of the disease, character of inflammation and mainly concern nervous and muscle fibers. Thus the phenomena of the thickening of axial cylinders of nervous fibers progressively increase, with the development of their fragmentation and vacuolization. The working hypertrophy of muscular fibers is finished by the dystrophy of myocytes and the development of sclerosis. The latter is contributed by inflammation, mainly of immune character. In final stage a mediastinal pleura, paraesophageal fat and diaphragm consolidate and knitted together.

LES pressure and relaxation are regulated by excitatory (eg, acetylcholine, substance P) and inhibitory (eg, nitric oxide, vasoactive intestinal peptide) neurotransmitters. Persons with achalasia lack nonadrenergic, noncholinergic, inhibitory ganglion cells, causing an imbalance in excitatory and inhibitory neurotransmission. The result is a hypertensive nonrelaxed esophageal sphincter.

Frequency

United States. The incidence of achalasia is approximately 1 per 100,000 people per year.

Sex

The male-to-female ratio of achalasia is 1:1.

Age

Achalasia typically occurs in adults aged 25-60 years. Less than 5% of cases occur in children.

Classification

Four stages of the disease are distinguished:

- 1) functional spasm without esophageal dilation;
- 2) constant spasm with a moderate esophageal dilation and maintained peristalsis;
- 3) cicatricial changes of the wall with expressed esophageal dilation, the peristalsis is absent;
- 4) considerable esophageal dilation with sigmoid-shaped elongation and the presence of erosive changes of esophageal mucosa.

Symptomatology and clinical course

Dysphagia in the onset of the disease wears a temporary intermittent character with further permanent interchange. The passing of food after several swallows delayed on the level of a lower part of breastbone. In some cases during meal the dysphagia arises suddenly without any cause. The majority of the patients with dysphagia swallow better warm or hot food.

Esophageal vomiting (regurgitation) is the outcome of accumulation in esophagus of two and more l. of fluid. In initial stages of the disease the regurgitation can arise during or at once after meal and is accompanied by discomfort pain sensations. In advanced stages observed regurgitation with a rotten smell. The regurgitation can occur during sleeping – the sign "of a wet pillow".

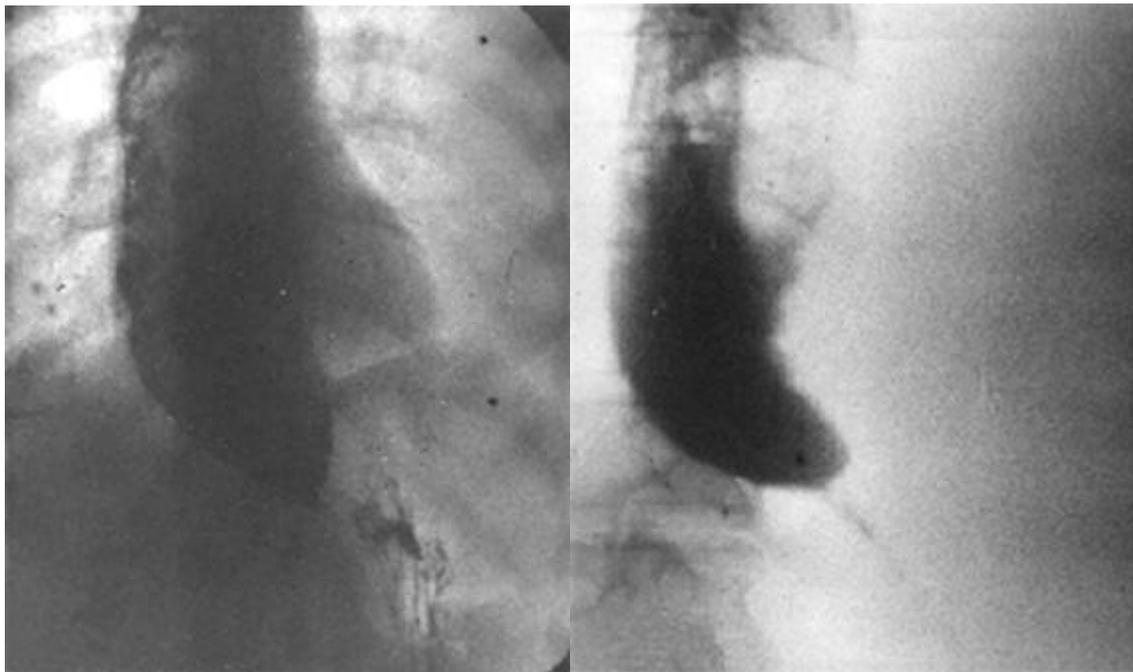

Splashing sounds and gurgling behind breastbone are rarely observed.

The sign of nocturnal cough arises owing to aspiration of fluid from esophagus into trachea. Thereby, the patients try to sleep in a sedentary position.

Pain and sense of tightness in the chest is the result of spasm and esophageal distention. With the developing of esophagitis, the pain wears a burning character.

Loss of weight is the outcome of prolonged disturbed food intake.

It is necessary to consider roentgenological contrast examination with barium swallow as the chief method, which enables to confirm the diagnosis. In the beginning of the disease revealed an inappreciable esophageal dilation and temporary delay of barium above the level of the inferior esophageal sphincter. In advanced stages of the disease observed a considerable esophageal dilation and elongation with a long delay of barium. Contours of a distal constricted part of esophagus described as the "rat tail" or "bird-beak" sign, without filling defects .

Esophageal achalasia

The endoscopic procedure reveals erosive changes of esophageal mucosa and enables to take a biopsy to rule out malignancy. Frequently in advanced stages it is failed to pass by endoscope a constricted part of esophagus and cardia.

Variants of clinical course and complications

The disease is characterized by remittent course with the change of the periods of dysphagia – from inappreciable to intensive. Even in advanced stages in minority of patients observed a latent course with complete disappearance of dysphagia in considerable esophageal dilation and cicatrical stenosis of cardia. Nevertheless later (from several months to several years) there comes an exacerbation of the disease with more severe course.

The bleeding arises owing to complications of erosive esophagitis at long duration of the disease.

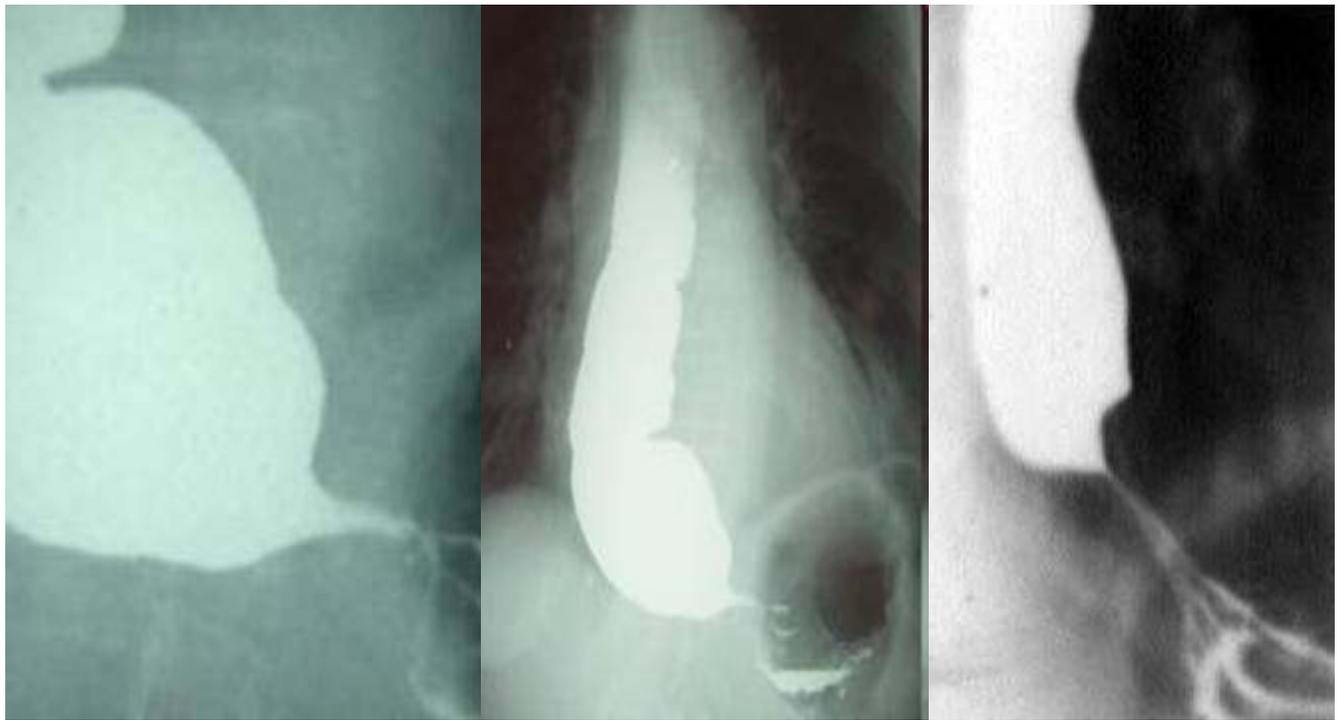

The malignancy occurs in the patients with phenomena of a chronic esophagitis and chronic character of the disease.

Pneumonia, abscesses, bronchiectases, atelectases and pneumosclerosis are frequently the outcomes of decreasing pulmonary excursion which results from compression by dilated esophagus.

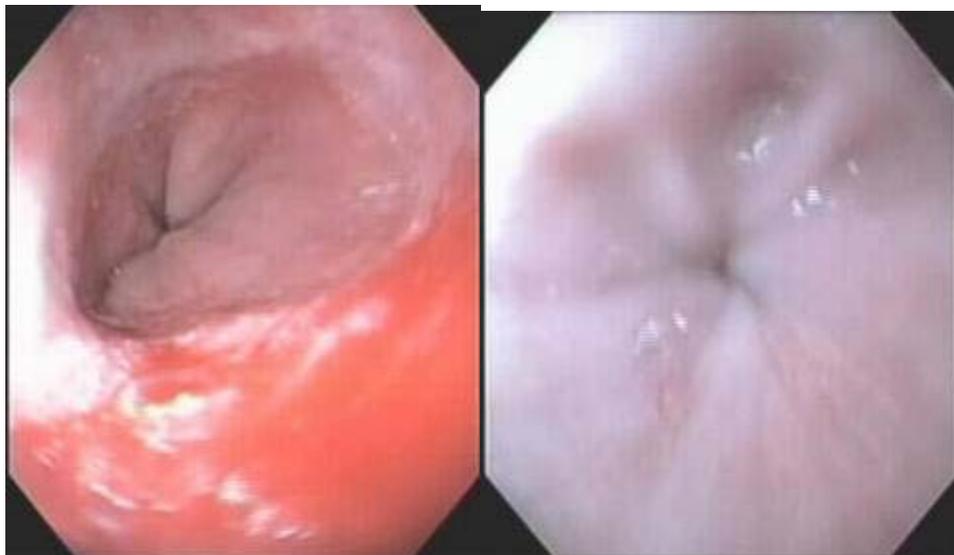

The diagnostic program

1. Anamnesis and physical findings.
2. General blood and urine analyses.
3. Chest X-radiography.
4. Esophagogastroscopy.
5. Contrast roentgenoscopy (barium swallow).

The esophagus appears dilated, and contrast material passes slowly into the stomach as the LES opens intermittently. The distal esophagus is narrowed and has been described as resembling a bird's beak

Esophageal achalasia

Esophageal achalasia

Differential diagnostics

Cancer of the lower part of esophagus and cardial part of stomach. The predominant place in differential diagnostics possesses X-ray examination. As opposed to achalasia, the cancer is characterized by irregular contours of constricted part of esophagus with filling defect. Endoscopic examination and biopsy allows to confirm the diagnosis.

Diaphragmatic hypotonia with inflection of esophagus also can be accompanied with dysphagia. However chest X-radiography enables to find out high standing of the left dome of diaphragm.

Pneumothorax. On the plain chest X-radiography the edge of dilated esophagus can resemble the edge of collapsed lung. Nevertheless in the patient with pneumothorax on the roentgenogram the lung pattern is absent.

Tactics and choice of treatment

The goal of therapy for achalasia is to relieve symptoms by eliminating the outflow resistance caused by the hypertensive and nonrelaxing LES. Once the obstruction is relieved, the food bolus can travel through the aperistaltic body of the esophagus by gravity.

Calcium channel blockers and nitrates are used to decrease LES pressure. Approximately 10% of patients benefit from this treatment. This treatment is used primarily in elderly patients who have contraindications to either pneumatic dilatation or surgery.

Endoscopic treatment includes an intrasphincteric injection of botulinum toxin to block the release of acetylcholine at the level of the LES, thereby restoring the balance between excitatory and inhibitory neurotransmitters. This treatment has limited value. Only 30% of patients treated endoscopically still have relief of dysphagia 1 year after treatment. Most patients need repeated botulinum toxin injections, with short-lasting clinical benefits. This treatment can cause an inflammatory reaction at the level of the gastroesophageal junction, making a subsequent myotomy very difficult. Compared with pneumatic dilation, botulinum toxin injection is associated with significantly higher

symptom recurrence rates at 12 months. Similarly, this treatment modality is less effective than laparoscopic Heller myotomy at 2-year follow-up. Use this treatment in elderly patients who are poor candidates for dilatation or surgery.

Pneumatic dilatation performed by a qualified gastroenterologist is the recommended treatment in those sporadic cases in which surgery is not appropriate. A balloon is inflated at the level of the gastroesophageal junction to blindly rupture the muscle fibers while leaving the mucosa intact. The success rate is 70-80%, and the perforation rate is approximately 5%. If a perforation occurs, emergency surgery is needed to close the perforation and to perform a myotomy. As many as 50% of patients may require more than 1 dilatation. The incidence of pathologic gastroesophageal reflux after the procedure is approximately 30%.

A laparoscopic Heller myotomy is considered by many to be the appropriate primary treatment of patients with achalasia (see Surgical Care). A Heller myotomy and a partial fundoplication performed from the chest (thoracoscopic) have a high incidence of gastroesophageal reflux.

Peroral endoscopic myotomy (POEM) has been recently introduced as a novel approach to achalasia. This procedure is performed under general anesthesia with endotracheal intubation. A 2-cm longitudinal mucosal incision is made on the mucosal surface to create a mucosal entry to the submucosal space. An anterior submucosal tunnel is created downwards, passing the gastroesophageal junction and about 3 cm into the proximal stomach. Once the submucosal tunnel is completed, section of the circular muscle fibers begins 2-3 cm distal to the mucosal entry, approximately 7 cm above the gastroesophageal junction. The myotomy is continued step by step distally until the gastric submucosa is reached, extending approximately 2-3 cm distal to the gastroesophageal junction. After identification and section of the circular muscle fibers of the lower esophagus and proximal stomach, the mucosal entry site is closed with hemostatic clips.

Several potential advantages of POEM compared with laparoscopic Heller myotomy have been proposed. The endoscopic approach should theoretically minimize postoperative pain. A longer myotomy can be performed, extending to the medium third of the esophagus, just below the aortic arch. A concomitant antireflux surgery may not be required because of the selective section of the circular muscle fibers without any dissection at the level of the gastroesophageal junction. In current practice, few data are available regarding clinical outcomes in small series of patients over very short

follow-up periods.

Based on the limited evidence available, POEM seems to be a promising new procedure. However, there are some concerns about this new technique. Endoscopic myotomy is a very demanding procedure, requiring major skills, with a very long learning curve. Even though several studies have reported significant reduction of LES pressure as demonstrated by manometry, the LES pressure was often between 15 and 20 mm Hg. It is known that a predictor of long-term success is an LES pressure around 10 mm Hg. Gastroesophageal reflux is reported in up to 50% of patients after POEM, replicating the results obtained when a myotomy alone was performed without an antireflux operation. Surgical revision in patients with recurrent dysphagia after POEM might be challenging. The presence of adhesions between the submucosal and longitudinal muscular layers after POEM might make the dissection at this level very difficult.

Diet. The food should be semisoft, without pungent relishes, chemically inactive and enriched with proteins, fat, carbohydrates and vitamins.

The medicament treatment should include local anesthetics, spasmolytics, and sedative drugs. Atropin and other anticholinergic agents only increase the spasm of a cardial sphincter, therefrom their usage is undesirable. The medicament treatment results only in temporary relief.

Cardiodilatation is indicated in I-II stage of achalasia. It is one of the chief methods of the treatment of this pathology. The treatment is performed as follows: under local anesthesia by aerosol or solution of anesthetic agent (lidocain, trimecain) through constricted part of the cardia under roentgenological check cardiodilatator (metal, pneumatic) is passed. The air is pumped up in balloon making pressure 200-350 mm H₂O. Repeated procedure is performed in 2-3 days. The course of dilatation includes 3-10 procedures, depending on obtained effect.

Surgical treatment is managed in III-IV stage of achalasia or in recurrence of the disease after dilatation.

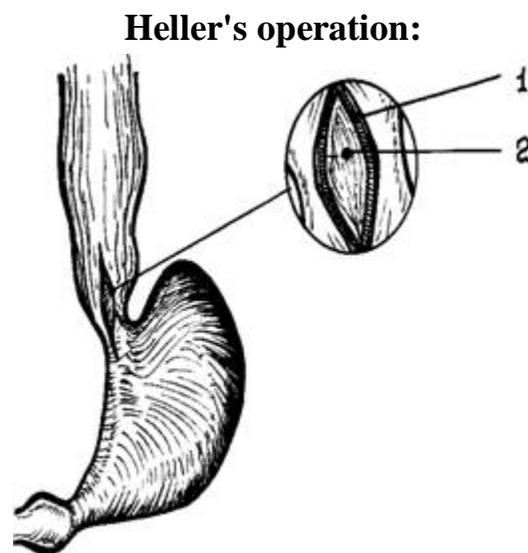

Because of excellent results, a short hospital stay, and a fast recovery time, the primary treatment is considered by many to be a laparoscopic Heller myotomy and partial fundoplication. In the author's experience and in the experience of many authors, this treatment provides a fine balance in relieving symptoms of dysphagia by performing the myotomy and in preventing gastroesophageal reflux by adding a partial wrap. A prospective, randomized study from Vanderbilt University indicated that there is significantly less risk of postoperative reflux following a Heller myotomy plus a partial fundoplication than there is after a Heller myotomy alone. The authors of this study also showed that in patients with achalasia, adding a partial fundoplication not only is more

effective in preventing postoperative reflux but also is more cost-effective at a time horizon of 10 years.

A partial fundoplication added to the myotomy entails better functional results when compared with a total fundoplication, with a lower risk of persistent or recurrent dysphagia. Recently, a multicenter, randomized controlled trial comparing partial anterior (Dor) with partial posterior (Toupet) fundoplication did not find significant differences in terms of postoperative incidence of gastroesophageal reflux. In current practice, a partial anterior fundoplication is more frequently performed since it is simpler to perform and covers the exposed esophageal mucosa.

Minimally invasive surgery for achalasia is performed under general anesthesia with the use of 5 trocars. A controlled division of the muscle fibers (myotomy) of the lower esophagus (5 cm) and the proximal stomach (1.5 cm) is carried out, followed by a partial fundoplication to prevent reflux

Heller's method (esophagomyotomy). Operation is performed through upper median laparotomy or left thoracotomy in VII intercostal space. After exposing of constricted part of esophagus and taking it on tourniquets a muscular layer of anterior wall of esophagus dissected down to mucosa. The myotomy performed from dilated part of esophagus to cardial part of stomach. The complete transection of all muscular layer of esophagus, particularly its circular fibers, is the requirement of relapse prevention.

Myotomia of the cardia (1 – muscles, 2– mucosa)

Shift of stomach fundus to the esophageal cardia

Nissen fundoplication

The defect of a muscular layer of esophageal wall is covered with a gastric fundus or by means of interrupted suture or diaphragmatic flap.

Patients remain hospitalized for 24-48 hours and return to regular activities in about 2 weeks.

The operation relieves symptoms in 85-95% of patients, and the incidence of postoperative reflux is about 20%.

For patients in whom surgery fails, they may be treated with an endoscopic dilatation first. If this fails, a second operation (extending the previous myotomy onto the anterior gastric wall) can be attempted once the cause of failure has been identified with imaging studies. The last resort is to surgically remove the esophagus (ie, esophagectomy).

Treatment options vary for patients with different degrees of illness severity. A study by

Reynoso et al suggests that among hospitalized patients with minor/moderate illness severity, laparoscopic myotomy for achalasia showed comparable or better outcomes than esophageal dilation. For major/extreme illness severity, dilation showed a comparable or better profile for hospitalized patients with achalasia.

Esophagectomy was the standard treatment in patients with achalasia and a markedly dilated or sigmoid-shaped esophagus, with Heller myotomy considered to be ineffective in such cases. However, in a study by Sweet and colleagues of 113 patients with achalasia, the investigators reported that (1) in most of the study's patients, even those with achalasia and a dilated esophagus, a laparoscopic Heller myotomy relieved dysphagia; (2) additional treatment was needed in about 20% of patients; and (3) in the end, 90% of patients had attained good swallowing ability. Esophagectomy was not required in any of the patients to maintain clinically adequate swallowing.

Cowgill et al reported on outcomes in 47 patients more than 10 years after laparoscopic Heller myotomy for achalasia. They found that notable complications were infrequent following the procedure and that no perioperative deaths had occurred. One patient underwent a second myotomy 5 years after the first, because of symptom recurrence. There were 33 surviving patients at the time of the study; the authors reported that the other patients died from causes unrelated to myotomy. Using a Likert scale and a Wilcoxon matched-pairs test to assess patients' symptoms before and after laparoscopic myotomy, Cowgill et al found significant postsurgery decreases in the frequency and severity scores for dysphagia, chest pain, vomiting, regurgitation, choking, and heartburn. They concluded that "the symptoms of achalasia are durably ameliorated by laparoscopic Heller myotomy during long-term follow-up evaluation."

Compared with pneumatic dilatation, laparoscopic Heller myotomy is associated with better results in terms of dysphagia improvement and postoperative gastroesophageal reflux rates, with a significantly lower risk of re-intervention. While the results are similar at a short-term follow-up, long-term follow-up shows that most patients after surgery are asymptomatic, compared with only 50% of patients even after multiple pneumatic dilatations.

Several studies have shown better outcomes after laparoscopic Heller myotomy than pneumatic dilatation in patients younger than 40 years. In addition, previous endoscopic treatment, such as botulinum toxin injection or pneumatic dilatation, may compromise the clinical outcome of laparoscopic Heller myotomy. Higher intraoperative complications rates and poorer long-term outcomes after laparoscopic Heller myotomy

have been reported in several series of patients previously treated with endoscopic treatments. These findings may be related to scar tissue at the level of the gastroesophageal junction, which makes surgical dissection of the anatomic planes much more difficult.

In 2011, Boeckxstaens et al[22] reported the results of a multicenter, randomized trial comparing pneumatic dilatation (95 patients) to laparoscopic Heller myotomy with Dor fundoplication (106 patients) for untreated esophageal achalasia. The perforation rate during pneumatic dilatation and laparoscopic Heller myotomy was 4% and 12%, respectively. Therapeutic success was defined as a drop in Eckardt score below 3. The study showed similar success rates after laparoscopic Heller myotomy (90%) and pneumatic dilatation (86%) over a 2-year follow-up period.

In conclusion, while pneumatic dilatation was considered the main treatment modality for patients with achalasia in the 1980s, with surgery having a secondary role in case of dilatation failure, in current practice pneumatic dilatation should be reserved for when surgical expertise is not available and for the treatment of recurrent dysphagia after myotomy.

One study only has compared in a retrospective fashion POEM and laparoscopic Heller myotomy.[28] Eighteen patients undergoing POEM were compared in a nonrandomized fashion to 55 patients treated by laparoscopic Heller myotomy. No differences were observed in terms of length of the myotomy, complication rate, and length of hospital stay. Veress needle decompression of the pneumoperitoneum was required intraoperatively in 7 (39%) patients undergoing POEM. Treatment success (Eckardt score ≤ 3) after POEM was achieved in 16 (89%) patients at median 6-month follow-up. Six weeks after POEM, routine follow-up manometry and timed-esophagram showed normalization of esophagogastric junction pressures and contrast column heights.

Only long-term follow-up and prospective trials comparing POEM with laparoscopic Heller myotomy and fundoplication will determine the role of this new technique in the treatment of esophageal achalasia.

Helerovsky's method. The operation is indicated for the patients with III-IV stage of the disease in case of considerable esophageal dilation, when performance of Heller's operation is impossible owing to cicatricial changes. However the indication for this operation should be restricted, because of frequent development of expressed esophagitis in postoperative period. The same accesses, as in Heller's operation are applied. Constricted part of esophagus to its dilation exposed and cardial part of stomach is mobilized. Dilated part of the esophagus is

anastomosed with the fundus of stomach.

ESOPHAGEAL STRICTURE

The cicatricial esophageal stenosis can arise owing to chemical, thermal and radial burns, and as a result of esophagitis or peptic ulcers. The most frequent cause of cicatricial strictures is considered to be chemical burns of esophagus, which are usually the result of accidentally or purposely (suicide) drink of acids or alkalis.

Disease processes that can produce esophageal strictures can be grouped into 3 general categories: (1) intrinsic diseases that narrow the esophageal lumen through inflammation, fibrosis, or neoplasia; (2) extrinsic diseases that compromise the esophageal lumen by direct invasion or lymph node enlargement; and (3) diseases that disrupt esophageal peristalsis and/or lower esophageal sphincter (LES) function by their effects on esophageal smooth muscle and its innervation.

Many diseases can cause esophageal stricture formation. These include acid peptic, autoimmune, infectious, caustic, congenital, iatrogenic, medication-induced, radiation-induced, malignant, and idiopathic disease processes.

The etiology of esophageal stricture can usually be identified using radiologic and endoscopic modalities and can be confirmed by endoscopic visualization and tissue biopsy. Use of manometry can be diagnostic when dysmotility is suspected as the primary process. Computed tomography (CT) scanning and endoscopic ultrasonography are valuable aids in the staging of malignant stricture. Fortunately, most benign esophageal strictures are amenable to pharmacologic, endoscopic, and/or surgical interventions.

Because peptic strictures account for 70-80% of all cases of esophageal stricture, peptic stricture is the focus of this article. A detailed discussion of possible benign and malignant processes associated with esophageal stricture and its management is beyond the scope of this article.

Frequency

United States Gastroesophageal reflux affects approximately 40% of adults. Esophageal strictures are estimated to occur in 7-23% of untreated patients with reflux disease.

Gastroesophageal reflux disease accounts for approximately 70-80% of all cases of esophageal stricture. Postoperative strictures account for about 10%, and corrosive strictures account for less than 5%.

The overall frequency of initial and subsequent dilations for peptic stricture appears to have decreased gradually since the introduction of proton pump inhibitors (PPIs) in the market

in 1989. This has been borne out by data at the author's institution and in 2 large community hospitals in Wisconsin. It is also in keeping with the general experience of gastroenterologists in the United States.

Mortality/Morbidity

The mortality rate of peptic strictures is not increased unless a procedure-related perforation occurs or the stricture is malignant. However, the morbidity for peptic strictures is significant.

Most patients undergo a chronic relapsing course with an increased risk of food impaction and pulmonary aspiration.

Frequently, coexistent Barrett esophagus and its attendant complications occur.

The need for repeated dilatation potentially increases the risk of perforation.

Race

Peptic strictures are 10-fold more common in whites than blacks or Asians. However, this is controversial as a recent retrospective study reported comparable frequencies between blacks and non-Hispanic whites. The authors reported that distribution of reflux esophagitis and grade and frequency of reflux-related esophageal ulcer and hiatal hernia were also similar in non-Hispanic whites and blacks. However, heartburn was more frequent and nausea/vomiting less frequent in non-Hispanic whites compared with blacks with erosive esophagitis or its complications.[2]

Sex

Peptic strictures are 2- to 3-fold more common in men than in women.

Age

Patients with peptic stricture tend to be older, with a longer duration of reflux symptoms.

Pathology

Peptic esophageal strictures are sequelae of gastroesophageal reflux -induced esophagitis, and they usually originate from the squamocolumnar junction and average 1-4 cm in length.

Two major factors involved in the development of a peptic esophageal stricture are as follows:

Dysfunctional lower esophageal sphincter: Mean LES pressures are lower in patients with peptic strictures compared with healthy controls or patients with milder degrees of reflux disease. A study by Ahtaridis et al showed that patients with peptic esophageal strictures had a

mean LES pressure of 4.9 mm Hg versus 20 mm Hg in control patients.[1] An LES pressure of less than 8 mm Hg appeared to correlate significantly with the presence of peptic esophageal stricture without any overlap in controls.

Disordered motility resulting in poor esophageal clearance: In the same study, Ahtaridis et al demonstrated that 64% of patients with strictures had motility disorders compared with 32% of patients without strictures.

Other possible associated factors include the following:

Presence of a hiatal hernia: Hiatal hernias are found in 10-15% of the general population, 42% of patients with reflux symptoms and no esophagitis, 63% of patients with esophagitis, and 85% of patients with peptic esophageal strictures. This suggests that hiatal hernias may play a significant role.

Acid and pepsin secretion: This does not appear to be a major factor. Patients with peptic esophageal strictures have been demonstrated to have the same acid and pepsin secretion rates as sex-matched and age-matched controls with esophagitis but no stricture formation. In fact, some authors believe that alkaline reflux may play an important role.

Gastric emptying: No good evidence suggests that delayed emptying plays a role in peptic esophageal strictures.

The morphological changes in esophageal burns pass four stages:

I – stage of acute esophagitis. Lasts from one to two months. It is characterized by edema and divestment of necrotic tissues. This stage is hazardous for erosive bleedings.

II – stage of chronic esophagitis. The ulcers of different sizes with granulating tissue in their bottom, focal constrictions of esophageal lumen are formed.

III – stage of cicatrical stricture of esophagus. Begins from 2-4th month and lasts to 2 years.

IV – stage of late complications. Develops in two years after the burn and is characterized by formed cicatrical stricture of esophagus.

Classification

According to the clinical course:

I. The period of acute manifestation has three degrees of severity:

1 - mild;

2 - moderate;

3 - severe.

II. The latent period (false improvement).

III. The period of cicatrization.

According to the depth of lesion:

I degree – superficial burn with the damage of epithelial layer of esophagus;

II degree – the burn with the damage of entire mucosa of esophagus;

III degree – the burn damage of all layers of esophagus;

IV degree – the spread of postburn necrosis on paraesophageal tissue and adjacent organs.

Symptomatology and clinical course

The clinical signs of esophageal burn directly depend on the period of lesion and degree of gravity.

Acute period

The mild degree of clinical course manifests by satisfactory general state of the patient. At swallowing the patient feels a moderate pain, sometimes salivation, hoarseness. Roentgenologically – the lumen of esophagus without changes, with free passage of barium, the mucous folds with regular contours, but in some places it is possible to observe its graduation. The esophageal peristalsis is maintained. As a rule, in 5-7 days the clinical manifestations of the burn disappear.

The moderate degree of gravity of acute period is characterized by acute substernal and pharyngeal pain at swallowing, repeated vomiting, feeling of fear and excitement. Tachycardia – 120-130 beats/min. The body temperature rises to 39°C. Oliguria develops frequently. Roentgenologically – the esophagus dilated, but in some places can be constricted as a result of edema or spasm. The lumen is filled with considerable amount of slime. The contours of mucosal folds are irregular, the peristalsis is weakened or absent at all. If there will be no complication, in 10-15 days the clinical manifestation of the disease disappear and general state of the patient is improved.

Severe degree is characterized by the clinic of shock. Pulse of weak filling and tension, expressed tachycardia, acute substernal pain. The excitement of the patient is accompanied by feeling of fear, further transmits into adynamia, frequently the patients are unconsciousness. The skin is pale, covered with cold sweat. One patient in four except esophageal burns, suffers from burn of the stomach. The clinical course of the disease is worsened by oliguria, which can

transfer into anuria, and also occurrence of other complications. It determines the unfavorable forecast.

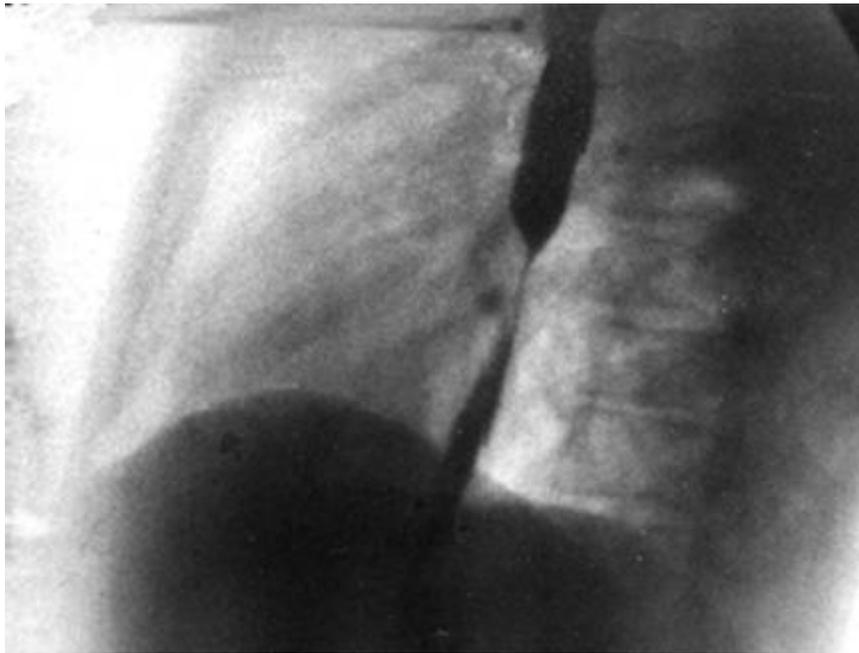

The barium swallow in the majority of patients is problematic. Nevertheless if the general state of the patient allows to carry out it, on the first day after a burn already have been observed expressed manifestations of esophagitis: the esophagus dilated, mucosal folds are failed to reveal. The deposits of destructive changed tissues in the lumen of esophagus resemble the picture of filling defects; the peristalsis is absent, complete atony.

Latent period

This period is connected with replacement of necrotic tissues by granulations. The general state of the patient is improved. The acute signs disappear. The patient swallows freely, without feeling of discomfort at passage of food.

Period of cicatrize

It frequently lasts from 1 to 12 months. It is connected with replacement of granulations by cicatricial tissue that results in progressing of esophageal stricture and disturbance of swallowing at first of solid, and further of liquid food. Such strictures develop at the orifice of esophagus, in projection of tracheal bifurcation and in the place of gastroesophageal juncture. The passage of food through the constricted regions of esophagus is possible at first only due to careful grinding and watering, but further it is inefficient. Thereafter food delay in esophagus, choking, salivation, belching and vomiting develop. If the stricture is located in the lower part of esophagus, the vomitis can be of putrefactive character. Progressing loss of weight observed, which without correction can transfer into cachexia. The level and degree of the stricture, its extension circumstantiated after X-ray examination.

Cicatricial stricture of the lower esophagus

Variants of clinical course and complications

The esophageal burns in 30 % of cases are accompanied by **disturbances of valvular function of epiglottis**. It in reinforced salivation causes the aspiration of fluid in trachea, infection of airways, development of bronchitis and pneumonia.

In 25 % of the patients the esophageal burn combined with gastric burn, mainly of its pyloric part. It can result in lot of complications, which sometimes prevail on the manifestations of esophageal burn. Especially dangerous among such complications of the early period is the gastric bleeding and perforation. The postburn stricture of pylorus belongs to the late complications.

Gastrointestinal bleedings usually occur in 3-10 days after the burn and are characteristic for the stage of formation of ulcers and granulations. Despite the rare arrosion of major vessels in such pathology, these bleedings are accompanied by considerable hemorrhage, because bleeds a considerable surface of the mucous membrane of esophagus or stomach.

Mediastinitis is mostly observed in deep burns of III-IV degree. It can be the outcome of perforation of esophagus or of hematogenic or lymphogenic spread of infection to mediastinum. The clinical manifestations mainly caused by a septic state of the patient and severe intoxication. The fever, difficult respiration, chest pain and tachycardia to 130 and more beats/min are observed. Temperature rises to 39-40°C and has hectic character.

Roentgenologically observed distention of the mediastinal shadow, sometimes detached mediastinal pleura. Pleurisy, pericarditis and lung abscesses can arise as the early complications of esophageal burns. To the late complications, except cicatricial stricture, it is necessary to regard tracheo-esophageal and broncho-esophageal fistula, and also malignancy of the cicatricial changed esophagus.

History

Patients with peptic strictures may present with heartburn, dysphagia, odynophagia, food impaction, weight loss, and chest pain.

Progressive dysphagia for solids is the most common presenting symptom. This may progress to include liquids.

Atypical presentations include chronic cough and asthma secondary to aspiration of food or acid.

The clinician cannot rely on the presence or absence of heartburn to definitely determine whether dysphagia is secondary to a peptic esophageal stricture.

- Of patients with peptic esophageal strictures, 25% have no previous history of heartburn.
- Heartburn may resolve with worsening of a peptic stricture.
- Approximately two thirds of patients with adenocarcinoma in Barrett esophagus have a history of long-standing heartburn.
- The abnormal esophageal motor activity in achalasia can produce a heartburn sensation.

Important points regarding dysphagia

- The obstruction is usually perceived at a point that is either above or at the level of the lesion.
- Dysphagia for solids and liquids simultaneously should alert the clinician to the possibility of a motility disorder such as achalasia or collagen vascular disorders.
- Dysphagia secondary to a Schatzki ring is usually intermittent and nonprogressive.
- Dysphagia for solids and liquids early in the course of disease should alert the clinician to the possibility of achalasia as an etiology of a peptic esophageal stricture.
- Benign esophageal strictures usually produce dysphagia with slow and insidious

progression (ie, months to years) of frequency and severity with minimal weight loss.

- Malignant esophageal strictures result in a rapid progression (ie, weeks to months) of severity and frequency of dysphagia and are associated frequently with significant weight loss.

Determining whether the patient takes any medications known to cause pill esophagitis is important.

Determining whether a history of collagen vascular disease or immunosuppression exists may provide clues to the underlying etiology.

Physical

Physical examination frequently does not provide clues to the cause of dysphagia.

Assessing the patient's nutritional status is important.

Patients with collagen vascular diseases may exhibit joint abnormalities, calcinosis, telangiectasias, sclerodactyly, or rashes.

The presence of atypical gastroesophageal reflux disease may be suggested by hoarse voice, posterior oropharyngeal erythema, diffuse dental erosions, wheezing, or epigastric tenderness.

Patients with adenocarcinoma of the gastroesophageal junction may have left supraclavicular lymphadenopathy (Virchow node).

Causes

Proximal or mid esophageal strictures

- Caustic ingestion (acid or alkali)
- Malignancy
- Radiation therapy[3, 4]
- Infectious esophagitis -Candida, herpes simplex virus (HSV), cytomegalovirus (CMV), human immunodeficiency virus (HIV)
- Acquired immunodeficiency syndrome (AIDS) and immunosuppression in patients who have received a transplant
- Medication-induced stricture (pill esophagitis) - Alendronate, ferrous sulfate, nonsteroidal anti-inflammatory drugs (NSAIDs), phenytoin, potassium chloride, quinidine, tetracycline, ascorbic acid.[5] Drug-induced esophagitis often occurs at

the anatomic site of narrowing, with the middle one-third behind the left atrium predominating in 75.6%. [6]

- Diseases of the skin - Pemphigus vulgaris, benign mucous membrane (cicatrical) pemphigoid, epidermolysis bullosa dystrophica
- Graft versus host disease
- Idiopathic eosinophilic esophagitis
- Extrinsic compression
- Squamous cell carcinoma
- Sequela of endoscopic submucosal dissection for superficial squamous cell neoplasms. [7]
- Miscellaneous - Trauma to the esophagus from external forces, foreign body, surgical anastomosis/postoperative stricture, congenital esophageal stenosis

Distal esophageal strictures

- Peptic stricture - Gastroesophageal reflux disease, Zollinger-Ellison syndrome
- Adenocarcinoma
- Collagen vascular disease - Scleroderma, systemic lupus erythematosus (SLE), rheumatoid arthritis
- Extrinsic compression
- Alkaline reflux following gastric resection
- Sclerotherapy and prolonged nasogastric intubation
- Crohn disease

The diagnostic program

1. Anamnesis and physical findings.

2. X-ray examination of esophagus and stomach.

- Barium esophagram provides an objective baseline record of the esophagus before medical therapy or endoscopic intervention.
- This study also provides information about the location, length, and diameter of the stricture and the smoothness or irregularity of the esophageal wall (road map).
- The information obtained can complement endoscopic findings.
- Lesions, such as diverticula and paraesophageal hernias, that potentially may lead to increased risk of complications during endoscopy can be identified.
- This study may be more sensitive than endoscopy for detection of subtle

narrowings of the esophagus such as those caused by rings and peptic strictures that are greater than 10 mm in diameter.

- This study has 100% sensitivity with luminal diameter less than 9 mm, and 90% sensitivity with luminal diameter greater than 10 mm.

3. Chest X-radiography.

- Chest radiograph, posteroanterior (PA) and lateral: Chest radiography should be used as an adjunct if extrinsic compression is considered a possible etiology of esophageal stricture.

CT scanning

- CT scans can be used to stage malignancies that produce esophageal strictures.
- Accuracy in estimating the depth of tumor invasion is 60-69%.
- Accuracy in determining spread to other organs is 82%.

4. Endoscopic examination of esophagus, stomach and duodenum.

- This procedure can be used to establish or confirm the diagnosis of esophageal stricture, to seek evidence of esophagitis, to exclude malignancy, to obtain biopsy and brush cytology specimens, and to implement therapy.
- EGD is more sensitive than barium esophagram in the identification of subtle mucosal lesions.
- Subtle strictures may be missed when smaller and thinner endoscopes are employed, especially in the setting of minimal sedation.

5. General blood analysis.

6. Coagulogram.

7. Biochemical investigation of plasma.

- Complete blood cell (CBC) count: Usually, the results of a CBC are within the reference range; however, anemia may develop due to chronic bleeding from severe esophagitis or carcinoma.
- Liver profile: Usually, the findings are within the reference range; however, the liver profile may be abnormal if metastatic disease in underlying malignancy is present.
- Complete metabolic panel: This study may allow assessment of the patient's nutritional status, especially in conjunction with weight loss.

8. Histologic Findings

- Initial histologic changes in the peptic stricture process include edema, cellular

infiltration, basal cell hyperplasia, and vascular changes with a slight increase in type III collagen deposition on healing.

- If untreated, the process can lead to progressive inflammation and ulceration involving the submucosa and muscularis mucosa. This can lead to damage of the muscular layer and the intrinsic nervous system of the esophagus, resulting in deposition of type I collagen with subsequent formation of scar tissue and stricture formation.

Differential diagnostics

It is necessary in advanced stages of esophageal and gastric strictures.

As there is the similar symptomatology, such cicatricial changes of the pyloroantral part of stomach can suggest [pylorostenosis](#) caused by peptic ulcer. The differential diagnosis is based on careful analysis of the history and endoscopic investigation of esophagus and stomach.

[Esophageal cancer](#). As this pathology can have the similar roentgenological picture, it requires thorough differential diagnostics. Besides anamnesis and clinical manifestations, the question of the diagnosis finally confirmed by histological investigation of a biopsy material, obtained during endoscopy.

Tactics and choice of treatment

The treatment of esophageal burns first of all should be guided to save the life of the patient, and also to prevent the development of esophageal strictures. The first aid must be given as soon as possible after taking of the chemical substance, which have caused the burn. In such cases by means of gastric tube and great amount of water (to 10-15 l.) immediately wash out the esophagus and stomach. It is better to use for this purpose the neutralizing solutions. If the burn is caused by acid applied 2 % solution of sodium hydrocarbonatis, and in the burns by alkalis – vinegar in the ratio 1:20 with water. For prophylaxis of shock and decreasing of psychoemotional excitement of the patient instituted anesthetizing agents. If asphyxia arise owing to edema of pharynx and epiglottis, a tracheostomy is performed.

The further aid – the treatment of shock and hypovolemia by massive intravenous infusions (up to 4-5 l. per day) of saline solutions, solutions of glucose, dextrans and blood plasma. With the purpose of detoxycation also applied forced diuresis.

Antibacterial therapy is nominated for prevention of infection complications.

In first two days after the burn the patients get parenteral feeding. Nevertheless, if the swallowing is not disturbed, it is possible to add feeding by grinding cold food. The early application of enteric feeding can be as a weak bougienage of esophagus and simultaneous prophylaxis of cicatricial strictures. The development of complications requires the treatment of their liquidation.

In the third period of the course of disease it is important not to miss a possible formation of cicatricial stenosis of esophagus. In overwhelming majority at timely and correct performance of esophageal dilatation it is possible to achieve positive effect and avoid multistep and hazardous operations. The dilatation is carried out by special [elastic thermolabile bougies](#). The first procedures of bougienage are necessary to carry out under the roentgenological check. It enables to prevent perforation of esophagus. The latter, as the complication of esophageal bougienage, can occur not only in places of cicatricial stricture, but also in the region of piriform sinus. Thereby the bougie penetrates in mediastinum and can result in mediastinitis. With the purpose of prevention of such complication the esophageal bougienage is better to carry out with conductor. It can be represented by a cord (thick thread), passed through the mouth and gastrostoma. The bougie should have the canal for conductor, nevertheless it is possible to apply the usual one with the loop, on its end.

Diet

The usual antireflux precautions and lifestyle modifications should be reinforced, although no published data exist showing that these measures are efficacious in peptic strictures.

- Patients are told to avoid fatty and spicy foods, alcohol, tobacco, chocolate, and peppermint.
- Patients should eat smaller meals, avoid eating in a hurried fashion, and chew their food well.
- Patients should be encouraged not to eat at least 2-3 hours before bedtime.
- Weight reduction should be encouraged.
- Ill-fitting dentures or poor dentition should be corrected if possible.

Traditionally, more emphasis has been placed on mechanical dilatation, and coexistent esophagitis has been relatively ignored. However, several studies have demonstrated that aggressive acid suppression using PPIs is extremely beneficial in the initial treatment of esophageal stricture, as well as long-term management.

- A dysphagia score developed by Dakkak et al in a study of 64 patients revealed that the stricture diameter only contributed to 30% of the dysphagia score and that esophagitis and other factors accounted for 70% of the score. A linear association existed between the dysphagia score only when the luminal diameter was less than 5 mm. Overall, the degree of dysphagia was worse with increasing esophagitis independent of the degree of stenosis.
- Smith et al showed in a randomized study of 366 patients that omeprazole 20 mg/d was superior to ranitidine 300 mg twice a day in preventing stricture recurrence with redilation rates of 30% and 46%, respectively, at 12 months ($P < 0.01$)
- Marks et al showed that the redilation rate in patients treated with omeprazole 20-40 mg/d was 41% versus 73% in patients treated with ranitidine 150-300 mg twice per day and almost reached significance ($P < 0.07$).[10] However, the omeprazole group showed higher rates of dysphagia relief and healing of esophagitis when compared with histamine 2 (H2) blockers.
- In contrast, 2 other studies by Swarbrick et al and Silvis et al did not show any significant differences in the redilation rates at 12 and 10 months, respectively.
- PPI treatment of patients with esophageal stricture is also more cost effective than H2 blocker therapy. Marks et al found that over a 6-month period, the cost of omeprazole therapy was \$1744 compared with \$2957 with H2 blockers.
- H2 blockers have not been shown to be any better than placebo in various trials, and no reliable data on prokinetic agents exist.

Surgical Care

In advanced cases if failed to reach the restore of esophageal patency by a bougienage, the esophagoplasty by stomach, small and large intestine is applied.

The following discussion concerns the endoscopic and surgical modalities employed for the management of peptic esophageal stricture. The choice of dilator and technique is dependent on many factors, the most important being stricture characteristics. It is also based on other factors, including patient tolerance, operator preference, and experience. No clear consensus on the optimal end point exists. In summary, dilation therapy should be tailored individually.

Endoscopic dilation dates to the 16th century, when physicians used wax wands for esophageal dilation.[13, 14] The word bougie is derived from Boujijah, an Algerian city that was the center of the medieval candle trade. The following 3 types of dilators are used:

- Mercury-filled bougies - Maloney or Hurst dilators
 - These dilators are indicated in uncomplicated strictures with diameters greater than 10-12 mm.
 - They are inexpensive and simple to perform without fluoroscopic guidance.
 - Minimal or no sedation is necessary.
 - Self-bougienage may be performed at home.
- Wire-guided polyvinyl bougies - Savary-Gilliard and American dilators
 - These dilators are relatively stiff and better suited to longer, tighter, and irregular strictures.
 - The need for fluoroscopy is variable.
 - The range is 5-20 mm, and these dilators are reusable.
 - Drawbacks include trauma to the laryngeal wall and patient discomfort.
 - American dilators are shorter, less tapered, and impregnated with barium for better fluoroscopic visualization.
- Through-the-scope (TTS) balloon dilators
 - These dilators are used through the endoscope, and they allow for direct visualization.
 - These are relatively expensive and not reusable.
 - Fluoroscopy is not mandatory, but it is useful in difficult cases.
 - Studies conflict about the benefits of balloon dilators compared with Savary dilators.

A prospective, randomized study with 17 patients in each arm comparing balloon dilators with Savary dilators was performed by Saeed et al over a 2-year period, with the end point being 45F.[15]

- Stricture recurrence was similar in the first year but lower in the second year for balloons.
- Fewer sessions were needed for balloons, 1.1 sessions +/- 0.1 versus 1.7 sessions +/- 0.2, and less procedural discomfort occurred ($P < 0.05$).
- Both devices were effective in relieving dysphagia.

Another prospective, randomized study by Scolapio et al included 251 patients with peptic strictures. Schatzki rings did not show any differences in complications, the degree of immediate relief, or the time to recurrent dysphagia.

- General rules of esophageal dilation

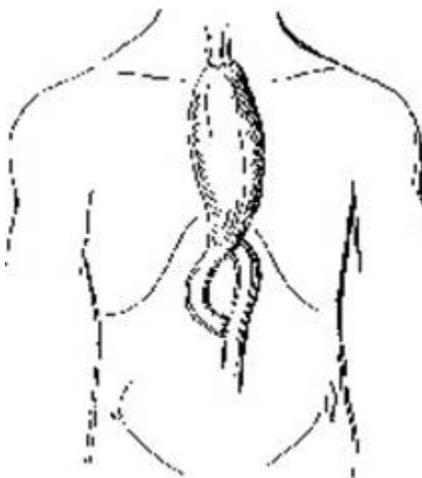

- Many authors have questioned the need for mandatory fluoroscopy, and no published data exist to advocate safety of fluoroscopy. However, one may consider using fluoroscopy in complicated strictures, especially in guiding the blind passage of a guidewire.
- Rule of 3s: The first bougie passed should be approximately equal to the estimated diameter of the stricture. Pass no more than 3 consecutive bougies of progressively increasing size after the first one that meets moderate resistance during any one dilation session. The rule of 3s has been questioned because of a lack of data verifying the increased efficacy or safety if one adheres to this rule. This rule was formulated for dilation using mercury-filled bougies resulting in dilation no greater than 1.3 mm in one session. However, polyvinyl dilators may not provide adequate tactile perception to follow this rule.
- A study by Kozarek et al showed only one perforation in 400 patients dilated with polyvinyl dilators to greater than 2 mm in one session.
- Balloon dilators frequently dilate greater than that prescribed by the rule of 3s without any increased risk of complications.
- No consensus exists regarding the end point of esophageal dilation for peptic strictures.
 - Most patients experience complete relief when dilated to 40-54F. Therefore, using this end point as a benchmark is recommended.
 - In summary, the extent of the dilatation should be individualized based on symptomatic response and technical difficulty encountered during therapy.
- Intralesional steroid injection
 - Limited anecdotal data exist showing that intralesional steroid injection of peptic strictures may be beneficial. The mechanism is unclear; it may inhibit collagen formation and enhance collagen degradation, thus increasing stricture compliance.
 - Triamcinolone 10 mg/mL in 0.5 mL aliquots was injected in 4 quadrants in 2 patients with a successful outcome as reported by Kirsch et al.
 - Lee et al showed a higher rate of achieving greater luminal diameters and duration between dilations in a nonrandomized cohort of patients with strictures of varying etiologies.[20] Similar results were obtained by Kochhar et al in 71 patients, although 8 injections of 20 mg of triamcinolone in 0.5-mL aliquots were given at the proximal margin and into the stricture itself.
 - A randomized prospective trial of Savary dilation with or without intralesional

steroids was conducted in 42 patients by Dunne et al ; it demonstrated a decreased need for second dilations in the steroid group (1.95 vs 5.5) at 1 year. Similar results were seen in a study by Ramage et al in 30 patients, but the latter study was also double blinded with a sham group. Two patients (13%) in the steroid group and 9 patients (60%) in the sham group needed repeat dilation over a 12-month period.

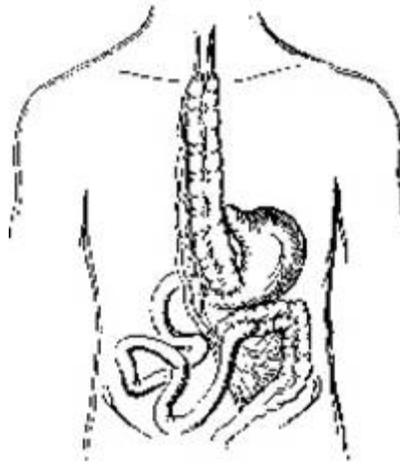

- Therefore, a trial of steroid injection may be reasonable in patients with benign strictures who experience no significant relief of dysphagia despite repeated dilations and aggressive antireflux therapy. Hishiki et al reported the use of repeated endoscopic dilatation with systemic steroids in a child with severe esophageal anastomotic stricture that did not respond to endoscopic dilatation and local steroid injection of the stricture. At 18 months follow-up, the child remained asymptomatic without any further endoscopic dilations.
- Endoscopic stricturoplasty: Two case series described a technique using a needle knife to make 4 quadrant incisions followed by Savary dilation. This was successful in 8 of 8 patients as reported by Raijman et al[25] and 5 of 6 patients as reported by Hagiwara et al.
- Pharyngoesophageal puncture is a term recently coined by Tang et al to describe the technique of endoscopic dilation of radiation-induced severe or complete pharyngoesophageal strictures. A combination of guide wires, endoscopic balloons, puncture and techniques learned from ERCP were successfully applied to 3 patients with severe/complete stenosis.
- Expandable polyester silicone-covered stent: Repici et al presented a case series of 15 patients whose condition had failed endoscopic therapy. A temporary placement of a stent for 6 weeks was successful in 12 patients over a long-term period (mean follow-up, 22.7 mo). However, the exact duration for stent placement remains unclear, as strictures can recur following stent removal. Furthermore, a variety of complications have been described following stent deployment. More recently, biodegradable stents have shown some promise in animal studies and were used to treat severe corrosive esophageal stenosis in a child.[32]
- The role of surgical treatment in peptic stricture remains in dispute. Indications include failed aggressive medical therapy or an unsuitable candidate for aggressive medical therapy. This is usually a rare occurrence in the era of PPI therapy. Various procedures advocated include the following:

- Esophageal-sparing procedures - Standard antireflux surgery (Nissen total or Belsey partial fundoplication), esophageal lengthening with antireflux surgery (Collis-Nissen or Belsey gastroplasty)
- Esophageal resection and reconstruction - Gastric or colon interposition or jejunal segment
- If the benign peptic stricture is dilatable, an esophageal-sparing operation is performed.
 - If the length of the esophagus is normal, standard antireflux surgery and postoperative dilation as necessary is recommended.
 - If the esophagus is short, performing Collis gastroplasty and postoperative dilation as necessary is recommended.
 - If the stricture is undilatable, esophageal resection and interposition is recommended.
- In the literature, some anecdotal reports exist of minimally invasive surgery, including laparoscopic transhiatal esophagectomy and laparoscopic Collis gastroplasty with Nissen fundoplication. With continuing advances in technology, whether or not minimally invasive surgery would play a major role in the surgical management of peptic stricture remains to be determined.

ESOPHAGEAL CANCER

Esophageal cancer is cancer that occurs in the esophagus — a long, hollow tube that runs from your throat to your stomach. Your esophagus carries food you swallow to your stomach to be digested.

Esophageal cancer usually begins in the cells that line the inside of the esophagus. Esophageal cancer can occur anywhere along the esophagus, but in people in the United States, it occurs most often in the lower portion of the esophagus. More men than women get esophageal cancer.

Esophageal cancer isn't common in the United States. In other areas of the world, such as Asia and parts of Africa, esophageal cancer is much more common.

Etiology

It's not clear what causes esophageal cancer. Esophageal cancer occurs when cells in your esophagus develop errors (mutations) in their DNA. The errors make cells grow and divide out of control. The accumulating abnormal cells form a tumor in the esophagus that can grow to invade nearby structures and spread to other parts of the body.

Types of esophageal cancer

Esophageal cancer is classified according to the type of cells that are involved. The type of esophageal cancer you have helps determine your treatment options. Types of esophageal cancer include:

- Adenocarcinoma. Adenocarcinoma begins in the cells of mucus-secreting glands in the esophagus. Adenocarcinoma occurs most often in the lower portion of the esophagus. Adenocarcinoma is the most common form of esophageal cancer in the United States, and it affects primarily white men.
- Squamous cell carcinoma. The squamous cells are flat, thin cells that line the surface of the esophagus. Squamous cell carcinoma occurs most often in the middle of the esophagus. Squamous cell carcinoma is the most prevalent esophageal cancer worldwide.
- Other rare types. Rare forms of esophageal cancer include choriocarcinoma, lymphoma, melanoma, sarcoma and small cell

Risk factors

It's thought that chronic irritation of your esophagus may contribute to the DNA changes that cause esophageal cancer. Factors that cause irritation in the cells of your esophagus and increase your risk of esophageal cancer include:

- Drinking alcohol
- Having bile reflux
- Chewing tobacco
- Having difficulty swallowing because of an esophageal sphincter that won't relax (achalasia)
- Drinking very hot liquids
- Eating few fruits and vegetables
- Eating foods preserved in lye, such as lutefisk, a Nordic recipe made from whitefish, and some olive recipes

- Having gastroesophageal reflux disease (GERD)
- Being obese
- Having precancerous changes in the cells of the esophagus (Barrett's esophagus)
- Undergoing radiation treatment to the chest or upper abdomen
- Smoking

Other risk factors include

- Being male
- Being between the ages of 45 and 70

Signs and symptoms

- Difficulty swallowing (dysphagia)
- Weight loss without trying
- Chest pain, pressure or burning
- Fatigue
- Frequent choking while eating
- Indigestion or heartburn
- Coughing or hoarseness

Early esophageal cancer typically causes no signs or symptoms.

If you've been diagnosed with Barrett's esophagus, a precancerous condition that increases your risk of esophageal cancer caused by chronic acid reflux, ask your doctor what signs and symptoms to watch for that may signal that your condition is worsening.

Screening for esophageal cancer isn't done routinely because of a lack of an easily identifiable high-risk group and the possible risks associated with endoscopy. If you have Barrett's esophagus, discuss the pros and cons of screening with your doctor.

Diagnostic

Using a scope to examine your esophagus (endoscopy). During endoscopy, your doctor passes a hollow tube equipped with a lens (endoscope) down your throat and into your esophagus. Using the endoscope, your doctor examines your esophagus looking for cancer or areas of irritation.

X-rays of your esophagus. Sometimes called a barium swallow, an upper gastrointestinal series or an esophagram, this series of X-rays is used to examine your esophagus. During the test, you drink a thick liquid (barium) that temporarily coats the lining of your esophagus, so

the lining shows up clearly on the X-rays.

Collecting a sample of tissue for testing (biopsy). A special scope passed down your throat into your esophagus (endoscope) or down your windpipe and into your lungs (bronchoscope) can be used to collect a sample of suspicious tissue (biopsy). What type of biopsy procedure you undergo depends on your situation. The tissue sample is sent to a laboratory to look for cancer cells.

Esophageal cancer staging

When you're diagnosed with esophageal cancer, your doctor works to determine the extent (stage) of the cancer. Your cancer's stage helps determine your treatment options. Tests used in staging esophageal cancer include computerized tomography (CT) and positron emission tomography (PET).

The stages of esophageal cancer are:

Stage I. This cancer occurs only in the top layer of cells lining your esophagus.

Stage II. The cancer has invaded deeper layers of your esophagus lining and may have spread to nearby lymph nodes.

Stage III. The cancer has spread to the deepest layers of the wall of your esophagus and to nearby tissues or lymph nodes.

Stage IV. The cancer has spread to other parts of your body.

Surgery

Surgery to remove the cancer can be used alone or in combination with other treatments. Operations used to treat esophageal cancer include:

Surgery to remove very small tumors. If your cancer is very small, confined to the superficial layers of your esophagus and hasn't spread, your surgeon may recommend removing the cancer and margin of healthy tissue that surrounds it. Surgery for very early-stage cancers can be done using an endoscope passed down your throat and into your esophagus.

Surgery to remove a portion of the esophagus (esophagectomy). Your surgeon removes the portion of your esophagus that contains the tumor and nearby lymph nodes. The remaining esophagus is reconnected to your stomach. Usually this is done by pulling the stomach up to meet the remaining esophagus. In some situations, a portion of the colon is used to replace the missing section of esophagus.

Surgery to remove part of your esophagus and the upper portion of your stomach (esophagogastrectomy). Your surgeon removes part of your esophagus, nearby lymph nodes and the upper part of your stomach. The remainder of your stomach is then pulled up and reattached to your esophagus. If necessary, part of your colon is used to help join the two.

Esophageal cancer surgery carries a risk of serious complications, such as infection, bleeding and leakage from the area where the remaining esophagus is reattached. Surgery to remove your esophagus can be performed as an open procedure using large incisions or with special surgical tools inserted through several small incisions in your skin (laparoscopically). How your surgery is performed depends on your situation and your surgeon's experience and preferences.

Surgery for supportive care

Besides treating the disease, surgery can help relieve symptoms or allow you to eat.

Relieving esophageal obstruction. A number of treatments are available to relieve esophageal obstruction. One option includes using an endoscope and special tools to widen the esophagus and place a metal tube (stent) to hold the esophagus open. Other options include surgery, radiation therapy, chemotherapy, laser therapy and photodynamic therapy.

Providing nutrition. A surgeon inserts a feeding tube (percutaneous gastrostomy) so you can receive nutrition directly into your stomach or intestine. This is usually temporary until the surgical site heals or until you're finished with chemotherapy and radiation therapy.

Chemotherapy

Chemotherapy is drug treatment that uses chemicals to kill cancer cells. Chemotherapy drugs are typically used before (neoadjuvant) or after (adjuvant) surgery in people with esophageal cancer. Chemotherapy can also be combined with radiation therapy. In people with advanced cancer that has spread beyond the esophagus, chemotherapy may be used alone to help relieve signs and symptoms caused by the cancer.

The chemotherapy side effects you experience depend on which chemotherapy drugs you receive.

Radiation therapy

Radiation therapy uses high-powered energy beams to kill cancer cells. Radiation can come from a machine outside your body that aims the beams at your cancer (external beam radiation). Or radiation can be placed inside your body near the cancer (brachytherapy).

Radiation therapy is most often combined with chemotherapy in people with esophageal cancer. It can be used before or after surgery. Radiation therapy is also used to relieve complications of advanced esophageal cancer, such as when a tumor grows large enough to stop food from passing to your stomach.

Side effects of radiation to the esophagus include sunburn-like skin reactions, painful or difficult swallowing, and accidental damage to nearby organs, such as the lungs and heart.

Combined chemotherapy and radiation

Combining chemotherapy and radiation therapy may enhance the effectiveness of each treatment. Combined chemotherapy and radiation may be the only treatment you receive, or combined therapy can be used before surgery. But combining chemotherapy and radiation treatments increases the likelihood and severity of side effects.

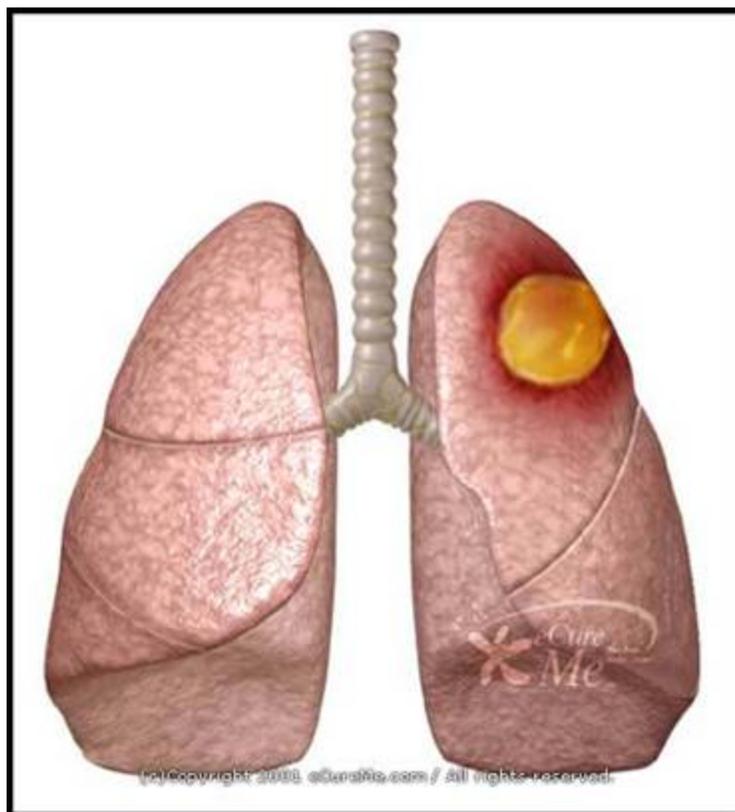

PURULENT DISEASES OF LUNGS AND PLEURA

Lung abscess is defined as necrosis of the pulmonary tissue and formation of cavities containing necrotic debris or fluid caused by microbial infection. The formation of multiple small (< 2 cm) abscesses is occasionally referred to as necrotizing pneumonia or lung gangrene. Both lung abscess and necrotizing pneumonia are manifestations of a similar pathologic process. Failure to recognize and treat lung abscess is associated with poor clinical outcome.

Lung abscess was a devastating disease in the preantibiotic era, when one third of the patients died, another one third recovered, and the remainder developed debilitating illnesses such as recurrent abscesses, chronic empyema, bronchiectasis, or other consequences of chronic pyogenic infections. In the early postantibiotic period, sulfonamides did not improve the outcome of patients with lung abscess until the penicillins and tetracyclines were available. Although resectional surgery was often considered a treatment option in the past, the role of surgery has greatly diminished over time because most patients with uncomplicated lung abscess eventually respond to prolonged antibiotic therapy.

Lung abscesses can be classified based on the duration and the likely etiology. Acute abscesses are less than 4-6 weeks old, whereas chronic abscesses are of longer duration. Primary abscess is infectious in origin, caused by aspiration or pneumonia in the healthy host; secondary abscess is caused by a preexisting condition (eg, obstruction), spread from an extrapulmonary site, bronchiectasis, and/or an immunocompromised state.

Most patients with primary lung abscess improve with antibiotics, with cure rates documented at 90-95%

Abscessing pneumonia is characterized by the multiple destructive foci 0,3-0,5 cm in size within 1-2 segments of lungs, which are not disposed to progression. The destruction is accompanied by expressed perifocal infiltration of a pulmonary tissue.

Abscess of lungs - purulent or ichorous destruction of necrotic sites of pulmonary tissue of one segment with formation of one or several cavities, filled by pus, and detached from adjacent parenchyma by a pyogenic capsule and expressed perifocal infiltration of surrounding pulmonary tissue. It arises at the persons with a maintained reactivity of the organism.

Gangrenous abscess is a purulent, ichorous necrosis of a pulmonary tissue within 2-3 segments, detached from adjacent pulmonary parenchyma, with the liability to formation of sequestrs. Depending on reactivity of the organism it can transform into purulent abscess (after the lysis of sequestrs) or gangrene.

Gangrene of lungs – a diffuse purulent, ichorous necrosis of the tissue without the tendency to defined demarcation with prompt dynamics of spreading of necrotic zone and destruction of the parenchyma. It is characterized by a grave intoxication, liability to a pleural complications and pulmonary bleeding. If only the one lobe is affected the gangrene is considered to be limited, if affected extensive areas of lungs the gangrene is wide-spread.

Etiology and pathogenesis

Lung abscesses have numerous infectious causes. Anaerobic bacteria continue to be accountable for most

cases. These bacteria predominate in the upper respiratory tract and are heavily concentrated in areas of oral-gingival disease. Other bacteria involved in lung abscesses are gram-positive and gram-negative organisms. However, lung cavities may not always be due to an underlying infection. Some evidence suggests that individuals with cyanotic heart disorders may also be more prone to lung abscess formation. The continuous hypoperfusion of the pulmonary tissues may predispose the individuals to chronic pulmonary infections.

The predominant factors which cause the disease:

- disturbances of bronchial patency with the development of atelectasis;
- infectious inflammatory process in a pulmonary tissue;
- regional disturbances of blood supply with a further necrosis of areas of pulmonary parenchyma.

The embodiment of these factors occurs in condition of the changed reactivity of the organism.

The states which result in the aspiration of contents of the upper parts of alimentary tract (traumas of head, craniovascular disturbances, alcoholism, narcomania, narcoses, epilepsy etc.) contribute to the pulmonary abscessing. And also factors, which are capable to provoke secondary immunodeficiency and suppression of reactive processes: diabetes mellitus, irradiation, long application of corticosteroids, antineoplastic therapy, some hematological disease, AIDS favor the purulent processes.

Factors contributing to lung abscess

Oral cavity disease

- Periodontal disease
- Gingivitis

Altered consciousness

- Alcoholism
- Coma
- Drug abuse
- Anesthesia
- Seizures

Immunocompromised host

- Steroid therapy
- Chemotherapy
- Malnutrition
- Multiple trauma

Esophageal disease

- Achalasia
- Reflux disease
- Depressed cough and gag reflex
- Esophageal obstruction

Bronchial obstruction

- Tumor
- Foreign body
- Stricture

Generalized sepsis

Pathology

The abscesses mainly develop in II and VI segments of lungs. They may be single and multiple. The abscess is confined from adjacent pulmonary tissue by a capsule, which represents a granulating tissue and dense leukocytic rampart. Usually it is possible to find out a draining bronchus. Later on in the wall of the abscess the amount of connective tissue fibers is enlarged.

In gangrene the pulmonary tissue is of black color, swollen, with cavities, and in some places transfers into the sites with dark green coloring. The macropreparatus is characteristically fetid.

Classification

According to pathogenesis:

- postpneumonic;
- aspirative;
- obturative;
- posttraumatic;
- hematogenous or septic;
- lymphogenous;

- thromboembolic.

According to the character of purulent process:

- single purulent abscesses;
- multiple purulent abscesses;
- bilateral purulent abscesses;
- gangrenous abscesses (single, multiple, uni- and bilateral);
- limited gangrene;
- wide-spread gangrene.

According to stages:

- 1 stage - necrotic pneumonia;
- 2 stages - destruction and rejection;
- 3 stages - cleaning and cicatrization.

According to the term of existence:

- acute;
- chronic.

Complications:

- pulmonary bleeding;
- pyopneumothorax;
- pleural empyema;
- sepsis;

- bronchogenic dissemination.

Symptomatology and clinical course

The clinical manifestations of acute purulent destruction of lungs depend on the size of the focus and character of destruction, reactivity of the organism and stage of the disease, peculiarities of the drainage of purulent cavities and complications.

At the first stage of **acute abscess** the patients complain of general weakness, headache, malaise, suppressed appetite, moderate chest pain, dyspnea, subfebrile temperature.

At the second stage the state of the patients is worsened. The fever rises to as high as 39-40°C and has a hectic character. At the same time the chest pain increases, which associates with a troubling cough and dyspnea. The condition of the patients is worsened and the intoxication increases. One can feel a foul-smelling from the mouth at cough. The amount of sputum is small, with a rusty tone. With the beginning of the draining of destructive cavities through bronchus the daily quantity of the sputum reaches 500 ml and more. At this time is possible hemoptysis. The sputum is foul-smelling. At sedimentation it divides into three layers:

- inferior – resembling a grey mass with detrites and flaps of a pulmonary tissue;
- medial – purulent, turbid, liquid;
- upper – mucous foamy layer.

Further in favourable cases there is a considerable improvement of state of the patients. The body temperature falls, the signs of intoxication reduce and the appetite increases.

The disease grades into the third stage, which is characterized by the regress of clinical manifestations, up to their complete disappearance.

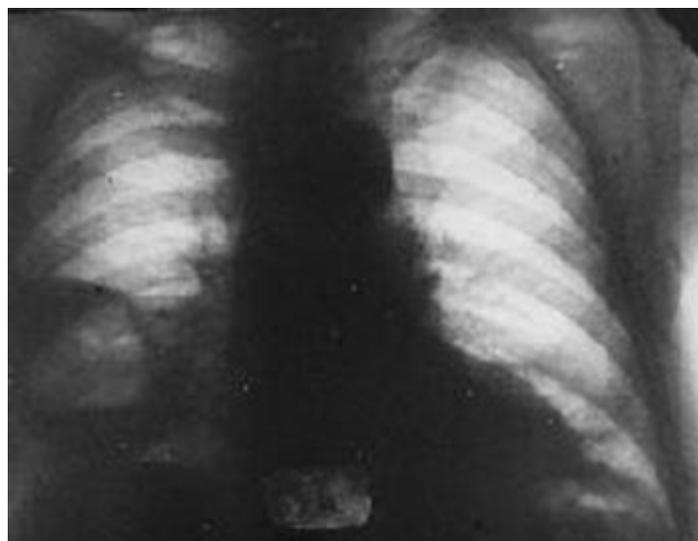

The physical signs good are well revealed at peripheral localization of the process. By palpation – weakened vocal fremitus. At percussion – a blunted sound over the site of the purulent focus and perifocal infiltration (at subpleural location of the abscess). By auscultation – tubular sound with a moist rales in the zone of purulent focus. Well-generated subpleural cavities of major sizes can be revealed by percussion by bandbox sound, on auscultation by moist rales on the background of amphoric respiration.

At X-ray of the chest at the stage of necrotic pneumonia is found out a rounded lesion with irregular contour. For the second stage is characteristic the enlightenment of the shadow with a further developing of the rounded cavity with air-fluid level (Kordin's symptom), gentle pyogenic sheath and the perifocal infiltration.

At the third stage on the place of suppuration observed expressed fibrosis, sometimes as a thin-walled annular formation.

Acute abscess of the right lower lobe before draining

Acute abscess of the right lower lobe after draining

Gangrenous abscess is characterized by a grave state of the patient, expressed purulent intoxication, cough with expectoration of a great amount (500 ml and more) of grey-green sputum with a foul-smelling, hectic body temperature. Roentgenologically the outline of the cavity is poorly defined, it contains a visible sequestrum that looks as a polymorphous shadow. The adjacent pulmonary tissue is infiltrated.

Gangrenous abscess

The clinic of a **pulmonary gangrene** differs by a terminal expression of signs. The state of the patients is critical. The patient is adynamic, exhausted, with edemas on legs. Dyspnea in rest, hemodynamic disturbances are evident. Dirty-grey or brown sputum with detrites, pieces of necrotic parenchyma and threads of blood excretes out with the cough up to 1 l. Early pleural complications are usual and represent with pulmonary bleeding, which may be profuse. Often it is associated with vital organ dysfunction and loss of consciousness.

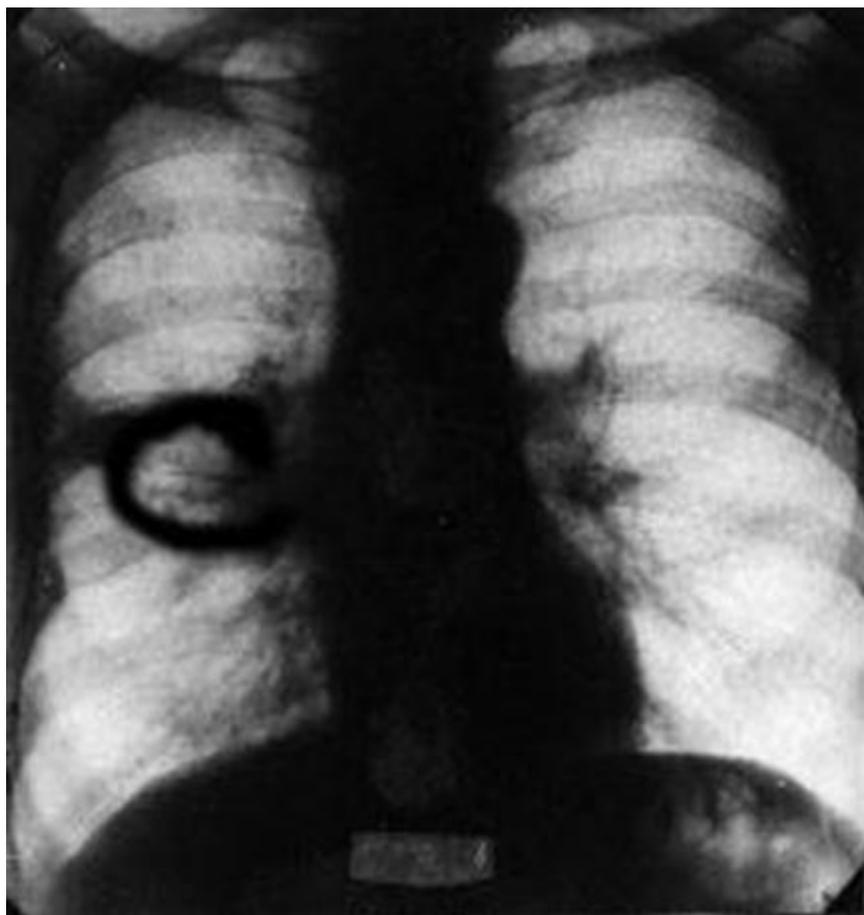

The intensive shadow which borrows a considerable area of lungs with a visible cavities, that contain sequestrum, fluid levels, is roentgenologically revealed. The shadow outline is irregular, but could be well defined if the process is within interlobar sulcus.

Pulmonary gangrene

Chronic abscess of lungs occurs at 12-15 % of cases. It is considered to be chronic at existence of a pulmonary abscess more than 6-8 weeks. It is characterized by a cyclic course. In the stage of remission the patients complain of a moderate dyspnea, cough with expectoration of a mucous or mucopurulent discharge. The exacerbation manifests by coughing up of 250-500 ml of a purulent foul sputum, chest pain, dyspnea, hectic temperature with the difference in 1,5-2°C. Dizziness, suppression of appetite, general weakness enlarges according to intoxication. The skin is pale with moderate cyanosis. The respiratory rate rises to 28-30 per min. In 6-8 months is noticed the clubbing of the fingers and deformation of the chest. The vocal fremitus is a little bit weakened on the side of lesion (particularly in peripheral localization of the process). The percussion reveals a short sound in projection of pathological process, the auscultation - a lot of moist rales on the background of amphoric respiration.

Roentgenologically chronic abscess is shown by one or several cavities of a spherical shape with a thick, dense pyogenic sheath. Exacerbation of the process manifests by a cavity with horizontal air-fluid level. The size of surrounding perifocal infiltration depends on the phase of process.

Chronic abscess of lungs

The blood analysis in pulmonary destruction is characterized by leukocytosis with deviation of the differential count to the left, lymphocytopenia, elevation of the erythrocyte sedimentation rate. Gangrenous change of the process is accompanied by a progressing anemia, sometimes by leukopenia. The hypoproteinemia arises from major losses of protein with purulent sputum. Intoxication and toxic lesion of liver leads to disproteinemia. It is associated with the enlarged concentration of mucoprotein, sialine acids, seromuroid, and fibrinogen.

The immunogram reveals the suppression of cellular and humoral immunity with a liability to hyperergy and autoaggression, depression of the mechanisms of nonspecific protection.

The cytological bronchial water lavage is characterized by expressed neutrocytosis, noncellular postdestructive insertions at lack or absence of alveolar macrophages.

Variants of clinical course and complications

According to the clinical course, there are such variants of the development of purulent diseases of lungs:

1. **Favorable course.** The adequate treatment results in prompt positive clinical, roentgenological and laboratory dynamics, and terminates by recovery.
2. **Non-progressive course.** A poor drainage of the suppurative focus and permanent purulent intoxication result in transferring of the process in chronic form.
3. **Progressing course.** Is predetermined by combination of a series of the unfavorable factors (low resistance of the organism, autoimmune aggression, high virulence of the infecting agent etc.). Characterized by diffusion of the zone of necrosis and destruction with transferring in gangrene.
4. **Incapsulated process.** Caused by the absence or complete obstruction of the draining bronchus under condition of satisfactory resistance of the organism.
5. **Complicated course.** Mostly is the result of progressive development of the pathological process.

Pulmonary bleeding arise suddenly, are associated with coughing out of a foamy, red blood and clots by portions or continuous stream. The most often source of a pulmonary bleeding are the bronchial arteries and vessels of a pulmonary tissue. The clinical manifestations of a pulmonary suppuration are accompanied by dizziness, weakness, dyspnea, chest pain. The hemodynamic disturbances depend on intensity of the bleeding. The auscultation of lungs from both sides reveals the moist rales (aspiration). If the pulmonary destruction is present the plain film of the chest shows the localization of the source of bleeding. After hospitalization of the patient with this complication the exclusive information is obtained with a fibrobronchoscopy.

According to degree the pulmonary bleedings are classified (V.Struchkov, 1985):

I degree – hemorrhage up to 300 ml.

1. Single hemoptysis.
2. Multiple hemoptysis.

II degree – hemorrhage up to 700 ml.

1. Single bleeding:
 - a) with fall in arterial pressure and decreasing of hemoglobin;
 - b) without fall in arterial pressure and decreasing of hemoglobin.
2. Multiple bleeding:
 - a) with fall in arterial pressure and decreasing of hemoglobin;
 - b) without fall in arterial pressure and decreasing of hemoglobin.

III degree - hemorrhage exceeds 700 ml.

1. Massive bleeding.
2. Fulminant, lethal bleeding.

The I degree of a pulmonary bleeding manifests by coughing out the sputum tinged with blood, the hemodynamic disturbance usually absent. At bleeding of II degree are observed decreasing of arterial pressure on 20-30 mm Hg, tachycardia to 100 beats/min, contents of hemoglobin within 60-80 g/l. The bleeding of III degree are accompanied with sharp decreasing of arterial pressure, rapid (more than 100-120 beats/min), small, sometimes thread pulse, and even its disappearance on peripheral arteries, tachypnea to 40 per 1 min, hemoglobin to 50-60 g/l. Probable the fulminant course up to the terminal state with prompt failure of cardiac activity and asphyxia by blood.

Sepsis manifests by multisystem lesions with progression of the syndrome of polyorganous failure, hematosepsis, purulent metastasizing (frequently in brain).

Characteristic complications for suppurative diseases of lungs such as pleural empyema and pyopneumothorax are described in separate parts.

The diagnostic program

1. Complaints and history of the disease.

Generally, most of the patients admitted to the hospital with a diagnosis of lung abscess have had symptoms for at least 2 weeks. These patients typically have an intermittent febrile course, productive cough, weight loss, general malaise, and night sweats. Initially, foul sputum is not observed in the course of the infection; however, after cavitation occurs, putrid expectorations are quite prevalent. The odor of the breath and sputum of a patient with an anaerobic lung abscess is often quite pronounced and noxious and may provide a clue to the diagnosis. Hemoptysis may occasionally follow the expectoration of putrid sputum.

Symptoms depend on whether the abscess is caused by anaerobic or other bacterial infection.

- Anaerobic infection in lung abscess
 - Patients often present with indolent symptoms that evolve over a period of weeks to months.
 - The usual symptoms are fever, cough with sputum production, night sweats, anorexia, and weight loss.
 - The expectorated sputum characteristically is foul smelling and bad

tasting.

- Patients may develop hemoptysis or pleurisy
- Other pathogens in lung abscess
- These patients generally present with conditions that are more emergent in nature and are usually treated while they have bacterial pneumonia.
- Cavitation occurs subsequently as parenchymal necrosis ensues.
- Abscesses from fungi, *Nocardia* species, and *Mycobacteria* species tend to have an indolent course and gradually progressive symptoms.

2. Physical findings.

The findings on physical examination of a patient with lung abscess are variable. Physical findings may be secondary to associated conditions such as underlying pneumonia or pleural effusion. The physical examination findings may also vary depending on the organisms involved, the severity and extent of the disease, and the patient's health status and comorbidities.

- Patients with lung abscesses may have low-grade fever in anaerobic infections and temperatures higher than 38.5°C in other infections.

- Generally, patients with in lung abscess have evidence of gingival disease.

- Clinical findings of concomitant consolidation may be present (eg, decreased breath sounds, dullness to percussion, bronchial breath sounds, coarse inspiratory crackles).

- The amphoric or cavernous breath sounds are only rarely elicited in modern practice.

- Evidence of pleural friction rub and signs of associated pleural effusion, empyema, and pyopneumothorax may be present. Signs include dullness to percussion, contralateral shift of the mediastinum, and absent breath sounds over the effusion.

- Digital clubbing may develop rapidly.

3. X-ray examination of chest in two planes (direct and lateral).

- A typical chest radiographic appearance of a lung abscess is an irregularly shaped cavity with an air-fluid level inside. Lung abscesses as a result of aspiration most frequently occur in the posterior segments of the upper lobes or the superior segments of the lower lobes.

- The wall thickness of a lung abscess progresses from thick to thin and from ill-defined to well-circumscribed as the surrounding lung infection resolves. The cavity wall can be smooth or ragged but is less commonly nodular, which raises the possibility of cavitating carcinoma.

- The extent of the air-fluid level within a lung abscess is often the same in posteroanterior or lateral views. The abscess may extend to the pleural surface, in which case it forms acute angles with the pleural surface.

- Anaerobic infection may be suggested by cavitation within a dense segmental consolidation in the dependent lung zones.

- Lung infection with a virulent organism results in more widespread tissue necrosis, which facilitates progression of underlying infection to pulmonary gangrene.

4. Up to one third of lung

5. Tomogram of lungs.

6. Computed tomography

- CT scanning of the lungs may help visualize the anatomy better than chest radiography. CT scanning is very useful in the identification of concomitant empyema or lung infarction.

- On CT scans, an abscess often is a rounded radiolucent lesion with a thick wall and ill-defined irregular margins.

- The vessels and bronchi are not displaced by the lesion, as they are by an empyema.

- The lung abscess is located within the parenchyma compared with loculated empyema, which may be difficult to distinguish on chest radiographs.

- The lesion forms acute angles with the pleural surface chest wall.

7. Examination of the sputum (bacteriological, cytological).

8. General blood and urine analyses.

- A complete white blood cell count with differential may reveal leukocytosis and a left shift.

- Obtain sputum for Gram stain, culture, and sensitivity.

- If tuberculosis is suspected, acid-fast bacilli stain and mycobacterial

culture is requested.

- Blood culture may be helpful in establishing the etiology.
- Obtain sputum for ova and parasite whenever a parasitic cause for lung abscess is suspected.

9. Biochemical blood analysis (protein and its fractions).

10. Immunogram.

11. Fibrobronchoscopy.

Differential diagnostics

Pneumonia

Primary bacterial pneumonias caused by single bacterial species other than the pneumococcus may account for up to 25% of community-acquired and 80% of hospital-acquired pneumonias. All of these pneumonias may have somewhat similar physical findings and x-ray evidence of pulmonary infiltration or consolidation. For proper treatment, it is crucial to identify the causative agent by blood culture and by sputum examination with stained smear and culture. Transtracheal aspiration, fiberoptic bronchoscopy, or even lung biopsy may be needed for specific diagnosis and treatment.

Streptococcal Pneumonia

Pneumonia due to hemolytic streptococci occurs usually as a sequela to viral infection of the respiratory tract, especially influenza or measles, or in persons with underlying pulmonary disease. The patients are usually in a severely toxic condition and cyanotic. Pleural effusion develops frequently and early and progresses to empyema in one-third of untreated patients. The diagnosis rests on finding large numbers of streptococci in smears of sputum and culturing hemolytic streptococci from blood and sputum.

The treatment of choice is with penicillin G in a dosage similar to that for pneumococcal pneumonia (see above). If treatment is started early, the prognosis is good.

Staphylococcal Pneumonia (picture 2)

Pneumonia caused by *Staphylococcus aureus* occurs as a sequela to viral infections of the respiratory tract (eg, influenza) and in debilitated (eg, postsurgical) patients or hospitalized infants, especially after antimicrobial drug administration. There is often a history of a mild illness with headache, cough, and generalized aches that abruptly changes to a very severe illness with high fever, chills, and exaggerated cough with purulent or blood-streaked sputum and deep cyanosis. There may be early signs of pleural effusion, empyema, or tension pneumothorax. X-ray examination reveals lung consolidation, pneumatoceles,

abscesses, empyema, and pneumothorax. The demonstration of pyopneumothorax and of cavities with air-fluid levels by x-ray is highly suggestive of Staphylococcal pneumonia. The diagnosis must be confirmed by stained smear of sputum (masses of white cells and gram-positive cocci, many intra-cellular) and culture (predominantly *S aureus*), and

also by means of cultures of pleural fluid and blood. The white count is usually more than 20,000//zL.

Initial therapy (based on sputum smear) consists of nafcillin, 6-12 g/d, or vancomycin, 2 g/d, given intravenously in divided doses as a bolus. If the staphylococcus proves to be penicillin-sensitive by laboratory test, penicillin G, 20-60 million units/d intravenously, is the antibiotic of choice. Drugs should be continued for several weeks. If empyema develops, drainage must be established. The prognosis varies with the underlying condition of the patient and the drug susceptibility of the organism.

Legionella Pneumonia

The eponym legionnaires' disease has been given to a serious pneumonia that afflicted people attending the American Legion Convention in Philadelphia in 1976. Other outbreaks have been diagnosed respectively at least since 1965, and sporadic infections have occurred at least since 1947 in many places.

Legionella pneumophila is a poorly staining gram-negative bacterium that grows slowly on special media (eg, charcoal-yeast extract) at 35 °C. There are at least 8 species of *Legionella*, some with multiple serotypes. These organisms can be recovered in human disease from sputum, bronchial washings, pleural fluid, lung biopsies, or blood. *Legionella* species occur in the environment and are acquired by humans from aerosols, dust from air-conditioning systems, water, or soil. The infection is not usually communicable from patient to contacts. Asymptomatic infection is common at all ages, whereas symptomatic infection is most often an opportunistic pneumonia in immunocompromised individuals.

Asymptomatic infection is evident only by a rise in specific antibodies. Symptomatic infection is observed mainly in elderly persons, smokers, and patients undergoing hemodialysis or renal transplant.

The incubation period is estimated to be 2-10 days. Initial symptoms are malaise, diffuse myalgias, and headache, followed in 12-48 hours by high, non-remittent fever and chills. Nausea, vomiting, and diarrhea are frequent early in the illness. On the third day a dry cough begins that is nonproductive or produces scanty mucoid, sometimes blood-streaked sputum. Dyspnea and hypoxia become marked as signs of consolidation develop. Pleuritic chest pain occurs in one-third of patients. Severe confusion or delirium may occur.

There is leukocytosis with a shift to the left, hyponatremia, abnormal liver function tests, and, occasionally, microscopic hematuria. Chest x-rays reveal patchy, often multilobar pulmonary consolidation, and, occasionally, small pleural effusions. The illness usually worsens for 4-7 days before improvement begins in those who recover. During severe outbreaks, the mortality rate has been 10% in those with manifest disease. Death is attributed to respiratory or renal failure or shock, with disseminated intravascular coagulation.

The diagnosis is based on a clinical picture compatible with the specific features of the disease and on

negative results of bacteriologic laboratory tests for other pneumonias. The organism can be identified by immunofluorescence in cultures, lung biopsy, and, rarely, sputum specimens. A retrospective diagnosis is based on a significant rise in specific serum antibodies detected by immunofluorescence.

The treatment of choice is erythromycin, 0.5-1 g every 6 hours intravenously or orally for 2-3 weeks. This usually results in improvement in 2-3 days. Rifampin, 10-20 mg/kg/d, has been suggested for patients who fail to respond to erythromycin. Assisted ventilation and management of shock are essential.

Pneumocystis carinii Pneumonia

This parasitic infection occurs in debilitated children or immunodeficient adults. It has been a prominent opportunistic infection in AIDS patients. The diagnosis is made by lung biopsy and the demonstration of typical cysts of *P. carinii* in impression smears of lung tissue stained with methenamine-silver. Early treatment with sulfamethoxazole-trimethoprim can cure the pneumonia. The same drug has been effective in prophylaxis during immunosuppression. An alternative, more toxic drug is pentamidine isethionate.

"MIXED" BACTERIAL PNEUMONIAS (Hypostatic Pneumonia, "Terminal" Pneumonia, Bronchopneumonia)

Essentials of Diagnosis

- Variable onset of fever, cough, dyspnea, expectoration.
- Symptoms and signs often masked by primary (debilitating) disease.
- Greenish-yellow sputum (purulent) with mixed flora.
- Leukocytosis (often absent in aged and debilitated patients).
- Patchy infiltration on chest x-ray.

General Considerations

Mixed bacterial pneumonias include those in which culture and smear reveal several organisms, not one of which can clearly be identified as the causative agent. These pneumonias usually appear as complications of anesthesia, surgery, aspiration, trauma, or various chronic illnesses (cardiac failure, advanced carcinoma, uremia). They are common complications of chronic pulmonary diseases such as bronchiectasis and emphysema. Old people are most commonly affected ("terminal" pneumonia). Patients treated with intermittent positive pressure breathing apparatus or immunosuppressive drugs may develop pneumonia caused by gram-negative rods.

The following findings in a debilitated, chronically ill, or aged person suggest a complicating pneumonia: (1) worsening of cough, dyspnea, cyanosis; (2) low-grade, irregular fever; (3) purulent sputum; and (4) patchy basal densities on a chest film (in addition to previously noted densities caused by a primary underlying

disease, if any), sometimes with local necrosis and cavitation.

Clinical Findings

A. Symptoms and Signs: The onset is usually insidious, with low-grade fever, cough, expectoration, and dyspnea that may become marked and lead to cyanosis. Physical findings are extremely variable and may not be impressive against a background of cardiac or pulmonary disease. The signs listed under Other Bacterial Pneumonias may also be present.

B. Laboratory Findings: The appearance of a greenish or yellowish (purulent) sputum should suggest a complicating pneumonia. Smears and cultures reveal a mixed flora, often including anaerobes. Predominant types should be noted. Leukocytosis is often absent in the aged and debilitated patient presenting with a mixed infection.

C. X-Ray Findings: X-ray (Picture 3) shows patchy, irregular infiltrations, most commonly posterior and basal (in bedridden patients). Abscess formation may be observed. Careful interpretation will avoid confusion with shadows due to preexisting heart or lung disease.

Differential Diagnosis

Mixed bacterial pneumonias must be differentiated from tuberculosis, carcinoma, and other specific mycotic, bacterial, and viral pulmonary infections (to which they may be secondary).

Treatment

Clear the airway and correct hypoxia. Unless a probably significant etiologic agent can be identified, give one of the new cephalosporins (eg, cefotaxime, 12 g/d intravenously) as initial therapy. This will be modified according to clinical and laboratory results.

Prognosis

The prognosis depends upon the nature and severity of the underlying pulmonary disease and varies with the predominating organism.

ASPIRATION PNEUMONIA

Aspiration pneumonia is an especially severe type of pneumonia, often with a high mortality rate. It results from the aspiration of gastric contents in addition to aspiration of upper respiratory flora in secretions. Important predisposing factors include impairment of the swallowing mechanism (eg, esophageal disease), inadequate cough reflex (eg, anesthesia, postoperative state, central nervous system disease, drug abuse), and impaired gastric emptying (eg, pyloric obstruction). Pulmonary injury is due in large part to the low pH (< 2.5) of gastric secretions.

Scattered areas of pulmonary edema and bronchospasm occur, and the x-ray appearance (pictures 4-5) may

be confused with that of pulmonary emboli, atelectasis, bronchopneumonia, and congestive heart failure.

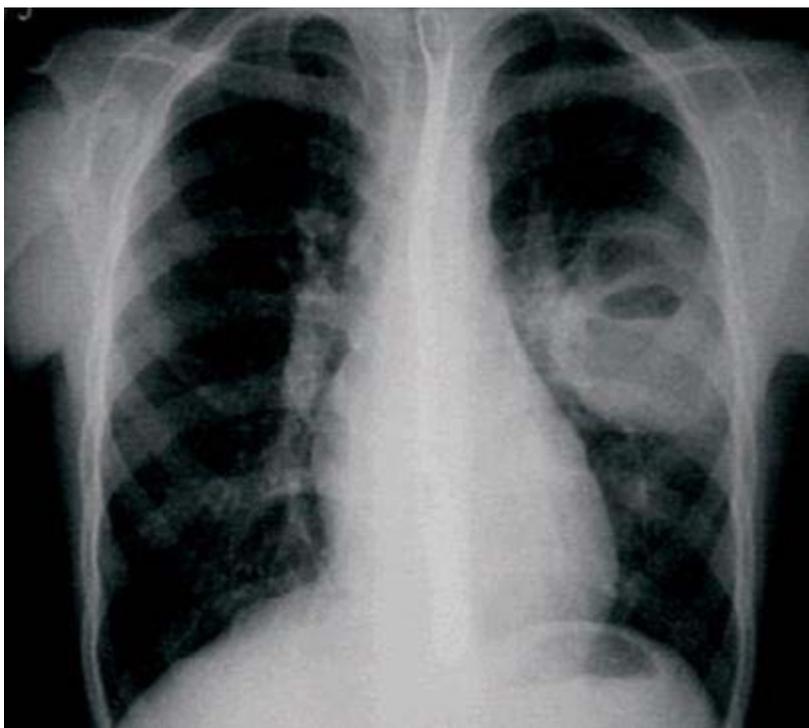

Removal of aspirated material by catheter suction or bronchoscopy may be attempted, but this usually fails to remove all aspirate completely. Corticosteroids (eg, prednisone, 100 mg orally on the first or second day) may reduce the intensity of the inflammatory reaction to acidic gastric secretion, but the value of corticosteroids in the treatment of aspiration pneumonia is not proved, and they increase the risk of superinfection. Some aspiration pneumonias have no bacterial component, but in many others a mixed bacterial flora is involved. Antimicrobial drugs directed against the latter (eg, penicillin G plus an aminoglycoside or the best available cephalosporin) are sometimes administered without waiting for evidence of progressive pulmonary infection. In doing so, however, there is a risk of favoring the development of resistant microorganisms. Therefore, administration of antimicrobials should not continue without laboratory and clinical evidence of microbial infection. Assisted ventilation and supplementary oxygen are beneficial.

The cancer of the central location due to the obturation of bronchus results in atelectasis of a segment or lobe of lungs, with probable further abscessing. For the differentiation used tomography (reveals the obturation of bronchus by tumour, lesion of central lymph nodes), cytological examination of sputum and bronchial outwashes. The determinant role belongs to fibrobronchoscopy with a biopsy and verification of the diagnosis.

Central lung carcinoma

The peripheral cancer of lungs with destruction on tomograms is characterized by cavity with irregular inner surface, which external outline connects with root of the lung because of lymphatic metastatic spreading. The central lymph nodes frequently enlarged. The diagnosis is improved by results of transthoracic puncture or catheterizing biopsy with cytological investigation, fibrobronchoscopy. If it is impossible to confirm the diagnosis the thoracotomy is indicated.

The peripheral cancer of lungs

The tubercular cavern is mainly located in the upper lobes of lungs, roentgenologically revealed on the background of characteristic changes in adjacent pulmonary tissue (calcification, dissemination), sometimes detected a draining bronchus. In the sputum mycobacteria of tuberculosis are frequently found.

The tubercular cavern

The suppurative cyst of lungs differs by a gradual onset, slow course of the suppuration, less expressed intoxication. Roentgenologically its cavity has the oval or rounded shape with a thin sheath and regular contour. Perifocal infiltration is not characteristic.

Tactics and choice of treatment

The tactics in acute pulmonary destruction should be mainly conservative.

1. The adequate antibacterial, antiinflammatory therapy consists of intravenous introduction of antibiotics of a wide spectrum activity.

ANTIBIOTICS IN LUNG ABSCESS

Anaerobic organisms[3]

- First choice - Clindamycin (Cleocin 3)
- Alternative - Penicillin
- Oral therapy - Clindamycin, metronidazole (Flagyl), amoxicillin (Amoxil)

Gram-negative organisms

- First choices - Cephalosporins, aminoglycosides, quinolones
- Alternatives - Penicillins and cephalexin (Biocef)
- Oral therapy - Trimethoprim/sulfamethoxazole (Septra)

Pseudomonal organisms: First choices include aminoglycosides, quinolones, and cephalosporin.

- Gram-positive organisms
- First choices - Oxacillin (Bactocill), clindamycin, cephalexin, nafcillin (Nafcil), and amoxicillin
- Alternatives - Cefuroxime (Ceftin) and clindamycin
- Oral therapy - Vancomycin (Lyphocin)

Nocardial organisms: First choices include trimethoprim/sulfamethoxazole and tetracycline (Sumycin).

With the purpose of maximal concentration of drugs in the pathological focus applied:

- Injection of antibiotics in the vessels of a pulmonary circulation by means of catheterization of central veins, pulmonary artery;
- Introduction of medicinal agents into respiratory tracts (in the second stage) – through the endotracheal microirrigator, nasogastric tube, during bronchoscopies, endoscopic catheterization of the abscess cavity through the draining bronchus, in aerosolic inhalations. The composition of medical admixtures includes: antibiotics, antiseptics (10 % dimexid, dioxydin, microcid etc.), enzymes;

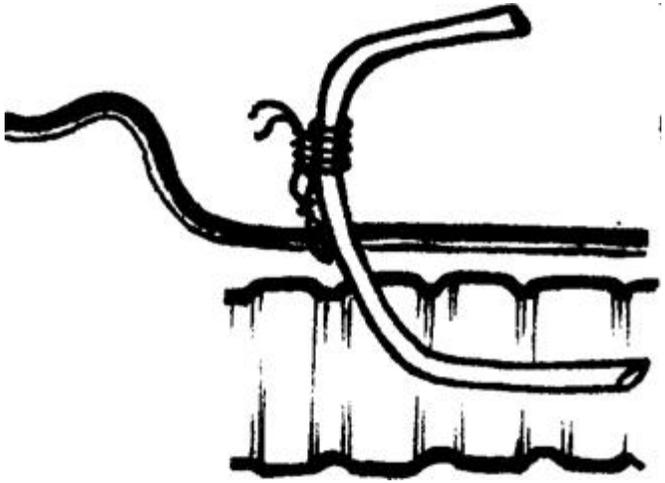

The steps of microtraheostomia:

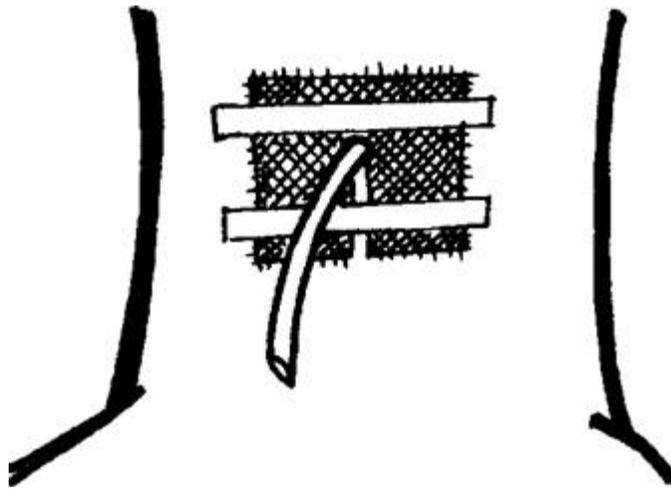

Tracheocentesis after local anesthesia

Insertion of the conductor

Incertion of the irrigator along the conductor

Skin wound

- Transcutaneous in the focus of destruction by means of puncture or draining with the usage of physical antiseptics (US, UVR, laser).
- Intrapleural;
- By means of electrophoresis.

2. Evacuation of purulent content of the cavities:

- In natural way by an active sanitation of tracheobronchial tree using repeated fibrobronchoscopies, aspirations through the endobronchial catheter, installations of medical agents through the microtracheostomy, aerosolic inhalations;
- Transthoracically by means of repeated punctures or external draining of peripheral cavities.

3. Detoxycation therapy (intra- and extracorporal).

4. Immune correction (under the control of immunogram):

- Active – staphylococcal anatoxin according to the plan;
- Passive – specific gamma-globulins, hyperimmune plasma;
- Non-specific (pyrimidine and purine derivatives, drugs of a thymus gland, splenin, levamisol,).

5. Homeostatic correction (oxygenotherapy, correction of anemia, hypoproteinemia, acidosis, microcirculatory disturbance).

6. Desensitizing, antiinflammatory therapy, regulation of activity of proteases: antihistamine, nonsteroid antiinflammatory agents, inhibitors of proteases, antioxidants.

7. Correction of dysfunction of the vital organs and systems, prevention of complications, symptomatic therapy.

Indications for operative management in acute destructive processes of lungs:

- Pulmonary bleeding of II- III degree;
- Progression of the process on the background of active and appropriate therapy;
- Tense pyopneumothorax, which is failed to liquidate by the draining of pleural space;
- Impossibility to rule out the suspicion on a malignant tumour.

Contraindications: decompensation of the vital functions and systems in the terminal stage, bilateral purulent destruction of lungs, concomitant incurable malignant tumours.

Several important factors must be considered prior to undertaking surgery. Because of the high risk of spillage of the abscess into the contralateral lung, it is almost essential that a double-lumen tube be used to protect the airway. If this is not available, surgery poses a very high risk of abscess in the other lung and a risk of ARDS. In such cases, postponing the surgery is a wise decision. Another, less-satisfactory method to deal with this problem includes positioning the patient in the prone position. The surgeon must be skilled in resecting the abscess and in rapid clamping of the bronchus to prevent spillage into the trachea. These factors are extremely important when dealing with the surgical aspects of treating a lung abscess. If doubt persists, postponing the surgery is best.

Surgical treatment is now rarely necessary and is almost never the initial choice in the treatment of lung abscesses. In current practice, fewer than 15% of patients need surgical intervention for the unchecked disease and for complications that occur in both the acute and chronic stages of the disease.

Surgical management is reserved for specific indications such as little or no response to medical treatment, inability to eliminate a carcinoma as a cause, critical hemoptysis, and complications of lung abscess (eg, empyema, bronchopleural fistula). In addition, if after 4-6 weeks of medical treatment a notable residual cavity remains and the patient is symptomatic, surgical resection is advocated.

The results of surgery are difficult to assess because of the varying patient population and the tremendous increase in illicit drug abuse, alcoholism, AIDS, and infections by

gram-negative and opportunistic organisms. These factors have increased the incidence of lung abscess and the associated morbidity.

A great deal of caution is needed during anesthesia when patients with lung abscess undergo surgery because spillage of the abscess material into the uninvolved lung can occur. Therefore, a double-lumen endotracheal tube is used in all cases.

A study by Nagasawa et al has shown that thoracoscopic surgery can lead to effective drainage of pediatric lung abscess without major complications. In addition, other benefits of thoracoscopy include rapid recovery, less pain, and minimal morbidity.

Operational incisions – anterolateral, lateral and posterolateral thoracotomy. The operation suggests segmental, polysegmental resection, lobectomy, bilobectomy combined intervention (with the decortication, pleurectomy).

Lateral access

Anterior access

Posterior access

The patients with chronic abscesses should be undergone the operative treatment after complete liquidation of exacerbation.

In a pulmonary gangrene the stabilization of the process on the background of active conservative treatment allows in future to apply conservative tactics up to recovery or making optimal conditions for operation (liquidation of intoxication, aggressive panbronchitis, diffuse infiltration of the parenchyma, pleural complications). The headlong progression of the gangrene during first days, despite the active correction,

occurrence of pulmonary bleeding requires urgent performance of operative management. Volume of the operation – pneumonectomy, bilobectomy, lobectomy.

PLEURAL EMPYEMA

The pleural empyema is a purulent inflammation of its visceral and parietal membranes, which is associated with accumulation of pus in a pleural space.

Etiology and pathogenesis

The causes of occurrence of acute pleural empyema are inflammatory, or purulent and destructive processes of lungs, abscesses of abdominal cavity (secondary pleural empyema), open and closed damages of chest, and also, in some cases, operative approaches on thoracic organs (primary pleural empyema).

A secondary pleural empyema occurs in 88 % of the patients. Thus develops fibrinous, exsudative, and then purulent pleurisy.

In case of pulmonary gangrene, purulent mediastinitis, subphrenic abscess the stage of exsudative pleurisy extremely short. The progression of the process results in transferring of focal pleural empyema into wide-spread.

Pathology

Macroscopically pleura is thickened, covered by pus with punctate hemorrhages. Microscopically it is diffusely ooazed with neutrophils. In cases, when the empyema overcome into chronic course, the pleura deposits the calcareous salts, thick pus encapsulated, sometimes with the development of fistula.

Classification

I. According to the etiological factor:

1. Specific.
2. Nonspecific.

II. According to the pathogenic factor:

1. Primary.
2. Secondary.

III. According to the clinical course:

1. Acute.
2. Chronic.

IV. According to extension of the process:

1. Focal.
2. Wide-spread.

V. According to the presence of lung destruction:

1. Empyema with destruction of pulmonary tissue.
2. Empyema without destruction of pulmonary tissue.
3. Pyopneumothorax.

VI. According to communication with environment:

1. Closed pleural empyema;
2. Open pleural empyema:
 - bronchopleural fistula;
 - thoracopleural fistula;
 - thoracopleurobronchial fistula;
 - cribrate lung.

Symptomatology and clinical course

The clinic of an acute pleural empyema depends on extension of the process, reactivity of organism and presence of complications.

The **pain** is the sign, which denote the involvement of pleural membranes in the process. Its intensity increases depending on depth of respiration and body position.

The **dyspnea** arises from accumulation of a purulent content in a pleural space and exception of particular volume of a pulmonary tissue from respiration. It's in direct ratio to amount of exudation in a pleural space.

The cough is manifestation of inflammation or purulent and destructive process in a pulmonary tissue.

Fever to 39-40°C, headache, sleeplessness, general malaise, and anorexia – all these are manifestations of intoxication.

The forced patient's position and restriction of breathing should be considered as outcomes of a pain syndrome. The extension of pleural empyema causes the swelling of thoracic wall, smoothing of intercostal spaces.

By palpation – diminished vocal fremitus on the part of lesion.

The data of percussion and auscultation depend on extension of the process and amount of pus in a pleural space. At percussion over the exudate it is possible to reveal short sound with oblique upper contour. Above the exudate – tympanic sound resulting from consolidation of pulmonary tissue. By auscultation – diminished or absent sound in a great amount of exudate.

The predominant roentgenological sign of a focal or wide-spread empyema – the presence of exudate. In localized acute pleural empyema observed a local intensive homogeneous shadow. Roentgenologically according to localization distinguished such types of a focal empyema:

- 1) apical;
- 2) paramediastinal;
- 3) parietal;
- 4) interlobar;
- 5) epiphrenic.

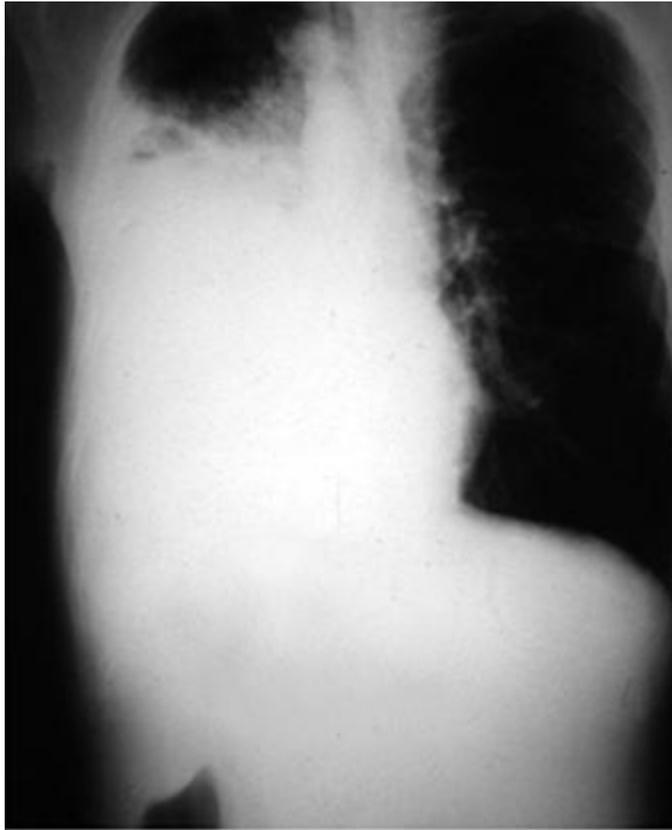

The wide-spread pleural empyema manifests by intensive homogeneous shadow in a basal parts with oblique upper contour (Damuaso' line). The diaphragmatic dome is failed to observe. The more pus contents in a pleural space, the higher the upper measure of exudate.

Left-side pleural empyema

Pleural empyema

Pleural empyema

Pleural empyema

Pleural empyema

Variants of clinical course and complications

The clinic of a focal pleural empyema depends on the site of the process. The apical empyema, due to involvement in the process of a vascular-nervous fascicle, manifests by intensive pain. The soft tissues of supraclavicular region are swelled. The percussion and auscultation has no information.

The pain syndrome in parietal (paracostal) empyema is more expressed. Thoracic excursion is restricted. The diminishing of respiratory sound can be obtained over the exudate.

The chief complaint in paramediastinal empyema is the heart pain. The location of the process in the upper mediastinum can cause the superior vena cava syndrome. The physical findings are vague.

In case of the basal (epiphrenic) empyema the patients complain of pain in subcostal area, which increases at respiration and irradiates in supraclavicular region. In some cases the pain irradiates in epigastric region. The palpation of intercostal spaces and hypochondrium is painful.

The clinical course of postoperative empyema depends on the character of operative approach (marginal resection of lung, lobectomy, pneumonectomy, operation on esophagus) and infection of the pleural space.

The clinical manifestations of posttraumatic empyema depend on the size of damage of the chest, lungs, mediastinal organs and complications (suppuration, hemothorax).

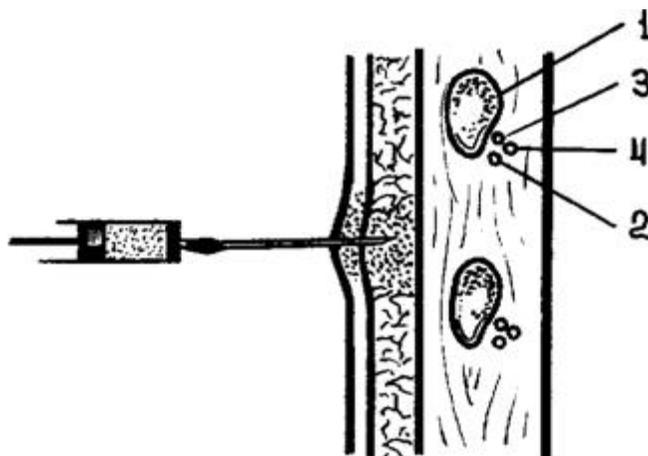

The involvement in the purulent process of a pulmonary tissue in acute empyema results in its fusion of membranes with formation of a bronchial or thoracopleural fistula (discharge of abscess through thoracic wall).

The inappropriate elimination of empyema results in chronic course, cribrate lung and pleurogenic cirrhosis of lungs.

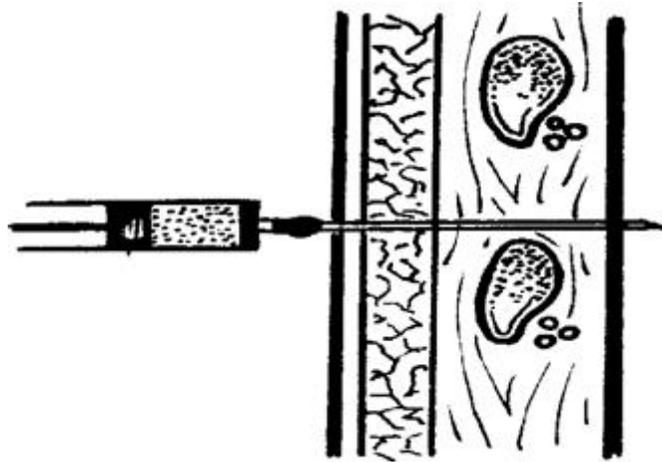

The diagnostic program

1. Complaints and history of the disease.
2. Physical findings.
3. Data of chest X-ray (in two planes, if necessary – laterography).
4. Pleural puncture.
5. The microbiological investigation of the exudate for its sensitivity to antibiotics.
6. General blood and urine analyses.
7. Biochemical blood analysis.
8. Pleurography (in transferring of the process into chronic form).

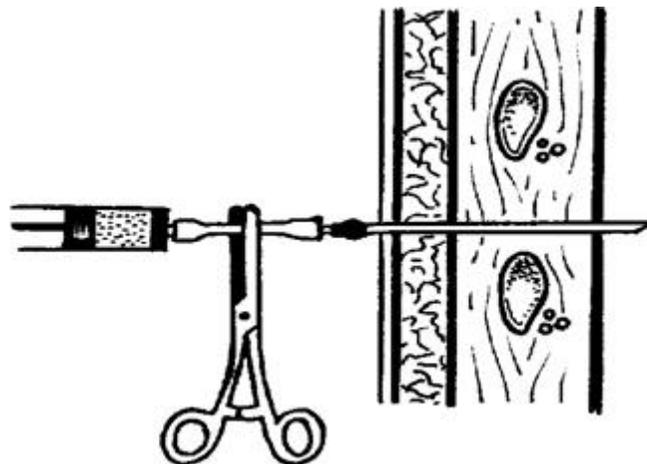

Pleural puncture:

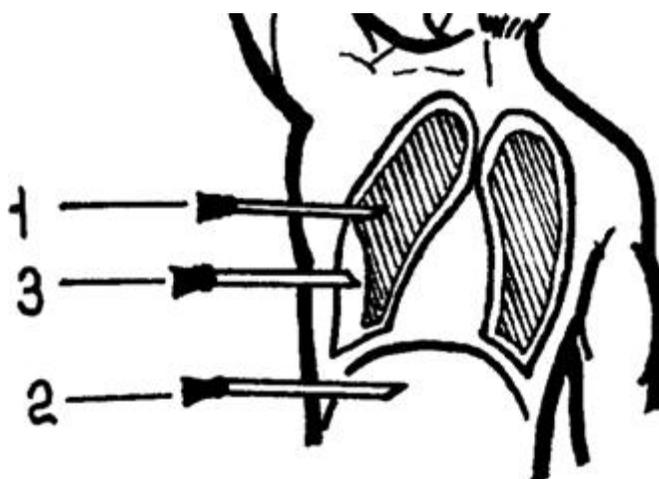

Local anesthesia

Thoracentesis

Aspiration of the fluid

Localization of the needle:

- 1 the needle damaged the lung
- 2 the needle damaged the diaphragm
- 3 the needle located in pleural sinus

Differential diagnostics

Pleuropneumonia complicated with exsudative pleurisy, in some cases resembles acute pleural empyema: a chest pain, fever, dyspnea, cough, and general weakness. The chest roentgenogram reveals hydrothorax (exsudative pleurisy, pleural empyema, hemothorax). The chief diagnostic method for differentiation is the thoracentesis. The presence of a serous (lucent, faint-yellow) exudate testifies about the pleuropneumonia, complicated with pleural effusion, and cloudy, foul-smelling exudate of white or greenish color – about acute empyema.

The major difficulties in differential diagnostics cause the limited forms of empyema.

The **Pancoast cancer** clinically and roentgenologically in most cases has almost the similar course to apical form of empyema. The transthoracic biopsy permits to confirm the diagnosis.

The **acute cholecystitis** is necessary to differentiate with the epiphrenic empyema. The pain in the right hypochondrium, fever, phrenic symptom are common for both diseases. However the objective findings, X-radiography of chest and the thoracentesis allow to differentiate these pathological processes.

The **tumour of anterior mediastinum** complicated by superior vena cava syndrome is necessary to differentiate with paramediastinal empyema. Nevertheless the body temperature in such patients, as a rule, normal. The upper cavography is possible to find out the shift of cava vein and its irregular contours (filling defect) due to growth of the mediastinal tumour.

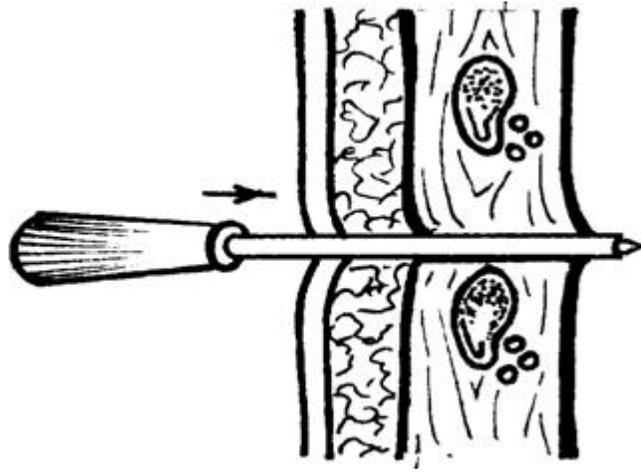

There are some difficulties in differential diagnostics of empyema with a **posttraumatic diaphragmatic hernia**. Such X-ray findings as deformation of diaphragm, additional shadows with a liquid level, intestinal loop suggest a diaphragmatic hernia. A laterography and contrast study of gastrointestinal tract is basic in differential diagnostics of this disease.

The atelectasis of a segment, and lobe of lung in some cases can cause misdiagnostics. Except X-ray chest examination (in two planes and tomography), these situations require necessity of diagnostic bronchoscopy, which reveals the cause of bronchial obturation (foreign body, endobronchial cancer etc.).

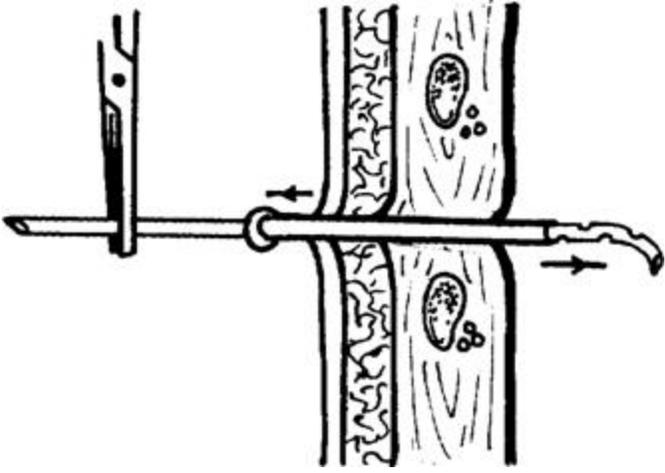

Tactics and choice of treatment

The presence of pus in a pleural space is the indication for its elimination. In the place of performed diagnostic thoracentesis carried out the draining of empyema's cavity, its sanation by means of antiseptic solutions. In a focal empyema the aspiration of pus is performed by thoracentesis and only in its inefficiency carried out a draining of pleural space.

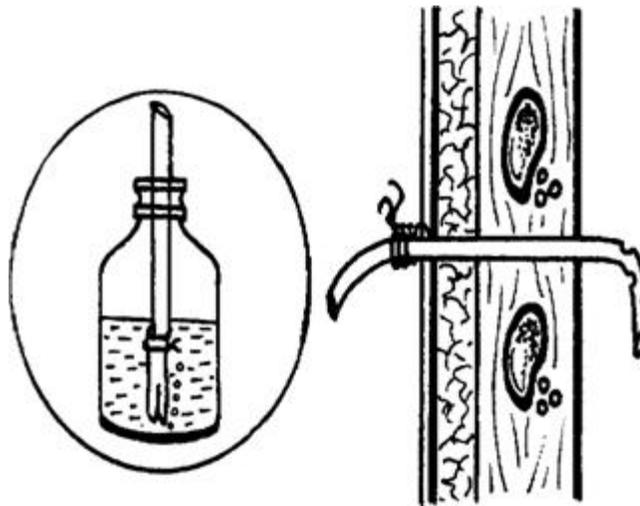

Pleural drainage:

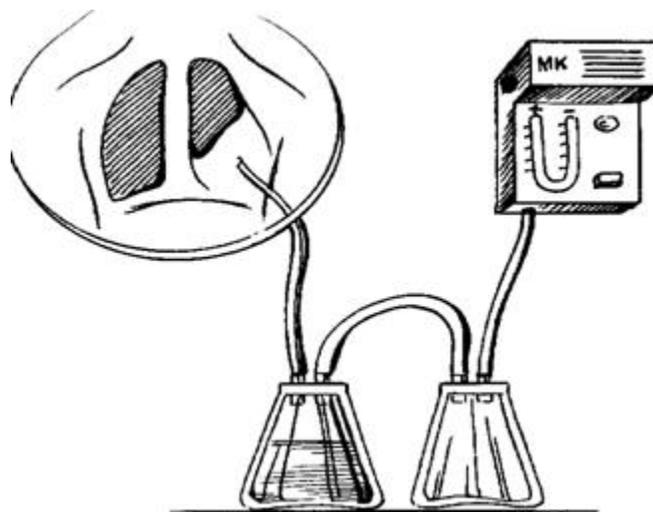

Trocar insertion

Incerption of drainage tube

Passive drainage by Bulau

Active aspiration

Intensive antibacterial and antiinflammatory therapy should be immediately instituted. For general improving used detoxication therapy (infusion of saline solutions, hemotransfusion, transfusion of proteins, solutions of dextran, haemodes, forced diuresis, hemosorption if necessary), therapy for rising up of immunological resistance of the organism.

During the empyema's sanitation decreases the amount of pus which discharges out through the drainage. The optimal variant of such course is the liquidation of empyema's cavity, then the drainage must be removed.

Transferring of the process into the chronic form (10-12 weeks) results in formation of a residual empyema's cavity, which is possible is to reveal by means of pleurography – introduction through the drainage of water-soluble contrast with the further X-radiography in 2 planes.

Operative approach is applied when the process has transferred into the chronic form, that is in case of residual empyema's cavity. Volume of the operation – pleurectomy, decortication of lung.

In some cases, when a bronchial fistula and great empyema's cavity has been formed, there is the necessity of performance of resection of lung and corrective thoracoplasty.

LUNG CYSTS

The cysts of lungs are the thin-walled cavitory formations, filled with air or liquid contents.

Inherent and acquired cyst are distinguished.

Etiology and pathogenesis

Inherent cysts arise from the abnormalities of the development of lungs under influence of the multiple chemical, physical, biological factors. Whether they can develop from a bronchial tree (bronchial) or from alveolar tissue (alveolar). Their occurrence resulting from the delay of the development of peripheral parts of bronchus with their expansion or agenesis of alveoli with dilatation of terminal bronchioles. Congenital cysts at first develop and grow as secretory formations. After communication with bronchus they finally form as air or hydroair cavities.

The acquired cysts represent fibrous cavities, which remain after abscesses, tubercular caverns, echinococci, posttraumatic intrapulmonary hematomas. The degenerative changes in the wall of bronchus with obliteration of its lumen by a cloggy secret owing to repeated inflammatory processes result in occurrence of acquired retentional cysts.

Pathology

Congenital cyst can be located in any part of lungs. The walls of bronchogenic cavities contain chaotically disposed elements of bronchus (cartilagous plates, muscle fibers, mucous glands), they are lined from inside by cylindrical or cubic epithelium. Squeezed alveolar cells line the walls of alveolar formations.

The acquired cyst are revealed in places of localization of previous diseases,. Their walls mainly consist of connective tissue. Epithelization is possible due to transferring of the epithelium from a draining bronchus at long existence.

The cysts could be uni- or multichamber, closed and open (depending on the presence of communication with bronchus).

Classification

According to parentage:

- congenital;
- acquired.

According to displacement:

- single, multiple;
- unilateral, bilateral.

Complications:

- Suppuration;
- Appearance of the valvular mechanism;
- Bleeding;
- Discharge into a pleural space (pneumothorax, pyopneumothorax, pleural empyema);
- Malignancy.

Symptomatology and clinical course

Clinical manifestations of uncomplicated pulmonary cysts are vague. Sometimes patients complain of a chest pain, periodic cough, and inflammatory diseases of respiratory tract in history. In children the signs are much expressed, the dyspnea associates with the compression of airways.

In great, superficially disposed cysts revealed delayed respiratory movements on affected side during breathing.

By palpation - weakened vocal fremitus.

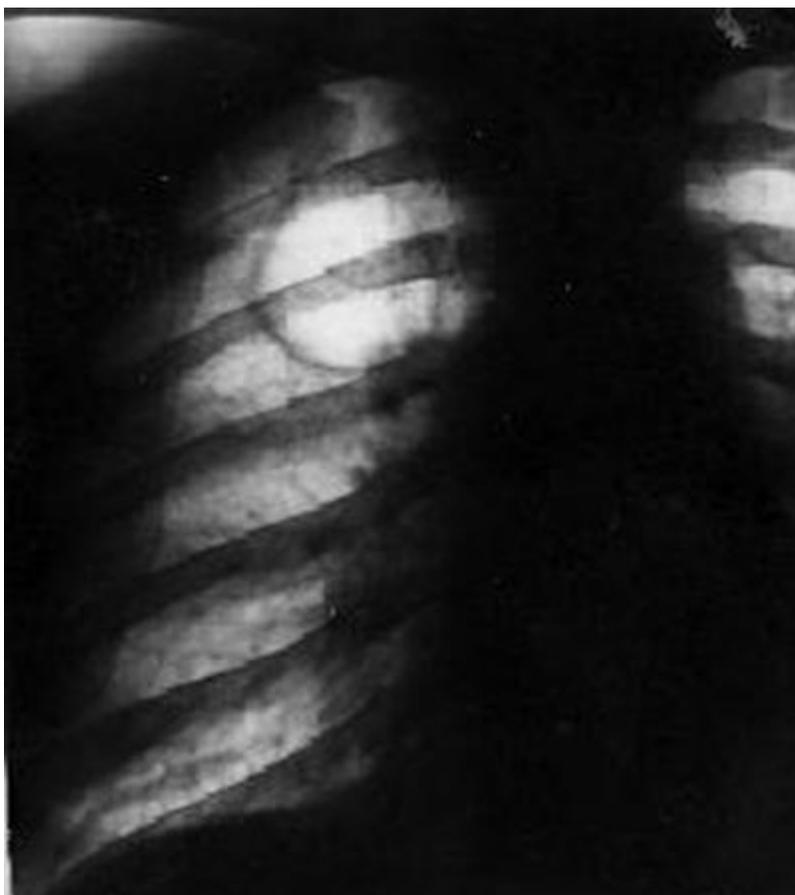

By percussion - short or bandbox sound, depending on contents.

By auscultation - weakened respiration, over the huge open cavities – amphoric.

At routine chest films the closed congenital cyst forms a homogeneous shadow of the spherical or oval shape of average intensity with rather regular edge on the background of an intact pulmonary tissue. During roentgenoscopy sometimes observed the change of its shape depending on the phase of breathing – elongation in inspiration (Escudero's syndrome). The character of the shadow is better to study on tomograms.

Acquired retentional cyst is roentgenologically shown by a shadow of irregular shape (piriform, spindle-shaped etc.), that displays the shape of the distended bronchus. The adjacent tissue, as a rule, changed due to

bronchiectases, pneumosclerosis, etc.

Cyst of the right lung

Open cysts are observed as thin-walled, good defined cavities of annular or oval shape.

On bronchograms congenital cysts are observed hypoplasia of segmental or lobar bronchus, lack of bronchial bifurcations, which tends to bone. Sometimes observed bronchiectases in the neighboring parts of lungs. A cystic cavity is infrequently defined.

The angiopulmonography reveals deformation of vascular branches, which circumflex the cyst.

Variants of clinical course and complications

The **suppuration** of the closed cysts resembles the development of a lung abscess with lesser expression of

signs of intoxication (protective role of epithelial wall).

Infection of the open cysts is characterized by a gradual long course, moderate manifestation of suppuration and late intoxication.

The tension (valvular) cysts arise more often in children. They are characterized by severe respiratory and hemodynamic disturbances, up to terminal, owing to inflexion of venous trunks, shift of mediastinum and compression of lungs. The predominant signs are increased dyspnea, cyanosis, chest pain, respiratory lag on affected side, auscultatory – absence or weakening of respiration, bandbox percussion sound over the cavity at mediastinal shift to the opposite side of the chest.

Pleural complications of pulmonary cysts, and also **bleeding** described in the relevant parts.

The malignant degeneration of pulmonary cysts occurs very rarely.

The diagnostic program

1. Complaints and history of the disease.
2. Physical methods of examination.
3. Routine chest film in two planes.
4. Lung tomography.
5. Bronchography.
6. Angiopulmonography.
7. General blood and urine analyses.

Differential diagnostics

The abscess of lungs, in contrast with a suppurative cyst, is characterized by prompt course, expressed purulent intoxication, roentgenologically its wall is irregular, with proper considerable perifocal infiltration.

The cancer with destruction differs by a thick wall with a tuberos inner surface, phenomena of lymphangitis in adjacent tissue. The determinant value has endoscopic examination or puncture with a biopsy and following morphological investigation.

The tubercular cavern displaced in the upper lobes, in adjacent tissue revealed fibrosis, petrifications,

dissemination, peribronchial lymphadenitis. In the sputum – mycobacterium of tuberculosis.

Opposite to cyst, in termed diseases, the circumflex deformation of vascular branches never observed at angiopulmonography.

The considerable difficulties can arise at differentiation of the closed congenital cysts.

The **tuberculoma** differs from them by characteristic localization. At X-ray examination the heterogeneity of the shadow with calcifications, early excentric destruction, "tubercular" background is observed.

The **benign tumours** sometimes possible to differentiate only after the results of cytological investigation of punctate or after operation.

The **echinococci cysts** on tomogram can have a double contour of chitinous and fibrous sheaths. In blood analyses observed eosinophilia. The final decision is taken out after carrying out immunological (indirect microagglutination test) allergic (Cacconi's reaction) tests.

Huge cysts, in contrast with open air cysts, are characterized by a subpleural location.

The diagnostic doubts at suspicion on a **diaphragmatic hernia** are solved by radiopaque examination of a gastrointestinal tract.

The **acquired cysts** differ from congenital by roentgenological signs of the lesion of surrounding tissues (pneumofibrosis, deforming bronchitis, secondary bronchiectases, and calcifications). Postpneumonic cavities are of irregular shape, with grooves and pockets, their walls different thick. During bronchography they filled through some small bronchi. Sometimes the verification is possible only after postoperative morphological investigation.

Tactics and choice of treatment

The pulmonary cysts require the surgical treatment. In case of complications the indication for operation becomes absolute. Contraindications: the severe respiratory disturbance, concomitant malignant nonresectable tumors, vital organs dysfunction in the stage of permanent decompensation, elderly age of the patients.

The volume of the operation: if the adjacent pulmonary tissue is intact – cystectomy, otherwise – segmental or wedged resection, lobectomy.

The conservative therapy is applied in suppuration of cysts with the purpose of preoperative preparation. It is the similar, which applied for abscesses of lungs.

SPONTANEOUS PNEUMOTHORAX

Spontaneous pneumothorax is the entry of air in a pleural space with the further lung collapse, which not associated with traumatic damage of chest or pulmonary tissue.

Etiology and pathogenesis

As a result of spontaneous disrupture of lung blebs and subpleural air cysts occurs the damage of pleural visceral membrane. It causes entry of air in pleural space. Owing to its leakage the elastic pulmonary tissue collapses. The degree of the collapse of lung depends on amount of air, that has penetrated a pleural space.

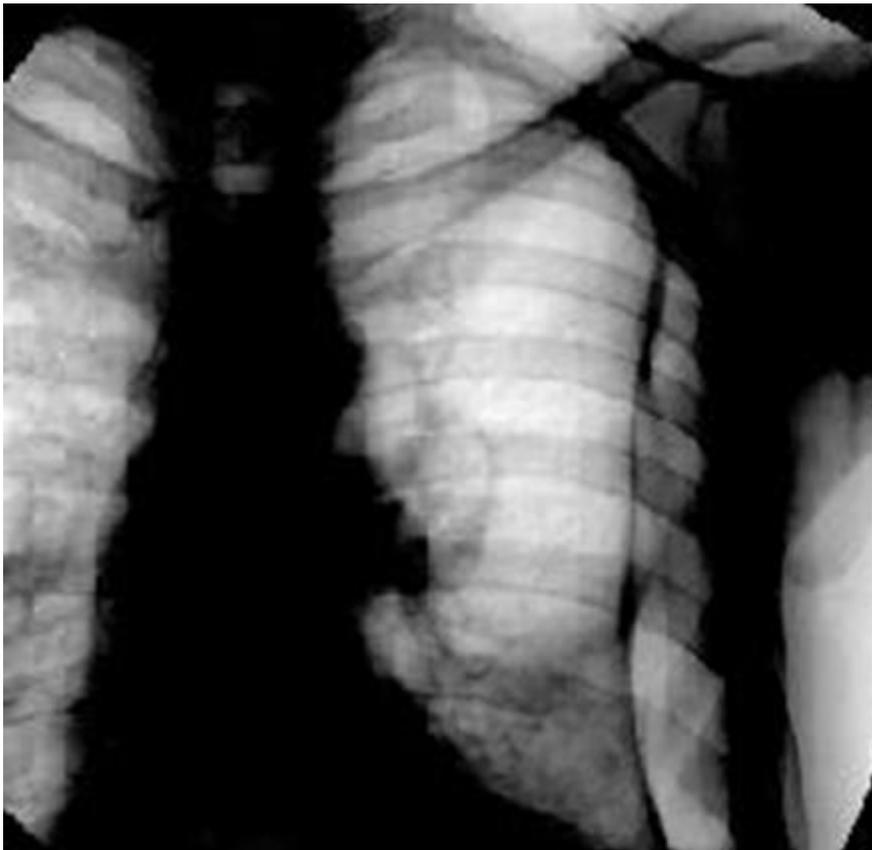

Pathology

Morphologically in spontaneous pneumothorax found out a focal bullous emphysema with disrupture of blebs, subpleural air cyst, and also disorders, which have caused disturbances of ventilating ability of bronchi. It can be bronchitis, pneumosclerosis, tuberculosis and fibrous alveolitis.

Classification

The pneumothorax can be:

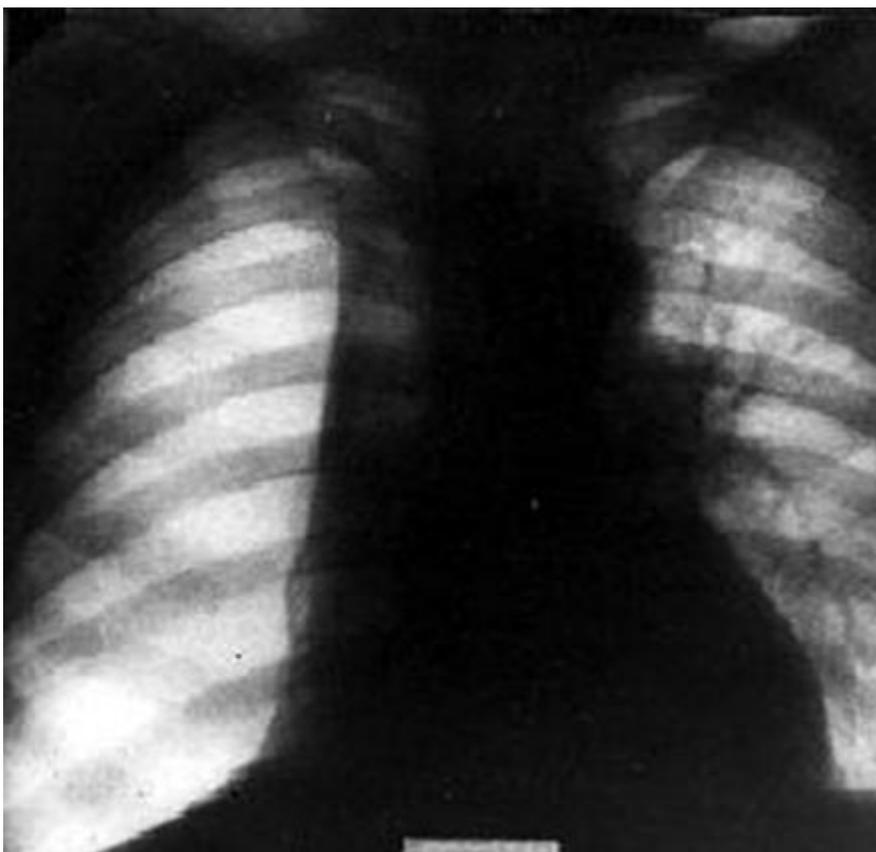

1. Unilateral or bilateral.
2. Partial (lung collapse to 1/3 of its volume).
3. Subtotal (lung collapse to 2/3 of its volume).
4. Total (lung collapse more than 2/3 of its volume).
5. Tension or valvular (complete collapse of lungs and shift of mediastinum in the opposite side).
6. Rigid (neglected pneumothorax with thickened visceral pleura).

Partial spontaneous pneumothorax

Subtotal spontaneous pneumothorax

Total spontaneous pneumothorax

Manifestation and clinical course

The onset of the disease is sudden. A state of the patient and expression of clinical manifestations depends on amount of air, which has entered the pleural space. Usually in normal conditions, and sometimes after physical activity, the patients suddenly feel acute pain on the side of lesion, dyspnea, pain in the heart region and heartbeating. An available also Acrocyanosis or total cyanosis of skin is observed. The circulatory disturbance depends on degree of hypoxia. Intensity of pain and dyspnea gradually decrease, but a dry troublesome cough appears.

Examination of the chest allows to observe expansion of intercostal spaces and restriction of respiratory excursion. By palpation - diminishing of vocal fremitus on the affected side. At percussion a chief sign of pneumothorax is the tympanic sound. Auscultation reveals weakened or sharply weakened breathing sounds. The cardiac tones are muffled, tachycardia.

The diagnosis of a spontaneous pneumothorax is confirmed by X-ray examination. On the plain roentgenogram the air is present in pleural space, and the margins of collapsed lung are found out on its background.

Thoracoscopy in pneumothorax possible to find out subpleural blebs of different sizes (0,5-3 cm), which are mainly disposed on the apex of lung.

Variants of clinical course and complications

The atypical (asymptomatic) spontaneous pneumothorax occurs in 20 % of the patients, and mainly revealed at X-ray examination. In most cases it is the partial pneumothorax.

The expressed pain syndrome and dyspnea, which resulting from collapse of lung, characterize subtotal and total pneumothorax.

The tension spontaneous pneumothorax is the most severe form of pneumothorax. It manifests by sudden onset, progressive increase of dyspnea, expressed cyanosis. The breathing is superficial, rapid, with active participation of auxiliary muscles. Mediastinal shift and flexion of vessels result in disturbance of cardiac activity up to the cardiac arrest, and requires urgent management.

Rigid pneumothorax (rigid lung). The neglected pneumothorax causes fibrinous exsudative pleurisy. On the surface of lung (visceral pleura) commissures are formed, that give no opportunity for lung expansion. The presence of residual pleural cavity and progressive development of a purulent infection result in occurrence of acute pleural empyema. In such cases the patients complain of the fever up to 38-38,5°C, general weakness and increasing of dyspnea. The phenomena of intoxication increase. Thus such patients require the treatment of pleural empyema.

The diagnostic program

1. Complaint and anamnesis of disease.
2. Physical findings.
3. Routine chest film (direct and lateral projection).
4. [Thoracentesis](#)
5. Thoracoscopy.
6. Tomography of lungs.

Differential diagnostics

Pleural effusion. This pathology manifests by more gradual onset. As opposite to pneumothorax, the complaints of chest pain predominate above the complaints of dyspnea. Frequently such patients specify on transferred undercooling.

As well as the spontaneous pneumothorax, the pleural effusion is characterized by diminishing of vocal fremitus, dullness of percussion sound, weakened or absent breathing sounds over the exudate. Nevertheless in the routine roentgenogram in such cases observed a homogeneous intensive shadow of a pleural space with oblique upper contour. The puncture of pleural space enables finally to confirm the diagnosis of pleural effusion.

Intercostal neuralgia. A predominant sign in clinical pattern is acute pain, which intensifies at physical activity, changes of body position and body movements, at deep breathing. The localization of pain coincides with zone of innervation of intercostal nerves.

Examination and chest X-radiography reveals no pathological changes.

Tactics and choice of treatment

Conservative treatment is applied in the patients with a partial pneumothorax. Thus thoracentesis in II intercostal space in the midclavicular line with aspiration of air is performed. The cases of its inefficiency, and also subtotal, total and tension pneumothorax require drainage of a pleural space with active aspiration of air.

The operative management is necessary, if there is no efficiency from active aspiration (in incomplete expansion of lung), recurrent of course of the process, presence of great subpleural blebs and rigid pneumothorax. Volume of operation depends on extension of the process: liquidation of alveolar fistula, wedged resection of lung or lobectomy.

PYOPNEUMOTHORAX

Pyopneumothorax is the discharge of lung abscess of into pleural space, which is accompanied by purulent inflammation of pleural membranes with a collapse of lung.

Etiology and pathogenesis

Peripheral placement of the purulent focus in a pulmonary tissue results in destruction (fusion) of visceral membrane. As a result of, the pus and air penetrate into a pleural space that leads to a purulent inflammation of parietal and visceral membranes of pleura. The disorder of hermeticity of a pleural space results in a lung collapse.

Among other causes of pyopneumothorax are the chest trauma, which results in collapse of lung, infection and purulent inflammation of pleural membranes.

As the basic causes of pyopneumothorax are considered:

- acute abscess of lung;
- gangrenous abscess of lung;
- gangrene of lung;
- suppurative cyst of lung;
- abscessing pneumonia;
- bronchiectatic disease;
- subphrenic abscess, which has discharged into pleural space;
- damage of esophagus;
- mediastinitis;
- chest trauma;
- operation and diagnostic manipulations on chest organs.

Pathology

Morphologically in pyopneumothorax pus and air are present in pleural space. In the lungs subpleural disposed purulent or necrotic foci, which connected with a pleural space through a pleuro-pulmonary fistula. From the outside the zone of disrapture is confined by perifocal inflammation. In the draining bronchus it is possible to see manifestations of deforming, frequently polypous bronchitis.

Classification

I. According to etiological factor:

1. Specific.
2. Nonspecific.

II. According to pathogenic factor:

1. Primary.
2. Secondary.

III. According to clinical course:

1. Asymptomatic form.
2. Mild form.
3. Acute form.

IV. According to extension of the process:

1. Localized pyopneumothorax:

- a) parietal;
- b) apical;
- c) epiphrenic;
- d) paramediastinal;
- e) polychamber.

2. Subtotal pyopneumothorax.

3. Total pyopneumothorax.

4. Tension pyopneumothorax.

Manifestation and clinical course

The clinic of pyopneumothorax depends on the size of the focus of destruction, which influences on degree of lung collapse, and on amount of purulent content in a pleural space.

The pain owing to discharge of the focus of destruction into pleural space often arises suddenly.

The dyspnea occurs as a result of collapse of lung owing to leakage of pus and air into pleural space. Its expression is in direct ratio to lung collapse. Therefore a dyspnea in rest observed in a subtotal and total pyopneumothorax. It sharply amplifies even at minor physical activity. Auxiliary muscles take part in order to force respiration.

The expectoration of sputum with ichorous smell is the outcome of destructive process in a pulmonary tissue. Its amount decreases after discharge of pus into pleural space.

Hectic fever with caused by enlargement of the area of resorption. The patients are adynamic, flaccid. Some of them are unconsciousness.

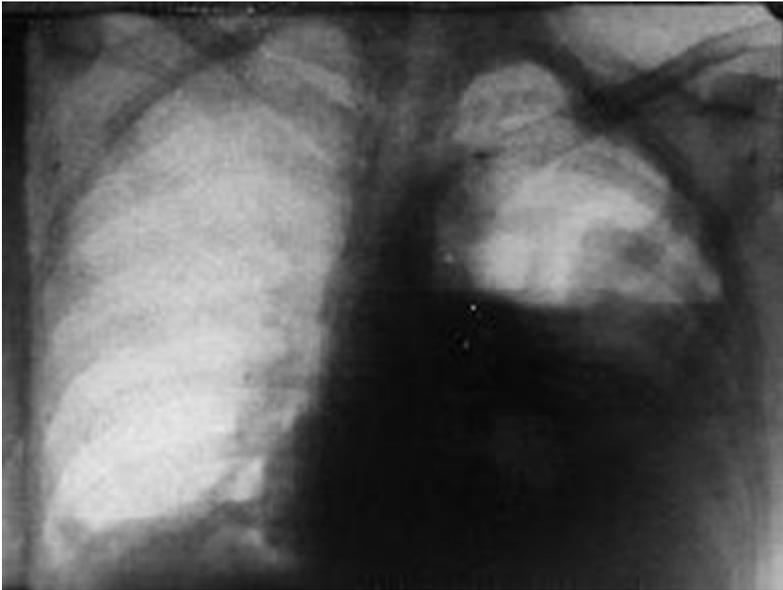

By objective examination the position of patients is forced, they sit in bed leaning upon the bed (subtotal, total pyopneumothorax). The affected hemithorax takes no part in respiration.

By palpation – diminished vocal fremitus on the side of lesion.

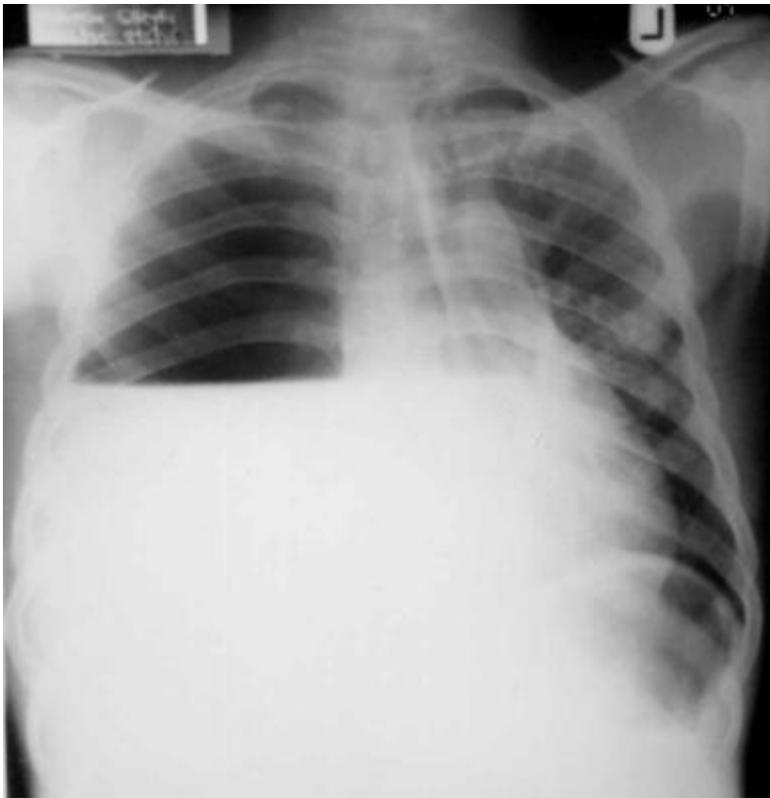

Percussion reveals a sharp shortening of sound over the zone of exudate and bandbox sound above the region of collapsed lung.

By auscultation there are no breathing sounds on the affected side. In case of localized pyopneumothorax – weakened or sharply weakened sound with a bronchial or amphoric tone.

The X-ray picture of pyopneumothorax depends on its form, but the obligatory sign is the air-fluid level in a pleural space with well-defined edge of collapsed lung on its background.

Left-side total pyopneumothorax

Pyopneumothorax

Pyopneumothorax

Variants of clinical course and complications

The clinical course of pyopneumothorax depends on adhesions between pleural membranes. It sometimes changes typical clinical course of a total lung collapse. The clinic of disease depends also on amount of a purulent exudate. Therefore according to extension of the process and size of destruction of lung distinguished acute, mild and asymptomatic forms of pyopneumothorax. Especially difficult for diagnostics is the asymptomatic form of localized pyopneumothorax. Dyspnea for such pathology not characteristic, as the adhesion of membranes prevents complete collapse of lung. Dyspnea is vague or absent at all in partial collapse. A diminished vocal fremitus on side of pathological process, shortening of percussion sound and weakened or sharply weakened breathing sounds over the collapsed lung and exudate are revealed. Roentgenological manifestations in localized pyopneumothorax not expressed and include horizontal fluid level, margin of partially collapsed lung and minor air in the pleural space.

In most cases after discharge of the destructive focus in a pleural space and collapse of lung observed the closure of bronchopleural fistula. Nevertheless the inflammatory process in a pulmonary tissue and pleural space is going on.

The diagnostic program

1. Complaint and history of disease.
2. Physical findings.
3. Chest X-radiography examination.
4. [Thoracentesis](#).
5. Pleurography.
6. Bacterial culture and antibiotic sensitivity.
7. General blood, and urine analyses.
8. Biochemical blood analysis.

Differential diagnostics

They're no special necessity for differential diagnostics of pyopneumothorax in the majority of patients. History (presence of the purulent focus in a pulmonary tissue), clinical course (acute pain and dyspnea at abscess discharge into pleural space), and also chest X-ray findings and thoracentesis frequently reliably permit to make the diagnosis.

In some cases a localized pyopneumothorax according to clinical course resembles a huge acute abscess of lungs. But the differences of roentgenological symptomatology permit to verify these pathological processes. In acute lung abscess the cavity of destruction localized in a pulmonary parenchyma, it is of rounded form with horizontal fluid level and expressed perifocal infiltration.

Tactics and choice of treatment

The purpose of treatment should include sanitation of the destructive focus in pulmonary tissue and liquidation of complications; that means elimination of pus and air from a pleural space and prompt expanding of lung.

1. Active sanitation of tracheobronchial tree by means of [tracheocentesis](#).
2. [Draining of pleural space](#), active aspiration of its content (air, pus) to expand the lungs.
3. Lavage of pleural space by antiseptic solutions.
4. Appropriate antibacterial, antiinflammatory and infusion therapy.

5. The therapy for rising up of immunological resistance of the organism (staphylococcal anatoxin according to scheme, antistaphylococcal gamma-globulin, antistaphylococcal plasma).
6. Endolymphatic introduction of immunity stimulators (thymalin, thymogen, T-activin).

The indications for operative management are the same, as in pleural empyema.

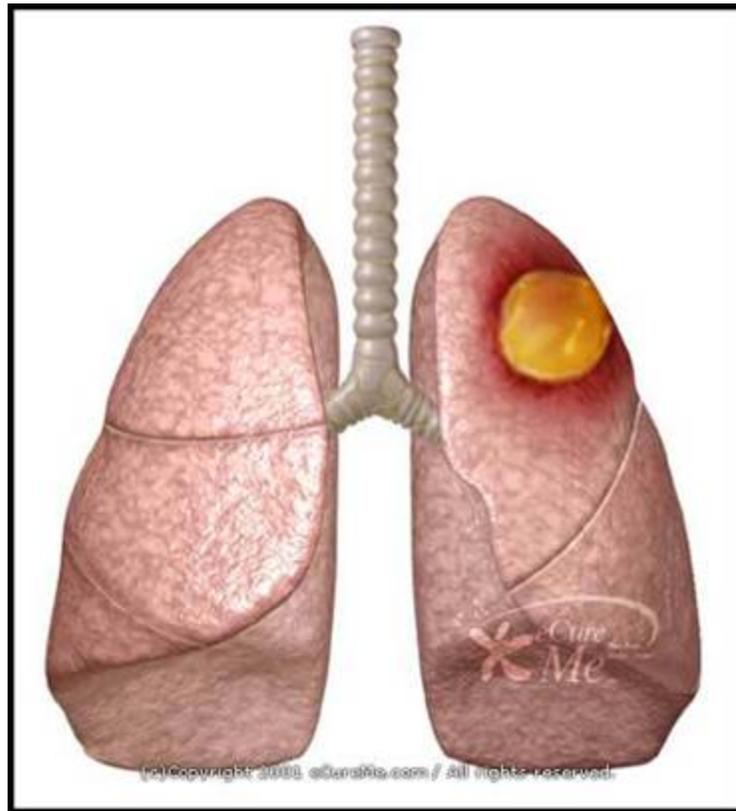

PURULENT DISEASES OF LUNGS AND PLEURA

Lung abscess is defined as necrosis of the pulmonary tissue and formation of cavities containing necrotic debris or fluid caused by microbial infection. The formation of multiple small (< 2 cm) abscesses is occasionally referred to as necrotizing pneumonia or lung gangrene. Both lung abscess and necrotizing pneumonia are manifestations of a similar pathologic process. Failure to recognize and treat lung abscess is associated with poor clinical outcome.

Lung abscess was a devastating disease in the preantibiotic era, when one third of the patients died, another one third recovered, and the remainder developed debilitating illnesses such as recurrent abscesses, chronic empyema, bronchiectasis, or other consequences of chronic pyogenic infections. In the early postantibiotic period, sulfonamides did not improve the outcome of patients with lung abscess until the penicillins and tetracyclines were available. Although resectional surgery was often considered a treatment option in the past, the role of surgery has greatly diminished over time because most patients with uncomplicated lung abscess eventually respond to prolonged antibiotic therapy.

Lung abscesses can be classified based on the duration and the likely etiology. Acute abscesses are less than 4-6 weeks old, whereas chronic abscesses are of longer duration. Primary abscess is infectious in origin, caused by aspiration or pneumonia in the healthy host; secondary abscess is caused by a preexisting condition (eg, obstruction), spread from an extrapulmonary site, bronchiectasis, and/or an immunocompromised state.

Most patients with primary lung abscess improve with antibiotics, with cure rates documented at 90-95%

Abscessing pneumonia is characterized by the multiple destructive foci 0,3-0,5 cm in size within 1-2 segments of lungs, which are not disposed to progression. The destruction is accompanied by expressed perifocal infiltration of a pulmonary tissue.

Abscess of lungs - purulent or ichorous destruction of necrotic sites of pulmonary tissue of one segment with formation of one or several cavities, filled by pus, and detached from adjacent parenchyma by a pyogenic capsule and expressed perifocal infiltration of surrounding pulmonary tissue. It arises at the persons with a maintained reactivity of the organism.

Gangrenous abscess is a purulent, ichorous necrosis of a pulmonary tissue within 2-3 segments, detached from adjacent pulmonary parenchyma, with the liability to formation of sequestrs. Depending on reactivity of the organism it can transform into purulent abscess (after the lysis of sequestrs) or gangrene.

Gangrene of lungs – a diffuse purulent, ichorous necrosis of the tissue without the tendency to defined demarcation with prompt dynamics of spreading of necrotic zone and destruction of the parenchyma. It is characterized by a grave intoxication, liability to a pleural complications and pulmonary bleeding. If only the one lobe is affected the gangrene is considered to be limited, if affected extensive areas of lungs the gangrene is wide-spread.

Etiology and pathogenesis

Lung abscesses have numerous infectious causes. Anaerobic bacteria continue to be accountable for most

cases. These bacteria predominate in the upper respiratory tract and are heavily concentrated in areas of oral-gingival disease. Other bacteria involved in lung abscesses are gram-positive and gram-negative organisms. However, lung cavities may not always be due to an underlying infection. Some evidence suggests that individuals with cyanotic heart disorders may also be more prone to lung abscess formation. The continuous hypoperfusion of the pulmonary tissues may predispose the individuals to chronic pulmonary infections.

The predominant factors which cause the disease:

- disturbances of bronchial patency with the development of atelectasis;
- infectious inflammatory process in a pulmonary tissue;
- regional disturbances of blood supply with a further necrosis of areas of pulmonary parenchyma.

The embodiment of these factors occurs in condition of the changed reactivity of the organism.

The states which result in the aspiration of contents of the upper parts of alimentary tract (traumas of head, craniovascular disturbances, alcoholism, narcomania, narcoses, epilepsy etc.) contribute to the pulmonary abscessing. And also factors, which are capable to provoke secondary immunodeficiency and suppression of reactive processes: diabetes mellitus, irradiation, long application of corticosteroids, antineoplastic therapy, some hematological disease, AIDS favor the purulent processes.

Factors contributing to lung abscess

Oral cavity disease

- Periodontal disease
- Gingivitis

Altered consciousness

- Alcoholism
- Coma
- Drug abuse
- Anesthesia
- Seizures

Immunocompromised host

- Steroid therapy
- Chemotherapy
- Malnutrition
- Multiple trauma

Esophageal disease

- Achalasia
- Reflux disease
- Depressed cough and gag reflex
- Esophageal obstruction

Bronchial obstruction

- Tumor
- Foreign body
- Stricture

Generalized sepsis

Pathology

The abscesses mainly develop in II and VI segments of lungs. They may be single and multiple. The abscess is confined from adjacent pulmonary tissue by a capsule, which represents a granulating tissue and dense leukocytic rampart. Usually it is possible to find out a draining bronchus. Later on in the wall of the abscess the amount of connective tissue fibers is enlarged.

In gangrene the pulmonary tissue is of black color, swollen, with cavities, and in some places transfers into the sites with dark green coloring. The macropreparatus is characteristically fetid.

Classification

According to pathogenesis:

- postpneumonic;
- aspirative;
- obturative;
- posttraumatic;
- hematogenous or septic;
- lymphogenous;

- thromboembolic.

According to the character of purulent process:

- single purulent abscesses;
- multiple purulent abscesses;
- bilateral purulent abscesses;
- gangrenous abscesses (single, multiple, uni- and bilateral);
- limited gangrene;
- wide-spread gangrene.

According to stages:

- 1 stage - necrotic pneumonia;
- 2 stages - destruction and rejection;
- 3 stages - cleaning and cicatrization.

According to the term of existence:

- acute;
- chronic.

Complications:

- pulmonary bleeding;
- pyopneumothorax;
- pleural empyema;
- sepsis;

- bronchogenic dissemination.

Symptomatology and clinical course

The clinical manifestations of acute purulent destruction of lungs depend on the size of the focus and character of destruction, reactivity of the organism and stage of the disease, peculiarities of the drainage of purulent cavities and complications.

At the first stage of **acute abscess** the patients complain of general weakness, headache, malaise, suppressed appetite, moderate chest pain, dyspnea, subfebrile temperature.

At the second stage the state of the patients is worsened. The fever rises to as high as 39-40°C and has a hectic character. At the same time the chest pain increases, which associates with a troubling cough and dyspnea. The condition of the patients is worsened and the intoxication increases. One can feel a foul-smelling from the mouth at cough. The amount of sputum is small, with a rusty tone. With the beginning of the draining of destructive cavities through bronchus the daily quantity of the sputum reaches 500 ml and more. At this time is possible hemoptysis. The sputum is foul-smelling. At sedimentation it divides into three layers:

- inferior – resembling a grey mass with detrites and flaps of a pulmonary tissue;
- medial – purulent, turbid, liquid;
- upper – mucous foamy layer.

Further in favourable cases there is a considerable improvement of state of the patients. The body temperature falls, the signs of intoxication reduce and the appetite increases.

The disease grades into the third stage, which is characterized by the regress of clinical manifestations, up to their complete disappearance.

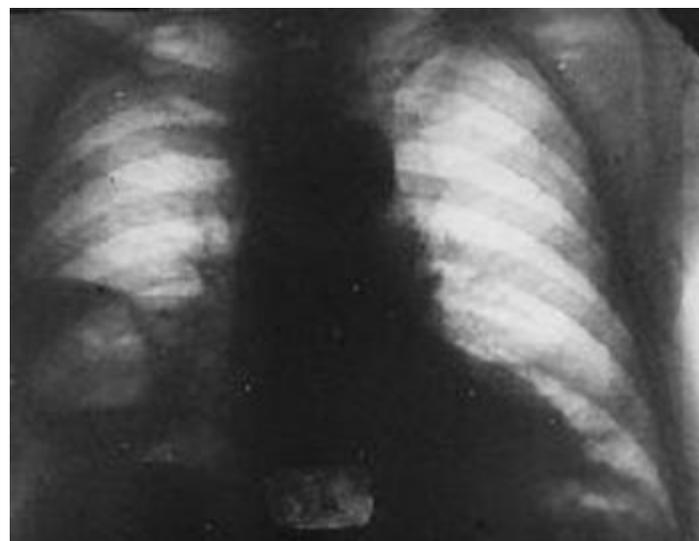

The physical signs good are well revealed at peripheral localization of the process. By palpation – weakened vocal fremitus. At percussion – a blunted sound over the site of the purulent focus and perifocal infiltration (at subpleural location of the abscess). By auscultation – tubular sound with a moist rales in the zone of purulent focus. Well-generated subpleural cavities of major sizes can be revealed by percussion by bandbox sound, on auscultation by moist rales on the background of amphoric respiration.

At X-ray of the chest at the stage of necrotic pneumonia is found out a rounded lesion with irregular contour. For the second stage is characteristic the enlightenment of the shadow with a further developing of the rounded cavity with air-fluid level (Kordin's symptom), gentle pyogenic sheath and the perifocal infiltration.

At the third stage on the place of suppuration observed expressed fibrosis, sometimes as a thin-walled annular formation.

Acute abscess of the right lower lobe before draining

Acute abscess of the right lower lobe after draining

Gangrenous abscess is characterized by a grave state of the patient, expressed purulent intoxication, cough with expectoration of a great amount (500 ml and more) of grey-green sputum with a foul-smelling, hectic body temperature. Roentgenologically the outline of the cavity is poorly defined, it contains a visible sequesters that look as a polymorphous shadow. The adjacent pulmonary tissue is infiltrated.

Gangrenous abscess

The clinic of a **pulmonary gangrene** differs by a terminal expression of signs. The state of the patients is critical. The patient is adynamic, exhausted, with edemas on legs. Dyspnea in rest, hemodynamic disturbances are evident. Dirty-grey or brown sputum with detrites, pieces of necrotic parenchyma and threads of blood excretes out with the cough up to 1 l. Early pleural complications are usual and represent with pulmonary bleeding, which may be profuse. Often it is associated with vital organ dysfunction and loss of consciousness.

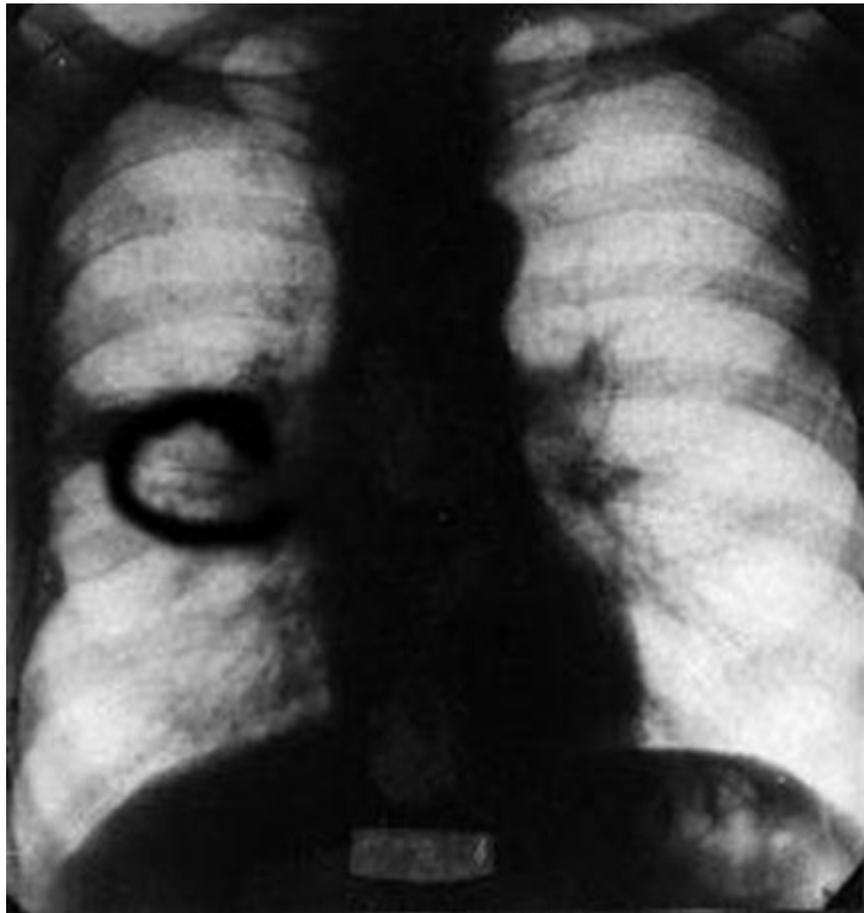

The intensive shadow which borrows a considerable area of lungs with a visible cavities, that contain sequesters, fluid levels, is roentgenologically revealed. The shadow outline is irregular, but could be well defined if the process is within interlobar sulcus.

Pulmonary gangrene

Chronic abscess of lungs occurs at 12-15 % of cases. It is considered to be chronic at existence of a pulmonary abscess more than 6-8 weeks. It is characterized by a cyclic course. In the stage of remission the patients complain of a moderate dyspnea, cough with expectoration of a mucous or mucopurulent discharge. The exacerbation manifests by coughing up of 250-500 ml of a purulent foul sputum, chest pain, dyspnea, hectic temperature with the difference in 1,5-2°C. Dizziness, suppression of appetite, general weakness enlarges according to intoxication. The skin is pale with moderate cyanosis. The respiratory rate rises to 28-30 per min. In 6-8 months is noticed the clubbing of the fingers and deformation of the chest. The vocal fremitus is a little bit weakened on the side of lesion (particularly in peripheral localization of the process). The percussion reveals a short sound in projection of pathological process, the auscultation - a lot of moist rales on the background of amphoric respiration.

Roentgenologically chronic abscess is shown by one or several cavities of a spherical shape with a thick, dense pyogenic sheath. Exacerbation of the process manifests by a cavity with horizontal air-fluid level. The size of surrounding perifocal infiltration depends on the phase of process.

Chronic abscess of lungs

The blood analysis in pulmonary destruction is characterized by leukocytosis with deviation of the differential count to the left, lymphocytopenia, elevation of the erythrocyte sedimentation rate. Gangrenous change of the process is accompanied by a progressing anemia, sometimes by leukopenia. The hypoproteinemia arises from major losses of protein with purulent sputum. Intoxication and toxic lesion of liver leads to disproteinemia. It is associated with the enlarged concentration of mucoprotein, sialine acids, seromuroid, and fibrinogen.

The immunogram reveals the suppression of cellular and humoral immunity with a liability to hyperergy and autoaggression, depression of the mechanisms of nonspecific protection.

The cytological bronchial water lavage is characterized by expressed neutrocytosis, noncellular postdestructive insertions at lack or absence of alveolar macrophages.

Variants of clinical course and complications

According to the clinical course, there are such variants of the development of purulent diseases of lungs:

1. **Favorable course.** The adequate treatment results in prompt positive clinical, roentgenological and laboratory dynamics, and terminates by recovery.
2. **Non-progressive course.** A poor drainage of the suppurative focus and permanent purulent intoxication result in transferring of the process in chronic form.
3. **Progressing course.** Is predetermined by combination of a series of the unfavorable factors (low resistance of the organism, autoimmune aggression, high virulence of the infecting agent etc.). Characterized by diffusion of the zone of necrosis and destruction with transferring in gangrene.
4. **Incapsulated process.** Caused by the absence or complete obstruction of the draining bronchus under condition of satisfactory resistance of the organism.
5. **Complicated course.** Mostly is the result of progressive development of the pathological process.

Pulmonary bleeding arise suddenly, are associated with coughing out of a foamy, red blood and clots by portions or continuous stream. The most often source of a pulmonary bleeding are the bronchial arteries and vessels of a pulmonary tissue. The clinical manifestations of a pulmonary suppuration are accompanied by dizziness, weakness, dyspnea, chest pain. The hemodynamic disturbances depend on intensity of the bleeding. The auscultation of lungs from both sides reveals the moist rales (aspiration). If the pulmonary destruction is present the plain film of the chest shows the localization of the source of bleeding. After hospitalization of the patient with this complication the exclusive information is obtained with a fibrobronchoscopy.

According to degree the pulmonary bleedings are classified (V.Struchkov, 1985):

I degree – hemorrhage up to 300 ml.

1. Single hemoptysis.
2. Multiple hemoptysis.

II degree – hemorrhage up to 700 ml.

1. Single bleeding:
 - a) with fall in arterial pressure and decreasing of hemoglobin;
 - b) without fall in arterial pressure and decreasing of hemoglobin.
2. Multiple bleeding:
 - a) with fall in arterial pressure and decreasing of hemoglobin;
 - b) without fall in arterial pressure and decreasing of hemoglobin.

III degree - hemorrhage exceeds 700 ml.

1. Massive bleeding.
2. Fulminant, lethal bleeding.

The I degree of a pulmonary bleeding manifests by coughing out the sputum tinged with blood, the hemodynamic disturbance usually absent. At bleeding of II degree are observed decreasing of arterial pressure on 20-30 mm Hg, tachycardia to 100 beats/min, contents of hemoglobin within 60-80 g/l. The bleeding of III degree are accompanied with sharp decreasing of arterial pressure, rapid (more than 100-120 beats/min), small, sometimes thread pulse, and even its disappearance on peripheral arteries, tachypnea to 40 per 1 min, hemoglobin to 50-60 g/l. Probable the fulminant course up to the terminal state with prompt failure of cardiac activity and asphyxia by blood.

Sepsis manifests by multisystem lesions with progression of the syndrome of polyorganous failure, hematosepsis, purulent metastasizing (frequently in brain).

Characteristic complications for suppurative diseases of lungs such as pleural empyema and pyopneumothorax are described in separate parts.

The diagnostic program

1. Complaints and history of the disease.

Generally, most of the patients admitted to the hospital with a diagnosis of lung abscess have had symptoms for at least 2 weeks. These patients typically have an intermittent febrile course, productive cough, weight loss, general malaise, and night sweats. Initially, foul sputum is not observed in the course of the infection; however, after cavitation occurs, putrid expectorations are quite prevalent. The odor of the breath and sputum of a patient with an anaerobic lung abscess is often quite pronounced and noxious and may provide a clue to the diagnosis. Hemoptysis may occasionally follow the expectoration of putrid sputum.

Symptoms depend on whether the abscess is caused by anaerobic or other bacterial infection.

- Anaerobic infection in lung abscess
 - Patients often present with indolent symptoms that evolve over a period of weeks to months.
 - The usual symptoms are fever, cough with sputum production, night sweats, anorexia, and weight loss.
 - The expectorated sputum characteristically is foul smelling and bad

tasting.

- Patients may develop hemoptysis or pleurisy
- Other pathogens in lung abscess
 - These patients generally present with conditions that are more emergent in nature and are usually treated while they have bacterial pneumonia.
 - Cavitation occurs subsequently as parenchymal necrosis ensues.
 - Abscesses from fungi, *Nocardia* species, and *Mycobacteria* species tend to have an indolent course and gradually progressive symptoms.

2. Physical findings.

The findings on physical examination of a patient with lung abscess are variable. Physical findings may be secondary to associated conditions such as underlying pneumonia or pleural effusion. The physical examination findings may also vary depending on the organisms involved, the severity and extent of the disease, and the patient's health status and comorbidities.

- Patients with lung abscesses may have low-grade fever in anaerobic infections and temperatures higher than 38.5°C in other infections.
- Generally, patients with in lung abscess have evidence of gingival disease.
- Clinical findings of concomitant consolidation may be present (eg, decreased breath sounds, dullness to percussion, bronchial breath sounds, coarse inspiratory crackles).
- The amphoric or cavernous breath sounds are only rarely elicited in modern practice.
- Evidence of pleural friction rub and signs of associated pleural effusion, empyema, and pyopneumothorax may be present. Signs include dullness to percussion, contralateral shift of the mediastinum, and absent breath sounds over the effusion.
- Digital clubbing may develop rapidly.

3. X-ray examination of chest in two planes (direct and lateral).

- A typical chest radiographic appearance of a lung abscess is an irregularly shaped cavity with an air-fluid level inside. Lung abscesses as a result of aspiration most frequently occur in the posterior segments of the upper lobes or the superior segments of the lower lobes.

- The wall thickness of a lung abscess progresses from thick to thin and from ill-defined to well-circumscribed as the surrounding lung infection resolves. The cavity wall can be smooth or ragged but is less commonly nodular, which raises the possibility of cavitating carcinoma.

- The extent of the air-fluid level within a lung abscess is often the same in posteroanterior or lateral views. The abscess may extend to the pleural surface, in which case it forms acute angles with the pleural surface.

- Anaerobic infection may be suggested by cavitation within a dense segmental consolidation in the dependent lung zones.

- Lung infection with a virulent organism results in more widespread tissue necrosis, which facilitates progression of underlying infection to pulmonary gangrene.

4. Up to one third of lung

5. Tomogram of lungs.

6. Computed tomography

- CT scanning of the lungs may help visualize the anatomy better than chest radiography. CT scanning is very useful in the identification of concomitant empyema or lung infarction.

- On CT scans, an abscess often is a rounded radiolucent lesion with a thick wall and ill-defined irregular margins.

- The vessels and bronchi are not displaced by the lesion, as they are by an empyema.

- The lung abscess is located within the parenchyma compared with loculated empyema, which may be difficult to distinguish on chest radiographs.

- The lesion forms acute angles with the pleural surface chest wall.

7. Examination of the sputum (bacteriological, cytological).

8. General blood and urine analyses.

- A complete white blood cell count with differential may reveal leukocytosis and a left shift.

- Obtain sputum for Gram stain, culture, and sensitivity.

- If tuberculosis is suspected, acid-fast bacilli stain and mycobacterial

culture is requested.

- Blood culture may be helpful in establishing the etiology.
- Obtain sputum for ova and parasite whenever a parasitic cause for lung abscess is suspected.

9. Biochemical blood analysis (protein and its fractions).

10. Immunogram.

11. Fibrobronchoscopy.

Differential diagnostics

Pneumonia

Primary bacterial pneumonias caused by single bacterial species other than the pneumococcus may account for up to 25% of community-acquired and 80% of hospital-acquired pneumonias. All of these pneumonias may have somewhat similar physical findings and x-ray evidence of pulmonary infiltration or consolidation. For proper treatment, it is crucial to identify the causative agent by blood culture and by sputum examination with stained smear and culture. Transtracheal aspiration, fiberoptic bronchoscopy, or even lung biopsy may be needed for specific diagnosis and treatment.

Streptococcal Pneumonia

Pneumonia due to hemolytic streptococci occurs usually as a sequela to viral infection of the respiratory tract, especially influenza or measles, or in persons with underlying pulmonary disease. The patients are usually in a severely toxic condition and cyanotic. Pleural effusion develops frequently and early and progresses to empyema in one-third of untreated patients. The diagnosis rests on finding large numbers of streptococci in smears of sputum and culturing hemolytic streptococci from blood and sputum.

The treatment of choice is with penicillin G in a dosage similar to that for pneumococcal pneumonia (see above). If treatment is started early, the prognosis is good.

Staphylococcal Pneumonia (picture 2)

Pneumonia caused by *Staphylococcus aureus* occurs as a sequela to viral infections of the respiratory tract (eg, influenza) and in debilitated (eg, postsurgical) patients or hospitalized infants, especially after antimicrobial drug administration. There is often a history of a mild illness with headache, cough, and generalized aches that abruptly changes to a very severe illness with high fever, chills, and exaggerated cough with purulent or blood-streaked sputum and deep cyanosis. There may be early signs of pleural effusion, empyema, or tension pneumothorax. X-ray examination reveals lung consolidation, pneumatoceles,

abscesses, empyema, and pneumothorax. The demonstration of pyopneumothorax and of cavities with air-fluid levels by x-ray is highly suggestive of Staphylococcal pneumonia. The diagnosis must be confirmed by stained smear of sputum (masses of white cells and gram-positive cocci, many intra-cellular) and culture (predominantly *S aureus*), and

also by means of cultures of pleural fluid and blood. The white count is usually more than 20,000//zL.

Initial therapy (based on sputum smear) consists of nafcillin, 6-12 g/d, or vancomycin, 2 g/d, given intravenously in divided doses as a bolus. If the staphylococcus proves to be penicillin-sensitive by laboratory test, penicillin G, 20-60 million units/d intravenously, is the antibiotic of choice. Drugs should be continued for several weeks. If empyema develops, drainage must be established. The prognosis varies with the underlying condition of the patient and the drug susceptibility of the organism.

Legionella Pneumonia

The eponym legionnaires' disease has been given to a serious pneumonia that afflicted people attending the American Legion Convention in Philadelphia in 1976. Other outbreaks have been diagnosed respectively at least since 1965, and sporadic infections have occurred at least since 1947 in many places.

Legionella pneumophila is a poorly staining gram-negative bacterium that grows slowly on special media (eg, charcoal-yeast extract) at 35 °C. There are at least 8 species of *Legionella*, some with multiple serotypes. These organisms can be recovered in human disease from sputum, bronchial washings, pleural fluid, lung biopsies, or blood. *Legionella* species occur in the environment and are acquired by humans from aerosols, dust from air-conditioning systems, water, or soil. The infection is not usually communicable from patient to contacts. Asymptomatic infection is common at all ages, whereas symptomatic infection is most often an opportunistic pneumonia in immunocompromised individuals.

Asymptomatic infection is evident only by a rise in specific antibodies. Symptomatic infection is observed mainly in elderly persons, smokers, and patients undergoing hemodialysis or renal transplant.

The incubation period is estimated to be 2-10 days. Initial symptoms are malaise, diffuse myalgias, and headache, followed in 12-48 hours by high, non-remittent fever and chills. Nausea, vomiting, and diarrhea are frequent early in the illness. On the third day a dry cough begins that is nonproductive or produces scanty mucoid, sometimes blood-streaked sputum. Dyspnea and hypoxia become marked as signs of consolidation develop. Pleuritic chest pain occurs in one-third of patients. Severe confusion or delirium may occur.

There is leukocytosis with a shift to the left, hyponatremia, abnormal liver function tests, and, occasionally, microscopic hematuria. Chest x-rays reveal patchy, often multilobar pulmonary consolidation, and, occasionally, small pleural effusions. The illness usually worsens for 4-7 days before improvement begins in those who recover. During severe outbreaks, the mortality rate has been 10% in those with manifest disease. Death is attributed to respiratory or renal failure or shock, with disseminated intravascular coagulation.

The diagnosis is based on a clinical picture compatible with the specific features of the disease and on

negative results of bacteriologic laboratory tests for other pneumonias. The organism can be identified by immunofluorescence in cultures, lung biopsy, and, rarely, sputum specimens. A retrospective diagnosis is based on a significant rise in specific serum antibodies detected by immunofluorescence.

The treatment of choice is erythromycin, 0.5-1 g every 6 hours intravenously or orally for 2-3 weeks. This usually results in improvement in 2-3 days. Rifampin, 10-20 mg/kg/d, has been suggested for patients who fail to respond to erythromycin. Assisted ventilation and management of shock are essential.

Pneumocystis carinii Pneumonia

This parasitic infection occurs in debilitated children or immunodeficient adults. It has been a prominent opportunistic infection in AIDS patients. The diagnosis is made by lung biopsy and the demonstration of typical cysts of *P. carinii* in impression smears of lung tissue stained with methenamine-silver. Early treatment with sulfamethoxazole-trimethoprim can cure the pneumonia. The same drug has been effective in prophylaxis during immunosuppression. An alternative, more toxic drug is pentamidine isethionate.

"MIXED" BACTERIAL PNEUMONIAS (Hypostatic Pneumonia, "Terminal" Pneumonia, Bronchopneumonia)

Essentials of Diagnosis

- Variable onset of fever, cough, dyspnea, expectoration.
- Symptoms and signs often masked by primary (debilitating) disease.
- Greenish-yellow sputum (purulent) with mixed flora.
- Leukocytosis (often absent in aged and debilitated patients).
- Patchy infiltration on chest x-ray.

General Considerations

Mixed bacterial pneumonias include those in which culture and smear reveal several organisms, not one of which can clearly be identified as the causative agent. These pneumonias usually appear as complications of anesthesia, surgery, aspiration, trauma, or various chronic illnesses (cardiac failure, advanced carcinoma, uremia). They are common complications of chronic pulmonary diseases such as bronchiectasis and emphysema. Old people are most commonly affected ("terminal" pneumonia). Patients treated with intermittent positive pressure breathing apparatus or immunosuppressive drugs may develop pneumonia caused by gram-negative rods.

The following findings in a debilitated, chronically ill, or aged person suggest a complicating pneumonia: (1) worsening of cough, dyspnea, cyanosis; (2) low-grade, irregular fever; (3) purulent sputum; and (4) patchy basal densities on a chest film (in addition to previously noted densities caused by a primary underlying

disease, if any), sometimes with local necrosis and cavitation.

Clinical Findings

A. Symptoms and Signs: The onset is usually insidious, with low-grade fever, cough, expectoration, and dyspnea that may become marked and lead to cyanosis. Physical findings are extremely variable and may not be impressive against a background of cardiac or pulmonary disease. The signs listed under Other Bacterial Pneumonias may also be present.

B. Laboratory Findings: The appearance of a greenish or yellowish (purulent) sputum should suggest a complicating pneumonia. Smears and cultures reveal a mixed flora, often including anaerobes. Predominant types should be noted. Leukocytosis is often absent in the aged and debilitated patient presenting with a mixed infection.

C. X-Ray Findings: X-ray (Picture 3) shows patchy, irregular infiltrations, most commonly posterior and basal (in bedridden patients). Abscess formation may be observed. Careful interpretation will avoid confusion with shadows due to preexisting heart or lung disease.

Differential Diagnosis

Mixed bacterial pneumonias must be differentiated from tuberculosis, carcinoma, and other specific mycotic, bacterial, and viral pulmonary infections (to which they may be secondary).

Treatment

Clear the airway and correct hypoxia. Unless a probably significant etiologic agent can be identified, give one of the new cephalosporins (eg, cefotaxime, 12 g/d intravenously) as initial therapy. This will be modified according to clinical and laboratory results.

Prognosis

The prognosis depends upon the nature and severity of the underlying pulmonary disease and varies with the predominating organism.

ASPIRATION PNEUMONIA

Aspiration pneumonia is an especially severe type of pneumonia, often with a high mortality rate. It results from the aspiration of gastric contents in addition to aspiration of upper respiratory flora in secretions. Important predisposing factors include impairment of the swallowing mechanism (eg, esophageal disease), inadequate cough reflex (eg, anesthesia, postoperative state, central nervous system disease, drug abuse), and impaired gastric emptying (eg, pyloric obstruction). Pulmonary injury is due in large part to the low pH (< 2.5) of gastric secretions.

Scattered areas of pulmonary edema and bronchospasm occur, and the x-ray appearance (pictures 4-5) may

be confused with that of pulmonary emboli, atelectasis, bronchopneumonia, and congestive heart failure.

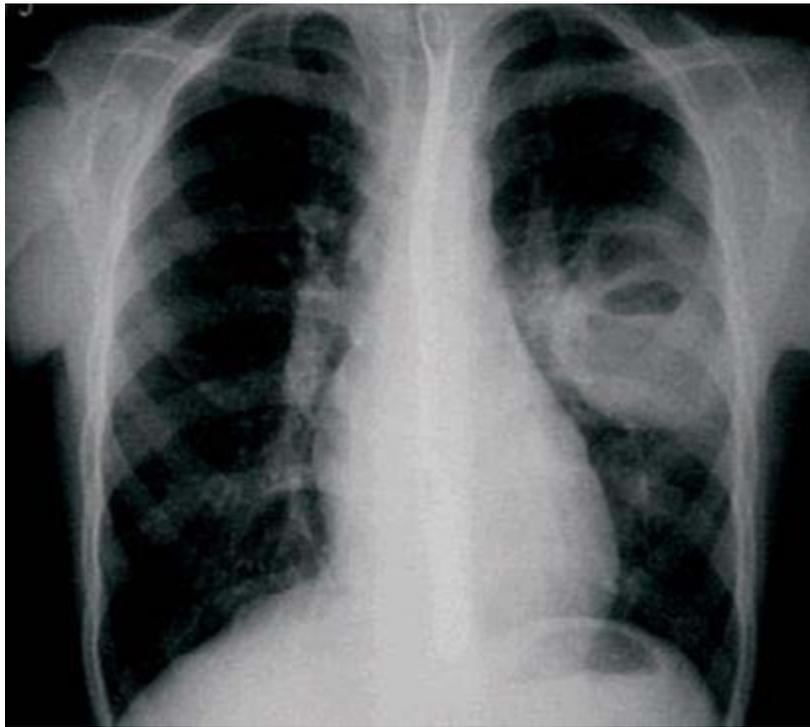

Removal of aspirated material by catheter suction or bronchoscopy may be attempted, but this usually fails to remove all aspirate completely. Corticosteroids (eg, prednisone, 100 mg orally on the first or second day) may reduce the intensity of the inflammatory reaction to acidic gastric secretion, but the value of corticosteroids in the treatment of aspiration pneumonia is not proved, and they increase the risk of superinfection. Some aspiration pneumonias have no bacterial component, but in many others a mixed bacterial flora is involved. Antimicrobial drugs directed against the latter (eg, penicillin G plus an aminoglycoside or the best available cephalosporin) are sometimes administered without waiting for evidence of progressive pulmonary infection. In doing so, however, there is a risk of favoring the development of resistant microorganisms. Therefore, administration of antimicrobials should not continue without laboratory and clinical evidence of microbial infection. Assisted ventilation and supplementary oxygen are beneficial.

The cancer of the central location due to the obturation of bronchus results in atelectasis of a segment or lobe of lungs, with probable further abscessing. For the differentiation used tomography (reveals the obturation of bronchus by tumour, lesion of central lymph nodes), cytological examination of sputum and bronchial outwashes. The determinant role belongs to fibrobronchoscopy with a biopsy and verification of the diagnosis.

Central lung carcinoma

The peripheral cancer of lungs with destruction on tomograms is characterized by cavity with irregular inner surface, which external outline connects with root of the lung because of lymphatic metastatic spreading. The central lymph nodes frequently enlarged. The diagnosis is improved by results of transthoracic puncture or catheterizing biopsy with cytological investigation, fibrobronchoscopy. If it is impossible to confirm the diagnosis the thoracotomy is indicated.

The peripheral cancer of lungs

The tubercular cavern is mainly located in the upper lobes of lungs, roentgenologically revealed on the background of characteristic changes in adjacent pulmonary tissue (calcification, dissemination), sometimes detected a draining bronchus. In the sputum mycobacteria of tuberculosis are frequently found.

The tubercular cavern

The suppurative cyst of lungs differs by a gradual onset, slow course of the suppuration, less expressed intoxication. Roentgenologically its cavity has the oval or rounded shape with a thin sheath and regular contour. Perifocal infiltration is not characteristic.

Tactics and choice of treatment

The tactics in acute pulmonary destruction should be mainly conservative.

1. The adequate antibacterial, antiinflammatory therapy consists of intravenous introduction of antibiotics of a wide spectrum activity.

ANTIBIOTICS IN LUNG ABSCESS

Anaerobic organisms[3]

- First choice - Clindamycin (Cleocin 3)
- Alternative - Penicillin
- Oral therapy - Clindamycin, metronidazole (Flagyl), amoxicillin (Amoxil)

Gram-negative organisms

- First choices - Cephalosporins, aminoglycosides, quinolones
- Alternatives - Penicillins and cephalexin (Biocef)
- Oral therapy - Trimethoprim/sulfamethoxazole (Septra)

Pseudomonal organisms: First choices include aminoglycosides, quinolones, and cephalosporin.

- Gram-positive organisms
- First choices - Oxacillin (Bactocill), clindamycin, cephalexin, nafcillin (Nafcil), and amoxicillin
- Alternatives - Cefuroxime (Ceftin) and clindamycin
- Oral therapy - Vancomycin (Lyphocin)

Nocardial organisms: First choices include trimethoprim/sulfamethoxazole and tetracycline (Sumycin).

With the purpose of maximal concentration of drugs in the pathological focus applied:

- Injection of antibiotics in the vessels of a pulmonary circulation by means of catheterization of central veins, pulmonary artery;
- Introduction of medicinal agents into respiratory tracts (in the second stage) – through the endotracheal microirrigator, nasogastric tube, during bronchoscopies, endoscopic catheterization of the abscess cavity through the draining bronchus, in aerosolic inhalations. The composition of medical admixtures includes: antibiotics, antiseptics (10 % dimexid, dioxydin, microcid etc.), enzymes;

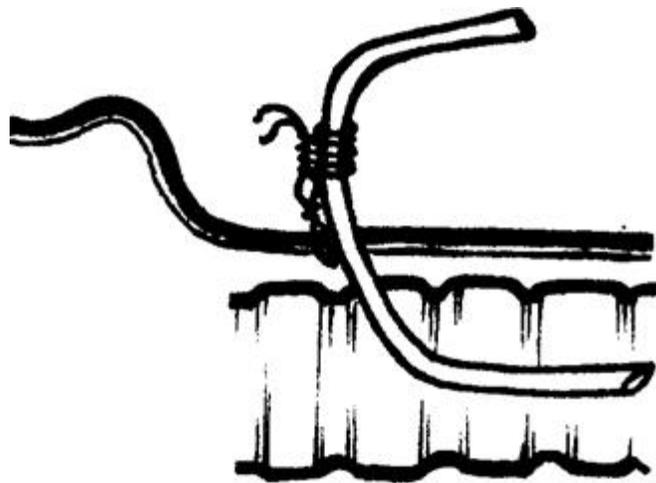

The steps of microtraheostomia:

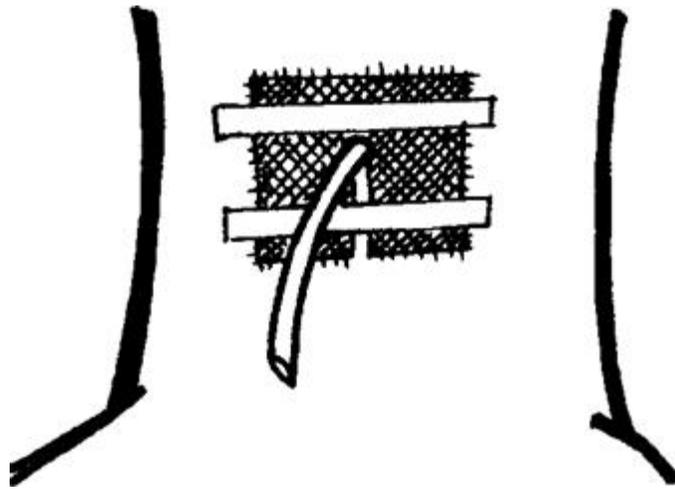

Tracheocentesis after local anesthesia

Insertion of the conductor

Incertion of the irrigator along the conductor

Skin wound

- Transcutaneous in the focus of destruction by means of puncture or draining with the usage of physical antiseptics (US, UVR, laser).
- Intrapleural;
- By means of electrophoresis.

2. Evacuation of purulent content of the cavities:

- In natural way by an active sanitation of tracheobronchial tree using repeated fibrobronchoscopies, aspirations through the endobronchial catheter, installations of medical agents through the microtracheostomy, aerosolic inhalations;
- Transthoracically by means of repeated punctures or external draining of peripheral cavities.

3. Detoxycation therapy (intra- and extracorporal).

4. Immune correction (under the control of immunogram):

- Active – staphylococcal anatoxin according to the plan;
- Passive – specific gamma-globulins, hyperimmune plasma;
- Non-specific (pirimidine and purine derivates, drugs of a thymus gland, splenin, levamisol,).

5. Homeostatic correction (oxygenotherapy, correction of anemia, hypoproteinemia, acidosis, microcirculatory disturbance).

6. Desensitizing, antiinflammatory therapy, regulation of activity of proteases: antihistamine, nonsteroid antiinflammatory agents, inhibitors of proteases, antioxidants.

7. Correction of dysfunction of the vital organs and systems, prevention of complications, symptomatic therapy.

Indications for operative management in acute destructive processes of lungs:

- Pulmonary bleeding of II- III degree;
- Progression of the process on the background of active and appropriate therapy;
- Tense pyopneumothorax, which is failed to liquidate by the draining of pleural space;
- Impossibility to rule out the suspicion on a malignant tumour.

Contraindications: decompensation of the vital functions and systems in the terminal stage, bilateral purulent destruction of lungs, concomitant incurable malignant tumours.

Several important factors must be considered prior to undertaking surgery. Because of the high risk of spillage of the abscess into the contralateral lung, it is almost essential that a double-lumen tube be used to protect the airway. If this is not available, surgery poses a very high risk of abscess in the other lung and a risk of ARDS. In such cases, postponing the surgery is a wise decision. Another, less-satisfactory method to deal with this problem includes positioning the patient in the prone position. The surgeon must be skilled in resecting the abscess and in rapid clamping of the bronchus to prevent spillage into the trachea. These factors are extremely important when dealing with the surgical aspects of treating a lung abscess. If doubt persists, postponing the surgery is best.

Surgical treatment is now rarely necessary and is almost never the initial choice in the treatment of lung abscesses. In current practice, fewer than 15% of patients need surgical intervention for the unchecked disease and for complications that occur in both the acute and chronic stages of the disease.

Surgical management is reserved for specific indications such as little or no response to medical treatment, inability to eliminate a carcinoma as a cause, critical hemoptysis, and complications of lung abscess (eg, empyema, bronchopleural fistula). In addition, if after 4-6 weeks of medical treatment a notable residual cavity remains and the patient is symptomatic, surgical resection is advocated.

The results of surgery are difficult to assess because of the varying patient population and the tremendous increase in illicit drug abuse, alcoholism, AIDS, and infections by

gram-negative and opportunistic organisms. These factors have increased the incidence of lung abscess and the associated morbidity.

A great deal of caution is needed during anesthesia when patients with lung abscess undergo surgery because spillage of the abscess material into the uninvolved lung can occur. Therefore, a double-lumen endotracheal tube is used in all cases.

A study by Nagasawa et al has shown that thoracoscopic surgery can lead to effective drainage of pediatric lung abscess without major complications. In addition, other benefits of thoracoscopy include rapid recovery, less pain, and minimal morbidity.

Operational incisions – anterolateral, lateral and posterolateral thoracotomy. The operation suggests segmental, polysegmental resection, lobectomy, bilobectomy combined intervention (with the decortication, pleurectomy).

Lateral access

Anterior access

Posterior access

The patients with chronic abscesses should be undergone the operative treatment after complete liquidation of exacerbation.

In a pulmonary gangrene the stabilization of the process on the background of active conservative treatment allows in future to apply conservative tactics up to recovery or making optimal conditions for operation (liquidation of intoxication, aggressive panbronchitis, diffuse infiltration of the parenchyma, pleural complications). The headlong progression of the gangrene during first days, despite the active correction,

occurrence of pulmonary bleeding requires urgent performance of operative management. Volume of the operation – pneumonectomy, bilobectomy, lobectomy.

PLEURAL EMPYEMA

The pleural empyema is a purulent inflammation of its visceral and parietal membranes, which is associated with accumulation of pus in a pleural space.

Etiology and pathogenesis

The causes of occurrence of acute pleural empyema are inflammatory, or purulent and destructive processes of lungs, abscesses of abdominal cavity (secondary pleural empyema), open and closed damages of chest, and also, in some cases, operative approaches on thoracic organs (primary pleural empyema).

A secondary pleural empyema occurs in 88 % of the patients. Thus develops fibrinous, exsudative, and then purulent pleurisy.

In case of pulmonary gangrene, purulent mediastinitis, subphrenic abscess the stage of exsudative pleurisy extremely short. The progression of the process results in transferring of focal pleural empyema into wide-spread.

Pathology

Macroscopically pleura is thickened, covered by pus with punctate hemorrhages. Microscopically it is diffusely oozed with neutrophils. In cases, when the empyema overcome into chronic course, the pleura deposits the calcareous salts, thick pus encapsulated, sometimes with the development of fistula.

Classification

I. According to the etiological factor:

1. Specific.
2. Nonspecific.

II. According to the pathogenic factor:

1. Primary.
2. Secondary.

III. According to the clinical course:

1. Acute.
2. Chronic.

IV. According to extension of the process:

1. Focal.
2. Wide-spread.

V. According to the presence of lung destruction:

1. Empyema with destruction of pulmonary tissue.
2. Empyema without destruction of pulmonary tissue.
3. Pyopneumothorax.

VI. According to communication with environment:

1. Closed pleural empyema;
2. Open pleural empyema:
 - bronchopleural fistula;
 - thoracopleural fistula;
 - thoracopleurobronchial fistula;
 - cribrate lung.

Symptomatology and clinical course

The clinic of an acute pleural empyema depends on extension of the process, reactivity of organism and presence of complications.

The pain is the sign, which denote the involvement of pleural membranes in the process. Its intensity increases depending on depth of respiration and body position.

The dyspnea arises from accumulation of a purulent content in a pleural space and exception of particular volume of a pulmonary tissue from respiration. It's in direct ratio to amount of exudation in a pleural space.

The cough is manifestation of inflammation or purulent and destructive process in a pulmonary tissue.

Fever to 39-40°C, headache, sleeplessness, general malaise, and anorexia – all these are manifestations of intoxication.

The forced patient's position and restriction of breathing should be considered as outcomes of a pain syndrome. The extension of pleural empyema causes the swelling of thoracic wall, smoothing of intercostal spaces.

By palpation – diminished vocal fremitus on the part of lesion.

The data of percussion and auscultation depend on extension of the process and amount of pus in a pleural space. At percussion over the exudate it is possible to reveal short sound with oblique upper contour. Above the exudate – tympanic sound resulting from consolidation of pulmonary tissue. By auscultation – diminished or absent sound in a great amount of exudate.

The predominant roentgenological sign of a focal or wide-spread empyema – the presence of exudate. In localized acute pleural empyema observed a local intensive homogeneous shadow. Roentgenologically according to localization distinguished such types of a focal empyema:

- 1) apical;
- 2) paramediastinal;
- 3) parietal;
- 4) interlobar;
- 5) epiphrenic.

The wide-spread pleural empyema manifests by intensive homogeneous shadow in a basal parts with oblique upper contour (Damuaso' line). The diaphragmatic dome is failed to observe. The more pus contents in a pleural space, the higher the upper measure of exudate.

Left-side pleural empyema

Pleural empyema

Pleural empyema

Pleural empyema

Pleural empyema

Variants of clinical course and complications

The clinic of a focal pleural empyema depends on the site of the process. The apical empyema, due to involvement in the process of a vascular-nervous fascicle, manifests by intensive pain. The soft tissues of supraclavicular region are swelled. The percussion and auscultation has no information.

The pain syndrome in parietal (paracostal) empyema is more expressed. Thoracic excursion is restricted. The diminishing of respiratory sound can be obtained over the exudate.

The chief complaint in paramediastinal empyema is the heart pain. The location of the process in the upper mediastinum can cause the superior vena cava syndrome. The physical findings are vague.

In case of the basal (epiphrenic) empyema the patients complain of pain in subcostal area, which increases at respiration and irradiates in supraclavicular region. In some cases the pain irradiates in epigastric region. The palpation of intercostal spaces and hypochondrium is painful.

The clinical course of postoperative empyema depends on the character of operative approach (marginal resection of lung, lobectomy, pneumonectomy, operation on esophagus) and infection of the pleural space.

The clinical manifestations of posttraumatic empyema depend on the size of damage of the chest, lungs, mediastinal organs and complications (suppuration, hemothorax).

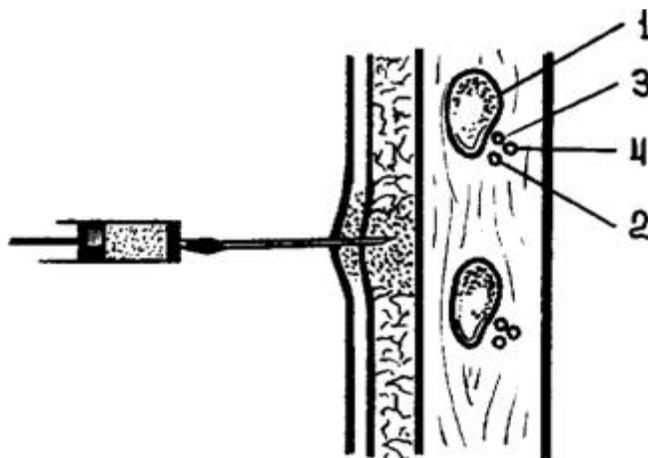

The involvement in the purulent process of a pulmonary tissue in acute empyema results in its fusion of membranes with formation of a bronchial or thoracopleural fistula (discharge of abscess through thoracic wall).

The inappropriate elimination of empyema results in chronic course, cribrate lung and pleurogenic cirrhosis of lungs.

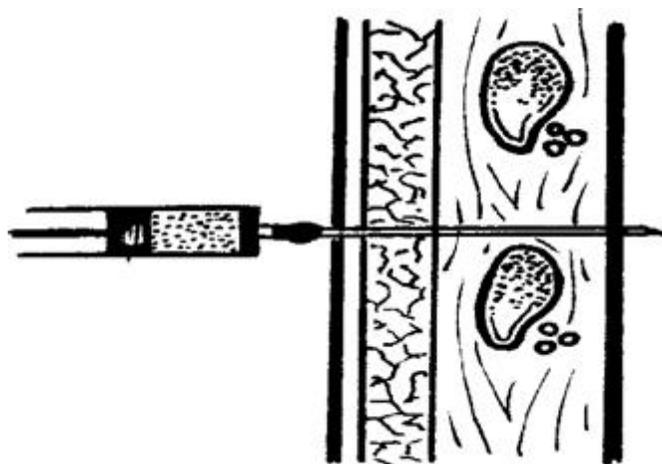

The diagnostic program

1. Complaints and history of the disease.
2. Physical findings.
3. Data of chest X-ray (in two planes, if necessary – laterography).
4. Pleural puncture.
5. The microbiological investigation of the exudate for its sensitivity to antibiotics.
6. General blood and urine analyses.
7. Biochemical blood analysis.
8. Pleurography (in transferring of the process into chronic form).

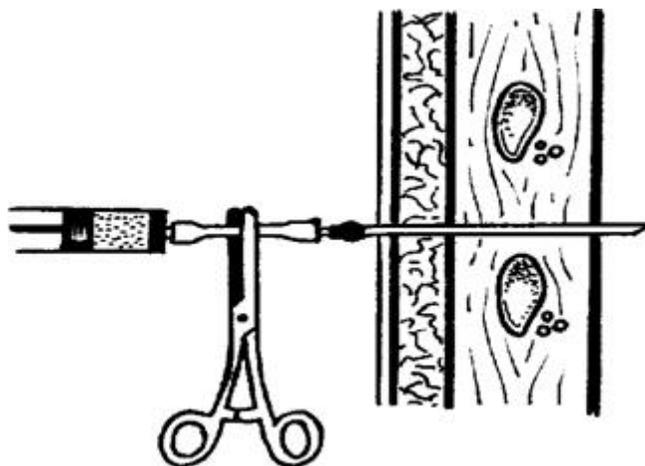

Pleural puncture:

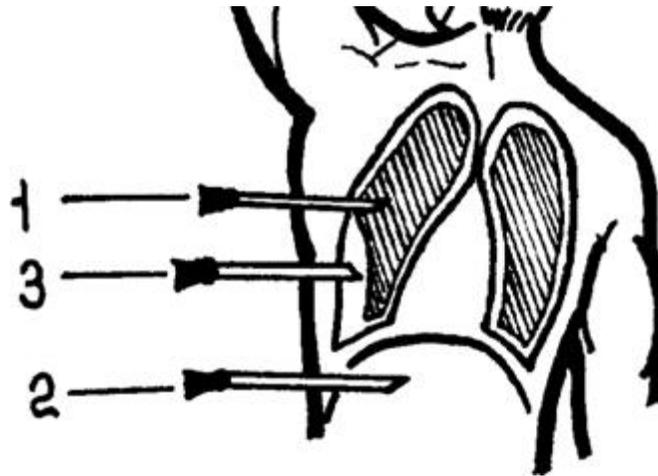

Local anesthesia

Thoracentesis

Aspiration of the fluid

Localization of the needle:

- 1 the needle damaged the lung
- 2 the needle damaged the diaphragm
- 3 the needle located in pleural sinus

Differential diagnostics

Pleuropneumonia complicated with exsudative pleurisy, in some cases resembles acute pleural empyema: a chest pain, fever, dyspnea, cough, and general weakness. The chest roentgenogram reveals hydrothorax (exsudative pleurisy, pleural empyema, hemothorax). The chief diagnostic method for differentiation is the thoracentesis. The presence of a serous (lucent, faint-yellow) exudate testifies about the pleuropneumonia, complicated with pleural effusion, and cloudy, foul-smelling exudate of white or greenish color – about acute empyema.

The major difficulties in differential diagnostics cause the limited forms of empyema.

The **Pancoast cancer** clinically and roentgenologically in most cases has almost the similar course to apical form of empyema. The transthoracic biopsy permits to confirm the diagnosis.

The **acute cholecystitis** is necessary to differentiate with the epiphrenic empyema. The pain in the right hypochondrium, fever, phrenic symptom are common for both diseases. However the objective findings, X-radiography of chest and the thoracentesis allow to differentiate these pathological processes.

The **tumour of anterior mediastinum** complicated by superior vena cava syndrome is necessary to differentiate with paramediastinal empyema. Nevertheless the body temperature in such patients, as a rule, normal. The upper cavography is possible to find out the shift of cava vein and its irregular contours (filling defect) due to growth of the mediastinal tumour.

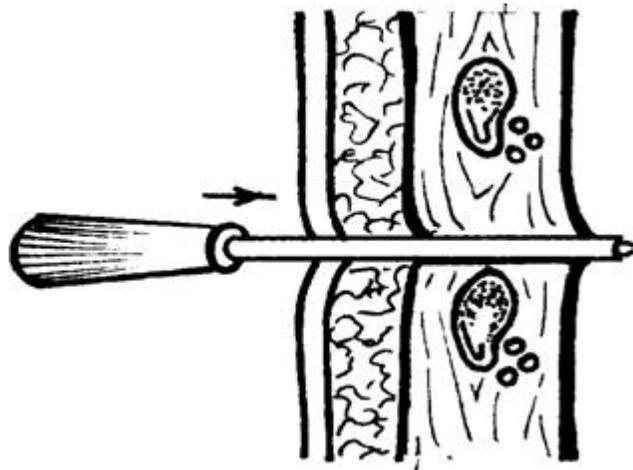

There are some difficulties in differential diagnostics of empyema with a **posttraumatic diaphragmatic hernia**. Such X-ray findings as deformation of diaphragm, additional shadows with a liquid level, intestinal loop suggest a diaphragmatic hernia. A laterography and contrast study of gastrointestinal tract is basic in differential diagnostics of this disease.

The atelectasis of a segment, and lobe of lung in some cases can cause misdiagnostics. Except X-ray chest examination (in two planes and tomography), these situations require necessity of diagnostic bronchoscopy, which reveals the cause of bronchial obturation (foreign body, endobronchial cancer etc.).

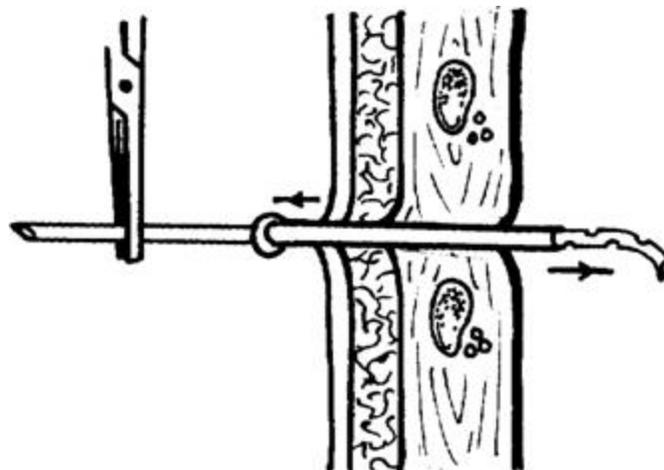

Tactics and choice of treatment

The presence of pus in a pleural space is the indication for its elimination. In the place of performed diagnostic thoracentesis carried out the draining of empyema's cavity, its sanation by means of antiseptic solutions. In a focal empyema the aspiration of pus is performed by thoracentesis and only in its inefficiency carried out a draining of pleural space.

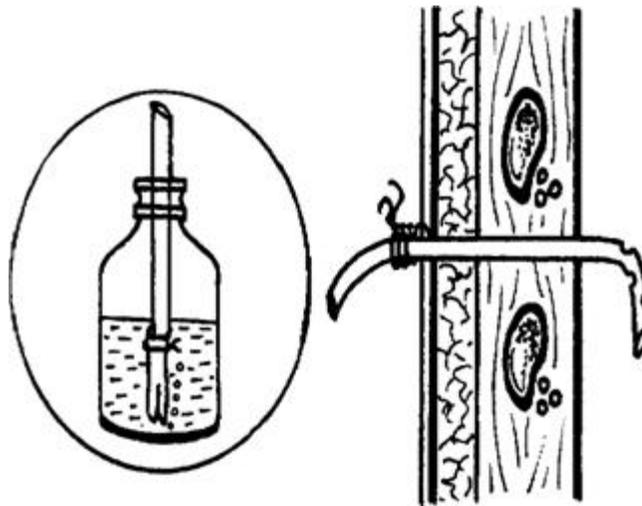

Pleural drainage:

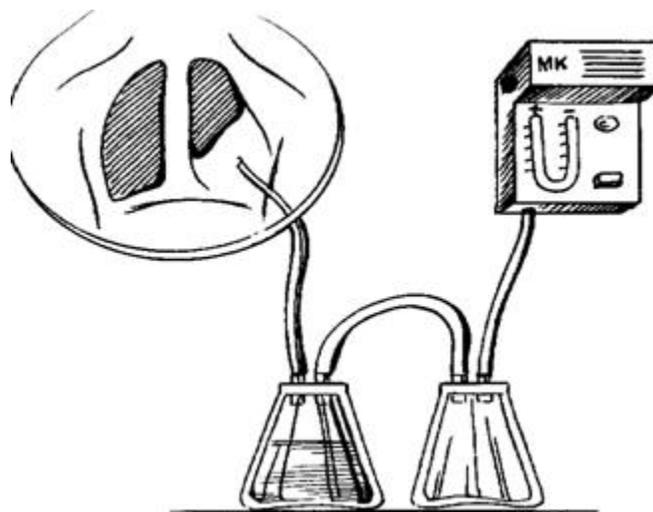

Trocar insertion

Incertion of drainage tube

Passive drainage by Bulau

Active aspiration

Intensive antibacterial and antiinflammatory therapy should be immediately instituted. For general improving used detoxication therapy (infusion of saline solutions, hemotransfusion, transfusion of proteins, solutions of dextran, haemodes, forced diuresis, hemosorption if necessary), therapy for rising up of immunological resistance of the organism.

During the empyema's sanitation decreases the amount of pus which discharges out through the drainage. The optimal variant of such course is the liquidation of empyema's cavity, then the drainage must be removed.

Transferring of the process into the chronic form (10-12 weeks) results in formation of a residual empyema's cavity, which is possible is to reveal by means of pleurography – introduction through the drainage of water-soluble contrast with the further X-radiography in 2 planes.

Operative approach is applied when the process has transferred into the chronic form, that is in case of residual empyema's cavity. Volume of the operation – pleurectomy, decortication of lung.

In some cases, when a bronchial fistula and great empyema's cavity has been formed, there is the necessity of performance of resection of lung and corrective thoracoplasty.

LUNG CYSTS

The cysts of lungs are the thin-walled cavitory formations, filled with air or liquid contents.

Inherent and acquired cyst are distinguished.

Etiology and pathogenesis

Inherent cysts arise from the abnormalities of the development of lungs under influence of the multiple chemical, physical, biological factors. Whether they can develop from a bronchial tree (bronchial) or from alveolar tissue (alveolar). Their occurrence resulting from the delay of the development of peripheral parts of bronchus with their expansion or agenesis of alveoli with dilatation of terminal bronchioles. Congenital cysts at first develop and grow as secretory formations. After communication with bronchus they finally form as air or hydroair cavities.

The acquired cysts represent fibrous cavities, which remain after abscesses, tubercular caverns, echinococci, posttraumatic intrapulmonary hematomas. The degenerative changes in the wall of bronchus with obliteration of its lumen by a cloggy secret owing to repeated inflammatory processes result in occurrence of acquired retentional cysts.

Pathology

Congenital cyst can be located in any part of lungs. The walls of bronchogenic cavities contain chaotically disposed elements of bronchus (cartilagous plates, muscle fibers, mucous glands), they are lined from inside by cylindrical or cubic epithelium. Squeezed alveolar cells line the walls of alveolar formations.

The acquired cyst are revealed in places of localization of previous diseases,. Their walls mainly consist of connective tissue. Epithelization is possible due to transferring of the epithelium from a draining bronchus at long existence.

The cysts could be uni- or multichamber, closed and open (depending on the presence of communication with bronchus).

Classification

According to parentage:

- congenital;
- acquired.

According to displacement:

- single, multiple;
- unilateral, bilateral.

Complications:

- Suppuration;
- Appearance of the valvular mechanism;
- Bleeding;
- Discharge into a pleural space (pneumothorax, pyopneumothorax, pleural empyema);
- Malignancy.

Symptomatology and clinical course

Clinical manifestations of uncomplicated pulmonary cysts are vague. Sometimes patients complain of a chest pain, periodic cough, and inflammatory diseases of respiratory tract in history. In children the signs are much expressed, the dyspnea associates with the compression of airways.

In great, superficially disposed cysts revealed delayed respiratory movements on affected side during breathing.

By palpation - weakened vocal fremitus.

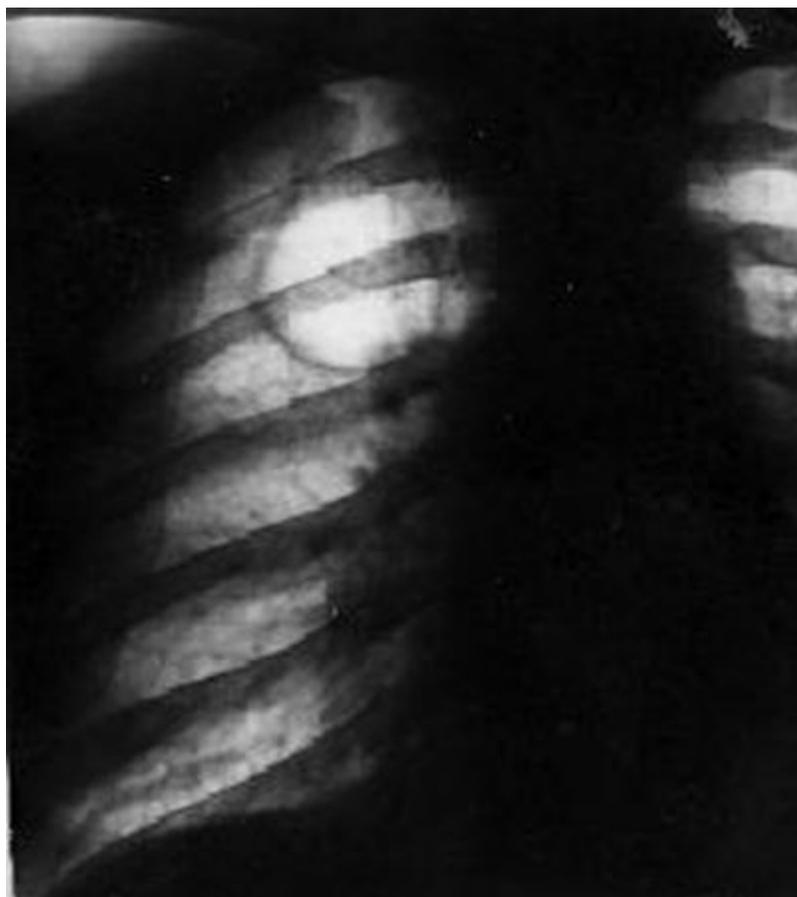

By percussion - short or bandbox sound, depending on contents.

By auscultation - weakened respiration, over the huge open cavities – amphoric.

At routine chest films the closed congenital cyst forms a homogeneous shadow of the spherical or oval shape of average intensity with rather regular edge on the background of an intact pulmonary tissue. During roentgenoscopy sometimes observed the change of its shape depending on the phase of breathing – elongation in inspiration (Escudero's syndrome). The character of the shadow is better to study on tomograms.

Acquired retentional cyst is roentgenologically shown by a shadow of irregular shape (piriform, spindle-shaped etc.), that displays the shape of the distended bronchus. The adjacent tissue, as a rule, changed due to

bronchiectases, pneumosclerosis, etc.

Cyst of the right lung

Open cysts are observed as thin-walled, good defined cavities of annular or oval shape.

On bronchograms congenital cysts are observed hypoplasia of segmental or lobar bronchus, lack of bronchial bifurcations, which tends to bone. Sometimes observed bronchiectases in the neighboring parts of lungs. A cystic cavity is infrequently defined.

The angiopulmonography reveals deformation of vascular branches, which circumflex the cyst.

Variants of clinical course and complications

The **suppuration** of the closed cysts resembles the development of a lung abscess with lesser expression of

signs of intoxication (protective role of epithelial wall).

Infection of the open cysts is characterized by a gradual long course, moderate manifestation of suppuration and late intoxication.

The tension (valvular) cysts arise more often in children. They are characterized by severe respiratory and hemodynamic disturbances, up to terminal, owing to inflexion of venous trunks, shift of mediastinum and compression of lungs. The predominant signs are increased dyspnea, cyanosis, chest pain, respiratory lag on affected side, auscultatory – absence or weakening of respiration, bandbox percussion sound over the cavity at mediastinal shift to the opposite side of the chest.

Pleural complications of pulmonary cysts, and also **bleeding** described in the relevant parts.

The malignant degeneration of pulmonary cysts occurs very rarely.

The diagnostic program

1. Complaints and history of the disease.
2. Physical methods of examination.
3. Routine chest film in two planes.
4. Lung tomography.
5. Bronchography.
6. Angiopulmonography.
7. General blood and urine analyses.

Differential diagnostics

The abscess of lungs, in contrast with a suppurative cyst, is characterized by prompt course, expressed purulent intoxication, roentgenologically its wall is irregular, with proper considerable perifocal infiltration.

The cancer with destruction differs by a thick wall with a tuberos inner surface, phenomena of lymphangitis in adjacent tissue. The determinant value has endoscopic examination or puncture with a biopsy and following morphological investigation.

The tubercular cavern displaced in the upper lobes, in adjacent tissue revealed fibrosis, petrifications,

dissemination, peribronchial lymphadenitis. In the sputum – mycobacterium of tuberculosis.

Opposite to cyst, in termed diseases, the circumflex deformation of vascular branches never observed at angiopulmonography.

The considerable difficulties can arise at differentiation of the closed congenital cysts.

The **tuberculoma** differs from them by characteristic localization. At X-ray examination the heterogeneity of the shadow with calcifications, early excentric destruction, "tubercular" background is observed.

The **benign tumours** sometimes possible to differentiate only after the results of cytological investigation of punctate or after operation.

The **echinococci cysts** on tomogram can have a double contour of chitinous and fibrous sheaths. In blood analyses observed eosinophilia. The final decision is taken out after carrying out immunological (indirect microagglutination test) allergic (Cacconi's reaction) tests.

Huge cysts, in contrast with open air cysts, are characterized by a subpleural location.

The diagnostic doubts at suspicion on a **diaphragmatic hernia** are solved by radiopaque examination of a gastrointestinal tract.

The **acquired cysts** differ from congenital by roentgenological signs of the lesion of surrounding tissues (pneumofibrosis, deforming bronchitis, secondary bronchiectases, and calcifications). Postpneumonic cavities are of irregular shape, with grooves and pockets, their walls different thick. During bronchography they filled through some small bronchi. Sometimes the verification is possible only after postoperative morphological investigation.

Tactics and choice of treatment

The pulmonary cysts require the surgical treatment. In case of complications the indication for operation becomes absolute. Contraindications: the severe respiratory disturbance, concomitant malignant nonresectable tumors, vital organs dysfunction in the stage of permanent decompensation, elderly age of the patients.

The volume of the operation: if the adjacent pulmonary tissue is intact – cystectomy, otherwise – segmental or wedged resection, lobectomy.

The conservative therapy is applied in suppuration of cysts with the purpose of preoperative preparation. It is the similar, which applied for abscesses of lungs.

SPONTANEOUS PNEUMOTHORAX

Spontaneous pneumothorax is the entry of air in a pleural space with the further lung collapse, which not associated with traumatic damage of chest or pulmonary tissue.

Etiology and pathogenesis

As a result of spontaneous disrapture of lung blebs and subpleural air cysts occurs the damage of pleural visceral membrane. It causes entry of air in pleural space. Owing to its leakage the elastic pulmonary tissue collapses. The degree of the collapse of lung depends on amount of air, that has penetrated a pleural space.

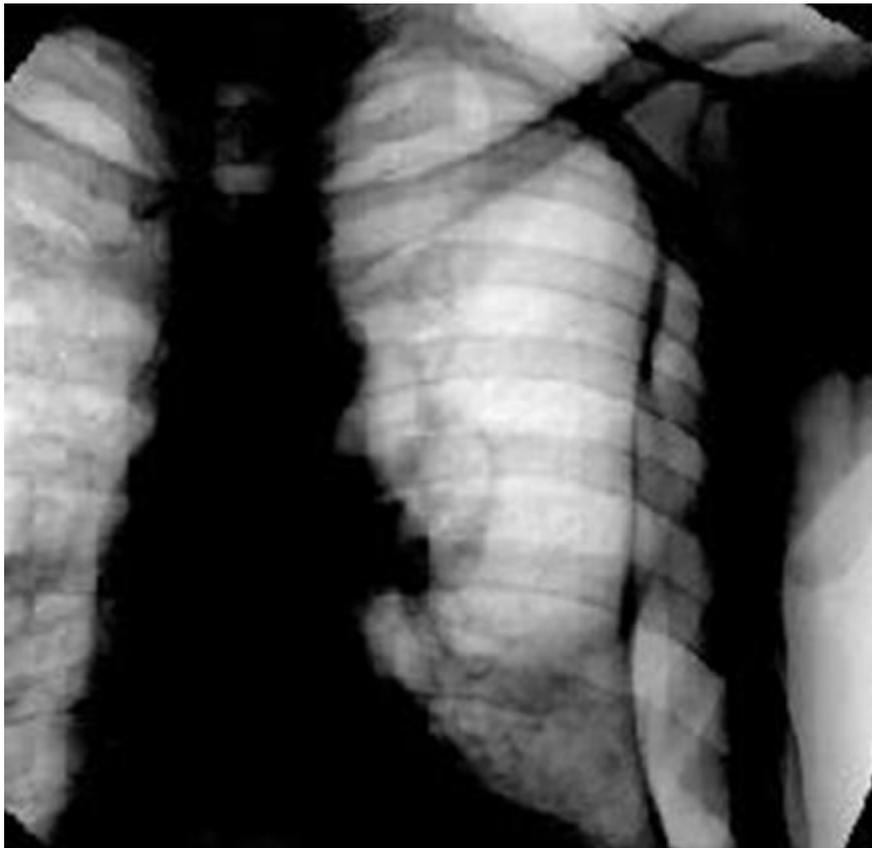

Pathology

Morphologically in spontaneous pneumothorax found out a focal bullous emphysema with disrapture of blebs, subpleural air cyst, and also disorders, which have caused disturbances of ventilating ability of bronchi. It can be bronchitis, pneumosclerosis, tuberculosis and fibrous alveolitis.

Classification

The pneumothorax can be:

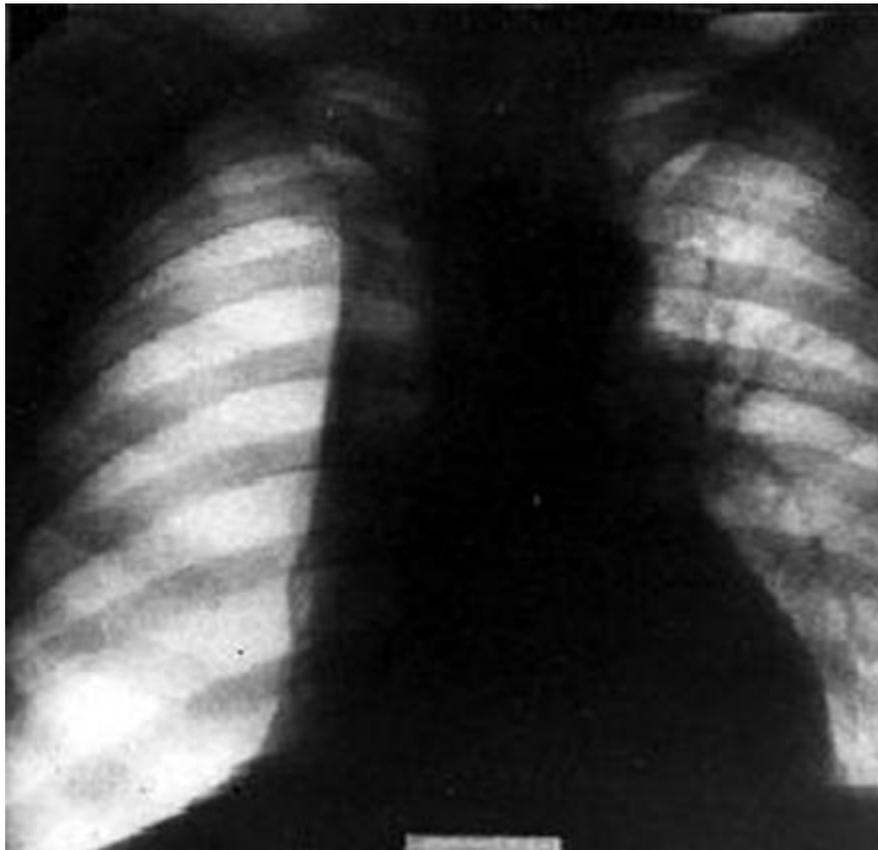

1. Unilateral or bilateral.
2. Partial (lung collapse to 1/3 of its volume).
3. Subtotal (lung collapse to 2/3 of its volume).
4. Total (lung collapse more than 2/3 of its volume).
5. Tension or valvular (complete collapse of lungs and shift of mediastinum in the opposite side).
6. Rigid (neglected pneumothorax with thickened visceral pleura).

Partial spontaneous pneumothorax

Subtotal spontaneous pneumothorax

Total spontaneous pneumothorax

Manifestation and clinical course

The onset of the disease is sudden. A state of the patient and expression of clinical manifestations depends on amount of air, which has entered the pleural space. Usually in normal conditions, and sometimes after physical activity, the patients suddenly feel acute pain on the side of lesion, dyspnea, pain in the heart region and heartbeating. An available also Acrocyanosis or total cyanosis of skin is observed. The circulatory disturbance depends on degree of hypoxia. Intensity of pain and dyspnea gradually decrease, but a dry troublesome cough appears.

Examination of the chest allows to observe expansion of intercostal spaces and restriction of respiratory excursion. By palpation - diminishing of vocal fremitus on the affected side. At percussion a chief sign of pneumothorax is the tympanic sound. Auscultation reveals weakened or sharply weakened breathing sounds. The cardiac tones are muffled, tachycardia.

The diagnosis of a spontaneous pneumothorax is confirmed by X-ray examination. On the plain roentgenogram the air is present in pleural space, and the margins of collapsed lung are found out on its background.

Thoracoscopy in pneumothorax possible to find out subpleural blebs of different sizes (0,5-3 cm), which are mainly disposed on the apex of lung.

Variants of clinical course and complications

The atypical (asymptomatic) spontaneous pneumothorax occurs in 20 % of the patients, and mainly revealed at X-ray examination. In most cases it is the partial pneumothorax.

The expressed pain syndrome and dyspnea, which resulting from collapse of lung, characterize subtotal and total pneumothorax.

The tension spontaneous pneumothorax is the most severe form of pneumothorax. It manifests by sudden onset, progressive increase of dyspnea, expressed cyanosis. The breathing is superficial, rapid, with active participation of auxiliary muscles. Mediastinal shift and flexion of vessels result in disturbance of cardiac activity up to the cardiac arrest, and requires urgent management.

Rigid pneumothorax (rigid lung). The neglected pneumothorax causes fibrinous exsudative pleurisy. On the surface of lung (visceral pleura) commissures are formed, that give no opportunity for lung expansion. The presence of residual pleural cavity and progressive development of a purulent infection result in occurrence of acute pleural empyema. In such cases the patients complain of the fever up to 38-38,5°C, general weakness and increasing of dyspnea. The phenomena of intoxication increase. Thus such patients require the treatment of pleural empyema.

The diagnostic program

1. Complaint and anamnesis of disease.
2. Physical findings.
3. Routine chest film (direct and lateral projection).
4. [Thoracentesis](#)
5. Thoracoscopy.
6. Tomography of lungs.

Differential diagnostics

Pleural effusion. This pathology manifests by more gradual onset. As opposite to pneumothorax, the complaints of chest pain predominate above the complaints of dyspnea. Frequently such patients specify on transferred undercooling.

As well as the spontaneous pneumothorax, the pleural effusion is characterized by diminishing of vocal fremitus, dullness of percussion sound, weakened or absent breathing sounds over the exudate. Nevertheless in the routine roentgenogram in such cases observed a homogeneous intensive shadow of a pleural space with oblique upper contour. The puncture of pleural space enables finally to confirm the diagnosis of pleural effusion.

Intercostal neuralgia. A predominant sign in clinical pattern is acute pain, which intensifies at physical activity, changes of body position and body movements, at deep breathing. The localization of pain coincides with zone of innervation of intercostal nerves.

Examination and chest X-radiography reveals no pathological changes.

Tactics and choice of treatment

Conservative treatment is applied in the patients with a partial pneumothorax. Thus thoracentesis in II intercostal space in the midclavicular line with aspiration of air is performed. The cases of its inefficiency, and also subtotal, total and tension pneumothorax require drainage of a pleural space with active aspiration of air.

The operative management is necessary, if there is no efficiency from active aspiration (in incomplete expansion of lung), recurrent of course of the process, presence of great subpleural blebs and rigid pneumothorax. Volume of operation depends on extension of the process: liquidation of alveolar fistula, wedged resection of lung or lobectomy.

PYOPNEUMOTHORAX

Pyopneumothorax is the discharge of lung abscess of into pleural space, which is accompanied by purulent inflammation of pleural membranes with a collapse of lung.

Etiology and pathogenesis

Peripheral placement of the purulent focus in a pulmonary tissue results in destruction (fusion) of visceral membrane. As a result of, the pus and air penetrate into a pleural space that leads to a purulent inflammation of parietal and visceral membranes of pleura. The disorder of hermeticity of a pleural space results in a lung collapse.

Among other causes of pyopneumothorax are the chest trauma, which results in collapse of lung, infection and purulent inflammation of pleural membranes.

As the basic causes of pyopneumothorax are considered:

- acute abscess of lung;
- gangrenous abscess of lung;
- gangrene of lung;
- suppurative cyst of lung;
- abscessing pneumonia;
- bronchiectatic disease;
- subphrenic abscess, which has discharged into pleural space;
- damage of esophagus;
- mediastinitis;
- chest trauma;
- operation and diagnostic manipulations on chest organs.

Pathology

Morphologically in pyopneumothorax pus and air are present in pleural space. In the lungs subpleural disposed purulent or necrotic foci, which connected with a pleural space through a pleuro-pulmonary fistula. From the outside the zone of disrapture is confined by perifocal inflammation. In the draining bronchus it is possible to see manifestations of deforming, frequently polypous bronchitis.

Classification

I. According to etiological factor:

1. Specific.
2. Nonspecific.

II. According to pathogenic factor:

1. Primary.
2. Secondary.

III. According to clinical course:

1. Asymptomatic form.
2. Mild form.
3. Acute form.

IV. According to extension of the process:

1. Localized pyopneumothorax:

- a) parietal;
- b) apical;
- c) epiphrenic;
- d) paramediastinal;
- e) polychamber.

2. Subtotal pyopneumothorax.

3. Total pyopneumothorax.

4. Tension pyopneumothorax.

Manifestation and clinical course

The clinic of pyopneumothorax depends on the size of the focus of destruction, which influences on degree of lung collapse, and on amount of purulent content in a pleural space.

The pain owing to discharge of the focus of destruction into pleural space often arises suddenly.

The dyspnea occurs as a result of collapse of lung owing to leakage of pus and air into pleural space. Its expression is in direct ratio to lung collapse. Therefore a dyspnea in rest observed in a subtotal and total pyopneumothorax. It sharply amplifies even at minor physical activity. Auxiliary muscles take part in order to force respiration.

The expectoration of sputum with ichorous smell is the outcome of destructive process in a pulmonary tissue. Its amount decreases after discharge of pus into pleural space.

Hectic fever with caused by enlargement of the area of resorption. The patients are adynamic, flaccid. Some of them are unconsciousness.

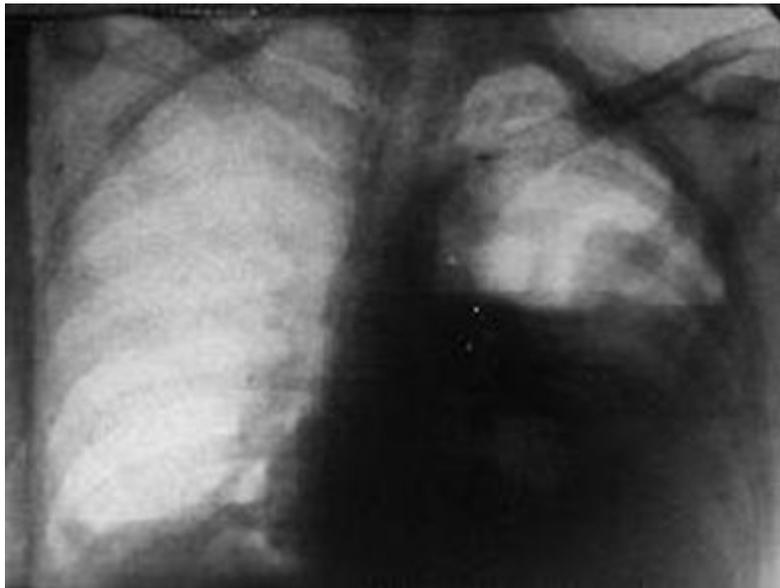

By objective examination the position of patients is forced, they sit in bed leaning upon the bed (subtotal, total pyopneumothorax). The affected hemithorax takes no part in respiration.

By palpation – diminished vocal fremitus on the side of lesion.

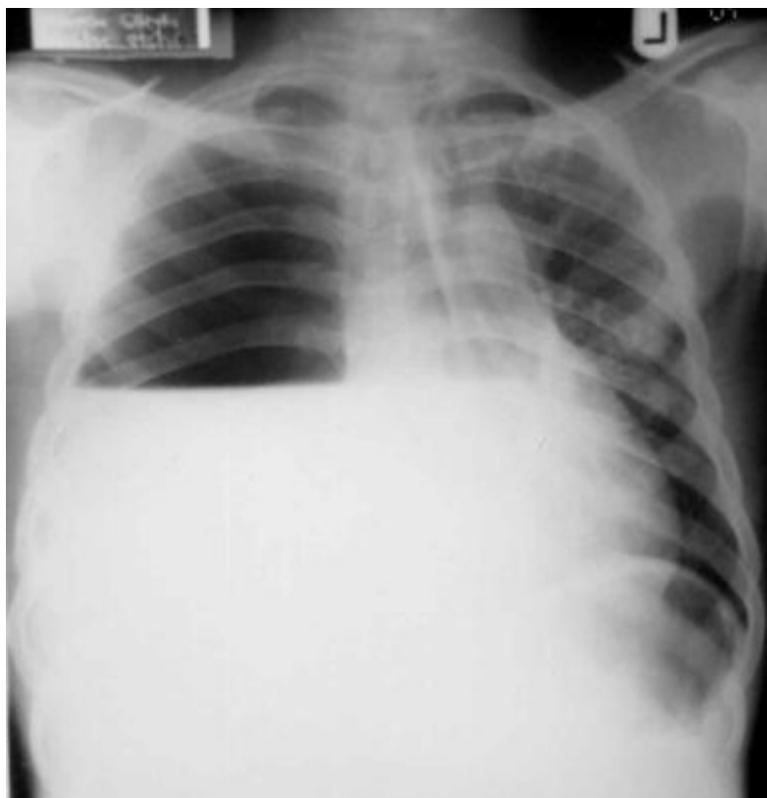

Percussion reveals a sharp shortening of sound over the zone of exudate and bandbox sound above the region of collapsed lung.

By auscultation there are no breathing sounds on the affected side. In case of localized pyopneumothorax – weakened or sharply weakened sound with a bronchial or amphoric tone.

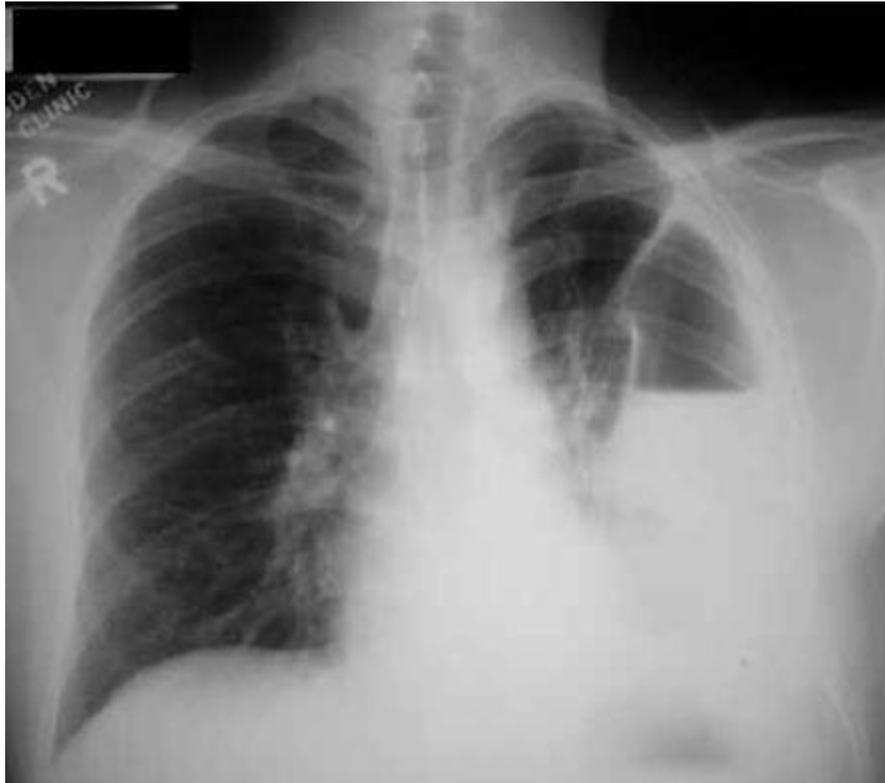

The X-ray picture of pyopneumothorax depends on its form, but the obligatory sign is the air-fluid level in a pleural space with well-defined edge of collapsed lung on its background.

Left-side total pyopneumothorax

Pyopneumothorax

Pyopneumothorax

Variants of clinical course and complications

The clinical course of pyopneumothorax depends on adhesions between pleural membranes. It sometimes changes typical clinical course of a total lung collapse. The clinic of disease depends also on amount of a purulent exudate. Therefore according to extension of the process and size of destruction of lung distinguished acute, mild and asymptomatic forms of pyopneumothorax. Especially difficult for diagnostics is the asymptomatic form of localized pyopneumothorax. Dyspnea for such pathology not characteristic, as the adhesion of membranes prevents complete collapse of lung. Dyspnea is vague or absent at all in partial collapse. A diminished vocal fremitus on side of pathological process, shortening of percussion sound and weakened or sharply weakened breathing sounds over the collapsed lung and exudate are revealed. Roentgenological manifestations in localized pyopneumothorax not expressed and include horizontal fluid level, margin of partially collapsed lung and minor air in the pleural space.

In most cases after discharge of the destructive focus in a pleural space and collapse of lung observed the closure of bronchopleural fistula. Nevertheless the inflammatory process in a pulmonary tissue and pleural space is going on.

The diagnostic program

1. Complaint and history of disease.
2. Physical findings.
3. Chest X-radiography examination.
4. [Thoracentesis](#).
5. Pleurography.
6. Bacterial culture and antibiotic sensitivity.
7. General blood, and urine analyses.
8. Biochemical blood analysis.

Differential diagnostics

They're no special necessity for differential diagnostics of pyopneumothorax in the majority of patients. History (presence of the purulent focus in a pulmonary tissue), clinical course (acute pain and dyspnea at abscess discharge into pleural space), and also chest X-ray findings and thoracentesis frequently reliably permit to make the diagnosis.

In some cases a localized pyopneumothorax according to clinical course resembles a huge acute abscess of lungs. But the differences of roentgenological symptomatology permit to verify these pathological processes. In acute lung abscess the cavity of destruction localized in a pulmonary parenchyma, it is of rounded form with horizontal fluid level and expressed perifocal infiltration.

Tactics and choice of treatment

The purpose of treatment should include sanitation of the destructive focus in pulmonary tissue and liquidation of complications; that means elimination of pus and air from a pleural space and prompt expanding of lung.

1. Active sanitation of tracheobronchial tree by means of [tracheocentesis](#).
2. [Draining of pleural space](#), active aspiration of its content (air, pus) to expand the lungs.
3. Lavage of pleural space by antiseptic solutions.
4. Appropriate antibacterial, antiinflammatory and infusion therapy.

5. The therapy for rising up of immunological resistance of the organism (staphylococcal anatoxin according to scheme, antistaphylococcal gamma-globulin, antistaphylococcal plasma).
6. Endolymphatic introduction of immunity stimulators (thymalin, thymogen, T-activin).

The indications for operative management are the same, as in pleural empyema.

CHEST TRAUMA .

Chest trauma is a significant source of morbidity and mortality in the United States. This article focuses on chest trauma caused by blunt mechanisms. Penetrating thoracic injuries are addressed in Penetrating Chest Trauma.

Blunt injury to the chest can affect any one or all components of the chest wall and thoracic cavity. These components include the bony skeleton (ribs, clavicles, scapulae, sternum), lungs and pleurae, tracheobronchial tree, esophagus, heart, great vessels of the chest, and the diaphragm. In the subsequent sections, each particular injury and injury pattern resulting from blunt mechanisms is discussed. The pathophysiology of these injuries is elucidated, and diagnostic and treatment measures are outlined.

Frequency

Trauma is responsible for more than 100,000 deaths annually in the United States. Estimates of thoracic trauma frequency indicate that injuries occur in 12 persons per million population per day. Approximately 33% of these injuries require hospital admission. Overall, blunt thoracic injuries are directly responsible for 20-25% of all deaths, and chest trauma is a major contributor in another 50% of deaths.

Pathophysiology

The major pathophysiologies encountered in blunt chest trauma involve derangements in the flow of air, blood, or both in combination. Blunt trauma commonly results in chest wall injuries (eg, rib fractures). The pain associated with these injuries can make breathing difficult, and this may compromise ventilation.

Direct lung injuries, such as pulmonary contusions, are frequently associated with major chest trauma and may impair ventilation by a similar mechanism.

Space-occupying lesions, such as pneumothoraces, hemothoraces, and hemopneumothoraces, interfere with oxygenation and ventilation by compressing otherwise healthy lung parenchyma. A situation of special concern is tension pneumothorax in which pressure continues to build in the affected hemithorax as air leaks from the pulmonary parenchyma into the pleural space. This can push mediastinal contents toward the opposite hemithorax. Distortion of the superior vena cava by this mediastinal shift can result in decreased blood return to the heart, circulatory compromise, and shock.

Relevant Anatomy

The thorax is bordered superiorly by the thoracic inlet, just cephalad to the clavicles. The major arterial blood supply to and venous drainage from the head and neck pass through the thoracic inlet.

The thoracic outlets form the superolateral borders of the thorax and transmit branches of the thoracic great vessels that supply blood to the upper extremities. The nerves that comprise the brachial plexus also access the upper extremities via the thoracic outlet. The veins that drain the arm, most importantly the axillary vein, empty into the subclavian vein, which returns to the chest via the thoracic outlet.

Inferiorly, the pleural cavities are separated from the peritoneal cavity by the hemidiaphragms. Communication routes between the thorax and abdomen are supplied by the diaphragmatic hiatuses, which allow egress of the aorta, esophagus, and vagal nerves into the abdomen and ingress of the vena cava and thoracic duct into the chest.

The chest wall is composed of layers of muscle, bony ribs, costal cartilages, sternum, clavicles, and scapulae. In addition, important neurovascular bundles course along each rib, containing an intercostal nerve, artery, and vein. The inner lining of the chest wall is the parietal pleura. The visceral pleura invests the lungs. Between the visceral and parietal pleurae is a potential space, which, under normal conditions, contains a small amount of fluid that serves mainly as a lubricant.

The lungs occupy most of the volume of each hemithorax. Each is divided into lobes. The right lung has 3 lobes, and the left lung has 2 lobes. Each lobe is further divided into segments.

The trachea enters through the thoracic inlet and descends to the carina at thoracic vertebral level 4, where it divides into the right and left mainstem bronchi. Each mainstem bronchus divides into lobar bronchi. The bronchi continue to arborize to supply the pulmonary segments and subsegments.

The heart is a mediastinal structure contained within the pericardium. The right atrium receives blood from the superior vena cava and inferior vena cava. Right atrial blood passes through the tricuspid valve into the right ventricle. Right ventricular contraction forces blood through the pulmonary valve and into the pulmonary arteries. Blood circulates through the lungs, where it acquires oxygen and releases carbon dioxide. Oxygenated blood courses through the pulmonary veins to the left atrium. The left heart receives small amounts of nonoxygenated blood via the thebesian veins, which drain the heart, and the bronchial veins.

Left atrial blood proceeds through the mitral valve into the left ventricle.

Left ventricular contraction propels blood through the aortic valve into the coronary circulation and the thoracic aorta, which exits the chest through the diaphragmatic hiatus into the abdomen. A ligamentous attachment (remnant of ductus arteriosus) exists between the descending thoracic aorta and pulmonary artery just beyond the take-off of the left subclavian artery.

The esophagus exits the neck to enter the posterior mediastinum. Through much of its course, it lies posterior to the trachea. In the upper thorax, it lies slightly to the right with the aortic arch and descending thoracic aorta to its left. Inferiorly, the esophagus turns leftward and enters the abdomen through the esophageal diaphragmatic hiatus. The thoracic duct arises primarily from the cisterna chyli in the abdomen. It traverses the diaphragm and runs cephalad through the posterior mediastinum in proximity to the spinal column. It enters the neck and veers to the left to empty into the left subclavian vein.

Clinical

The clinical presentation of patients with blunt chest trauma varies widely and ranges from minor reports of pain to florid shock. The presentation depends on the mechanism of injury and the organ systems injured.

Obtaining as detailed a clinical history as possible is extremely important in the assessment of a patient with a blunt thoracic trauma. The time of injury, mechanism of injury, estimates of MVA velocity and deceleration, and evidence of associated injury to other systems (eg, loss of consciousness) are all salient features of an adequate clinical history. Information should be obtained directly from the patient whenever possible and from other witnesses to the accident if available.

Classification

The closed damages of the chest are divided:

I. According to the injury of other organs:

1. Isolated trauma.
2. Combined trauma (craniocerebral, with damage of abdominal organs, with damage of bones).

II. According to the mechanism of trauma:

1. Contusion.
2. Compression.
3. Commotion.
4. Fracture.

III. According to the character of the chest viscerae damage:

1. Without damage of viscerae.
2. With damage of viscerae (lungs, trachea, bronchi, esophagus, heart, vessels, diaphragm etc.).

IV. According to the character of complications:

1. Uncomplicated.
2. Complicated:
 - 1) Early (pneumothorax, hemothorax, subcutaneous, mediastinal emphysema floative rib fracture, traumatic shock, asphyxia);
 - 2) Late (posttraumatic pneumonia, posttraumatic pleurisy, suppurative diseases of lungs and pleura).

V. According to the state of cardiopulmonary system:

1. Without phenomena of respiratory failure.
2. Acute respiratory failure (of I, II, III degree).
3. Without phenomena of cardiovascular failure.
4. Acute cardiovascular failure (of I, II, III degree).

VI. According to the gravity of a trauma:

1. Mild.
2. Moderate.
3. Severe.

RIB FRACTURE

Simple rib fractures are the most common injury sustained following blunt chest trauma, accounting for more than half of thoracic injuries from nonpenetrating trauma. Approximately 10% of all patients admitted after blunt chest trauma have one or more rib fractures. These fractures are rarely life-threatening in themselves but can be an external marker of more severe visceral injury inside the abdomen and the chest.

The most common mechanism of injury for rib fractures in elderly persons is a fall from height or from standing. In adults, motor vehicle accident (MVA) is the most common mechanism. Youths sustain rib fractures most often secondary to recreational and athletic activities.

Rib fractures may compromise ventilation by a variety of mechanisms. Pain from rib fractures can cause respiratory splinting, resulting in atelectasis and pneumonia. Multiple contiguous rib fractures (ie, flail chest) interfere with normal costovertebral and diaphragmatic muscle excursion, potentially causing ventilatory insufficiency. Fragments of fractured ribs can also act as penetrating objects leading to the formation of a hemothorax or a pneumothorax. Ribs commonly fracture at the point of impact or at the posterior angle (structurally their weakest area). Ribs four through nine (4-9) are the most commonly injured.

Physical

Rib fractures are the most common blunt thoracic injuries. Ribs 4-10 are most frequently involved. Patients usually report inspiratory chest pain and discomfort over the fractured rib or ribs. Physical findings include local tenderness and crepitus over the site of the fracture. If a pneumothorax is present, breath sounds may be decreased and resonance to percussion may be increased. Rib fractures may also be a marker for other associated significant injury, both intrathoracic and extrathoracic. In one report, 50% of patients with blunt cardiac injury have rib fractures. Fractures of ribs 8-12 should raise the suggestion of associated abdominal injuries. Lee and colleagues reported a 1.4- and 1.7-fold increase in the incidence of splenic and hepatic injury, respectively, in those with rib fractures.

Paradoxical chest wall excursion with inspiration is seen with flail chest. A flail chest occurs when a large segment of ribs is not attached to the spine. These ribs are broken in at least 2 places on each rib. The paradoxical movement occurs because the middle section of the rib between the 2 fracture sites moves in response to intrathoracic pressure changes not intercostal muscle contractions.

Specific signs of ventilatory insufficiency include cyanosis, tachypnea, retractions, and use of accessory muscles for ventilation.

If fracture of the lower ribs is suspected, assess the patient for abdominal tenderness and costal margin tenderness, which could raise suspicion for injury to intra-abdominal organs.[14]

Chest radiographs

Anteroposterior (AP) and lateral chest films are used routinely to assist in the diagnosis of rib fractures, yet sensitivity as low as 50% has been reported. Delayed or follow-up radiographs can be very helpful.

Chest radiographs are much more useful in the diagnosis of underlying injuries, including hemothorax, pneumothorax, lung contusion, atelectasis, pneumonia, and vascular injuries.

Findings of sternal fracture[3] or scapular fracture[15] should increase suspicion for rib fractures.

Chest CT scan

A chest CT scan is more sensitive than plain radiographs for detecting rib fractures. The modality can also provide information regarding the number of ribs involved.

If complications from rib fractures are suspected clinically or diagnosed by plain radiographs, a chest CT scan may be helpful to document specific injuries, to characterize extent of injury, and to plan for definitive management.

An associated CT scan of the abdomen with intravenous contrast should be considered in cases involving lower rib fractures with suspected or known injury to the liver and/or the spleen.

The fracture of the VI-VIII left ribs

First and second rib fractures

First and second rib fractures are considered a separate entity from other rib fractures because of the excessive energy transfer required to injure these sturdy and well-protected structures. First and second rib fractures are harbingers of associated cranial, major vascular, thoracic, and abdominal injuries. The clinician should aggressively seek to exclude the presence of these other injuries.

Pain control and pulmonary toilet are the specific treatment measures for rib fractures. First and second rib fractures do not require surgical therapy. An exception to this would be the need to excise a greatly displaced bone fragment.

Treatment

Elderly patients with 3 or more rib fractures have been shown to have a 5-fold increased mortality rate and a 4-fold increased incidence of pneumonia. Effective pain control is the cornerstone of medical therapy for patients with rib fractures. For most patients, this consists of oral or parenteral analgesic agents. Intercostal nerve blocks may be feasible for those with severe pain who do not have numerous rib fractures. A local anesthetic with a relatively long duration of action (eg, bupivacaine) can be used. Patients with multiple rib fractures whose pain is difficult to control can be treated with epidural analgesia.

Adjunctive measures in the care of these patients include early mobilization and aggressive pulmonary toilet. Rib fractures do not require surgery. Pain relief and the establishment of adequate ventilation are the therapeutic goals for this injury. Rarely, a fractured rib lacerates an intercostal artery or other vessel, which requires surgical control to achieve hemostasis acutely. In the chronic phase, nonunion and persistent pain may also require an operation.

The direct force of traumatizing factor on the chest wall results in rib fracture.

The pain localized in the zone of damage, is the chief clinical manifestation. The pain intensifies at respiration, cough and change of a body position of the patient. The overwhelming majority of the patients complain of crepitation of ribs in the fracture site.

At examination the respiratory lag on affected side is observed.

Crepitating of osseous fragment revealed by palpation, and depending on number of injured ribs – diminished

breathing sounds by auscultation.

On chest roentgenograms the break in continuity of bone fragments of ribs is observed.

Floating rib fracture (flail chest)

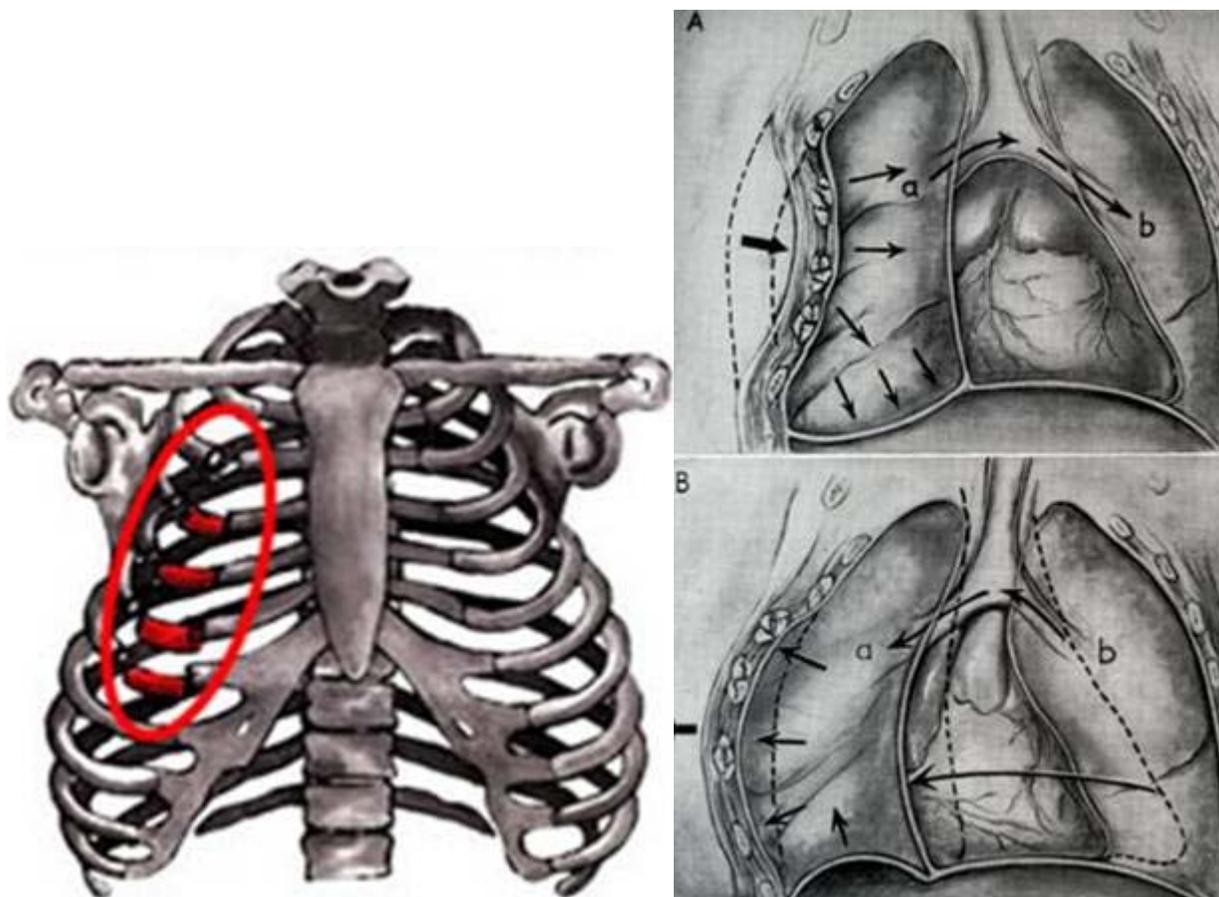

This is one of the most severe complication of the closed trauma of the chest. The floatation arises from fracture of three and more ribs along two anatomic lines. The multiple rib fractures produce an unstable segment of chest wall that moves paradoxically inward upon inspiration and balloons outward during expiration (flail chest). Thereby the respiration disturbed not only in the area of a floating segment, but also in all lungs. The permanent movement of flail chest result in rocking shift of mediastinum, which causes deviation of its organs. As a result the respiratory failure is associated with cardiovascular.

A flail chest, by definition, involves 3 or more consecutive rib fractures in 2 or more places, which produces a free-floating, unstable segment of chest wall. Separation of the bony ribs from their cartilaginous attachments, termed costochondral separation, can also cause flail chest. Patients report pain at the fracture sites, pain upon inspiration, and, frequently, dyspnea. Physical examination reveals paradoxical motion of the flail segment. The chest wall moves inward with inspiration and outward with expiration. Tenderness at the fracture sites is the rule. Dyspnea, tachypnea, and tachycardia may be present. The patient may overtly exhibit labored respiration due to the increased work of breathing induced by the paradoxical motion of the flail segment.

A significant amount of force is required to produce a flail segment. Therefore, associated injuries are common and should be aggressively sought. The clinician should specifically be aware of the high incidence of associated thoracic injuries such as pulmonary contusions and closed head injuries, which, in combination, significantly increase the mortality associated with flail chest.

All of the treatment modalities mentioned above for patients with rib fractures are appropriate for those with flail chest. Respiratory distress or insufficiency can ensue in some patients with flail chest because of severe pain secondary to the multiple rib fractures, the increased work of breathing, and the associated pulmonary contusion. This may necessitate endotracheal intubation and positive pressure mechanical ventilation. Intravenous fluids are administered judiciously because fluid overloading can precipitate respiratory failure, especially in patients with significant pulmonary contusions.

In an attempt to stabilize the chest wall and to avoid endotracheal intubation and mechanical ventilation, various operations have been devised for correcting flail chest. These include pericostal sutures, the application of external fixation devices, or the placement of plates or pins for internal fixation. With improved understanding of pulmonary mechanics and better mechanical ventilatory support, surgical therapy has not been proven superior to the supportive and medical measures discussed. However, most authors would agree that stabilization is warranted if a thoracotomy is indicated for another reason.

Flail chest

Classification

1. Central floating segment – a multiple rib fracture along parasternal or midclavicular lines.
2. Anterolateral floating segment – a multiple rib fracture along parasternal and anteaillary lines.

3. Lateral floating segment – a multiple rib fracture along anterior and posterior axillary lines.
4. Posterior floating segment – a multiple rib fracture along postaxillary and paravertebral lines.

Symptomatology and clinical course

The patient's state is grave or extremely grave. The expressed pain syndrome frequently results in traumatic shock. The patient is restless. Observed the cyanosis of skin, tachypnea, and tachycardia to 120-160 beat/min of weak filling and tension. Arterial pressure at first elevated, then its decrease observed. At examination characteristic paradoxical respiratory movements of chest, inward upon inspiration and outward during expiration, crepitus of bone fragments by palpation are revealed. Breathing sounds diminished on the side of damage by auscultation.

In case of floating rib fracture the chest X-ray examination reveals multiple, double rib fracture with deformity of the chest.

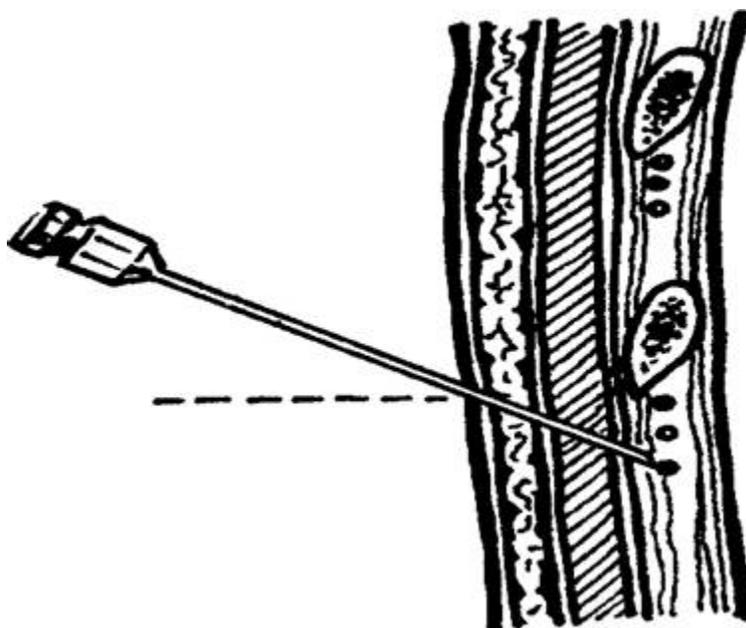

Flail chest

In 75 % of cases the multiple rib fracture is the cause of injury of lungs, pneumothorax or pneumohemothorax.

Treatment

Pain relief in closed trauma of the chest is achieved by means of different blocks:

1. Vagosympathetic block;
2. Alcohol - novocaine block of the site of fracture;
3. Paravertebral block.

Alcohol - novocaine block of the site of fracture

Except blocks, in some cases analgesics and opiates are instituted. On 2-3 day desirable the administration of electrophoresis with novocaine. For prophylaxis of congested phenomena in a pulmonary tissue used respiratory gymnastics, forced ventilation of lungs, inhalations.

The methods of reduction of the skeleton of the flail chest are divided onto three groups:

1. External fixation of a movable segment by means of suturing for intercostal muscles and traction during 2-3 weeks;
2. Intramedullary costal osteosynthesis;
3. Mechanical ventilation (often with positive end-expiratory pressure).

BREASTBONE FRACTURE

Most sternal fractures are caused by MVAs. The upper and middle thirds of the bone are most commonly affected in a transverse fashion. Patients report pain around the injured area. Inspiratory pain or a sense of dyspnea may be present. Physical examination reveals local tenderness and swelling. Ecchymosis is noted in the area around the fracture. A palpable defect or fracture-related crepitus may be present.

Associated injuries occur in 55-70% of patients with sternal fractures. The most common associated injuries are rib fractures, long bone fractures, and closed head injuries. The association of blunt cardiac injuries with sternal fractures has been a source of great debate. Blunt cardiac injuries are diagnosed in fewer than 20% of patients with sternal fractures. Caution should be used before completely excluding myocardial injury. The workup should begin with an ECG.

Most sternal fractures require no therapy specifically directed at correcting the injury. Patients are treated with analgesics and are advised to minimize activities that involve the use of pectoral and shoulder girdle muscles. The most important aspect of the care for these patients is to exclude blunt myocardial and other associated injuries. Patients who are experiencing severe pain related to the fracture and those with a badly displaced fracture are candidates for open reduction and internal fixation. Various techniques have been described, including wire suturing and the placement of plates and screws. The latter technique is associated with better outcomes.

The fracture of breastbone is commonly caused by direct forces at the site of the sternum. Usually it is the outcome of compression or result of trauma to vehicle helm.

The fracture in most cases located in the upper and medial thirds of breastbone.

The patients complain of severe pain in the site of fracture, which intensifies at respiration and movements. The pain behind the sternum and in the heart area follows the contusion of lungs and heart. Sometimes hemoptysis is observed.

Examination reveals the deformity of breastbone in the site of fracture. Displaced fragments are palpated here, that accompanied by severe pain syndrome.

By auscultation, if there are no intrapleural complications, the respiration in the first 2-3 days is vesicular from both sides. Then the fine bubbling rales are auscultated which is the first objective manifestation of a posttraumatic pneumonia.

The complete fracture of breastbone is characterized by a break in continuity of both cortical plates with a local dislocation of fragments.

Fracture of breastbone

The diagnostic program

1. Complaints and history of the disease.
2. Physical findings.
3. Chest roentgenograms in two planes.

Treatment

The sternal fracture without displacement of fragments requires conservative treatment. The fracture of the

corpus of breastbone with dislocation of fragments quite often requires operative treatment with performance of osteosynthesis.

POSTTRAUMATIC PNEUMOTHORAX

Pneumothorax is defined as the presence of air or gas in the pleural cavity, that is, in the potential space between the visceral and parietal pleura of the lung. The result is collapse of the lung on the affected side. Air can enter the intrapleural space through a communication from the chest wall (ie, trauma) or through the lung parenchyma across the visceral pleura.

Spontaneous pneumothorax is a commonly encountered problem with approaches to treatment that can vary from observation to aggressive intervention. Spontaneous pneumothorax occurs in people without underlying lung disease and in the absence of an inciting event. In other words, air is present in the intrapleural space without preceding trauma and without underlying clinical or radiologic evidence of lung disease. However, many patients whose condition is labeled as spontaneous pneumothorax have subclinical lung disease. Patients are typically between age 18 and 40 years.

Spontaneous pneumothoraces in most patients occur from the rupture of blebs and bullae. Although primary spontaneous pneumothorax (PSP) is defined as a lack of underlying pulmonary disease, these patients have asymptomatic blebs and bullae detected on computed tomography scans or upon thoracotomy. PSP is typically observed in tall, young people without parenchymal lung disease and is thought to be related to increased shear forces in the apex.

Traumatic pneumothorax results from injury, typically blunt trauma or penetrating trauma that disrupts the parietal or visceral pleura (see the images below). The mechanisms of injury are secondary to medical or surgical procedures. Pneumothoraces due to trauma are relatively straightforward and usually require tube thoracostomy.

Pathophysiology

The pleural space has a negative pressure, with the chest wall tending to spring outward and the lung's elastic recoil tending to collapse. If the pleural space is invaded by gas from a ruptured bleb, the lung collapses until equilibrium is achieved or the rupture is sealed. As the pneumothorax enlarges, the lung becomes smaller. The main physiologic consequence of this process is a decrease in vital capacity and partial pressure of oxygen.

Tension pneumothorax occurs anytime a disruption involves the visceral pleura, parietal pleura, or the tracheobronchial tree. This condition develops when injured tissue forms a 1-way valve, allowing air inflow into the pleural space and prohibiting air outflow. The volume of this nonabsorbable intrapleural air increases with each inspiration because of the 1-way valve

effect. In addition to this mechanism, the positive pressure used with mechanical ventilation therapy can cause air trapping. As a result, pressure rises within the affected hemithorax.

As the pressure increases, the ipsilateral lung collapses and causes hypoxia. Further pressure build-up causes the mediastinum to shift toward the contralateral side and impinge on and compress both the contralateral lung and the vasculature entering the right atrium of the heart. Hypoxia results as the collapsed lung on the affected side and the compressed lung on the contralateral side compromise effective gas exchange. This hypoxia and decreased venous return caused by compression of the relatively thin walls of the atria impair cardiac function. The inferior vena cava is thought to be the first to kink and restrict blood flow back to the heart. It is most evident in trauma patients who may be hypovolemic with reduced venous blood return to the heart.

Arising from numerous causes, this condition rapidly progresses to respiratory insufficiency, cardiovascular collapse, and, ultimately, death if unrecognized and untreated.

Classification

I. According to extension of process:

1. Unilateral.
2. Bilateral.

II. According to degree of a lung collapse:

1. Partial (collapse of lung to 1/3 of its volume).
2. Subtotal (collapse of lung to 2/3 of its volume).
3. Total (collapse of lung exceeding 2/3 of its volume).

Estimating the size of the pneumothorax

In evaluating the chest radiograph, first impressions of pneumothorax size can be misleading. The following methods may be used to estimate the size of the pneumothorax:

Calculate the ratio of the transverse radius of the pneumothorax (cubed) to the transverse radius of the hemithorax (cubed). To express the pneumothorax size as a percentage, multiply the fractional size by 100. This formula assumes a constant shape of the lung when it collapses and is invalid if pleural adhesions are present. The ratio of lung size to hemithorax size to

estimate pneumothorax size avoids the subjective underestimation of pneumothorax expressed as a percentage of previous lung volume.

A 2.5-cm margin of gas peripheral to the collapsing lung corresponds to a pneumothorax of about 30%. Complete collapse of the lung is a 100% pneumothorax.

A simple approach involves measuring the distance from the apex of the lung to the top margin of the visceral pleura (thoracic cupola) on the upright chest radiograph, such that a small pneumothorax is a distance to the apex that measures less than 3 cm and large pneumothorax has greater than 3 cm distance to the apex.

III. According to the mechanism of occurrence:

1. Closed.
2. Open.
3. Valvular.

The closed pneumothorax is the complication, which arises from the damage of visceral pleural membrane, which results in entry of air in a pleural space and atelectasis of lung. In chest trauma the cause of occurrence of the closed pneumothorax is the perforation of a visceral pleura and pulmonary tissue by the fragment of fractured rib.

The open pneumothorax results from formation of hole in a chest wall at massive trauma and free entry of air during inspiration inward a pleural space, and during expiration – outward.

The valvular pneumothorax occurs at damage of a pulmonary tissue or chest wall with formation of the valve, when the air during inspiration enters a pleural space, and during expiration, due to valve closure, does not exits outside. It is the most dangerous form of pneumothorax, which results in a complete pulmonary collapse, shift of mediastinum, inflection of major vessels and cardiac arrest.

Symptomatology and clinical course

The chief clinical manifestation of posttraumatic pneumothorax, which results from a pulmonary collapse, is the rest dyspnea, which amplifies at a minor exertion. This sign arises due to atelectasis of lung and its exclusion from breathing. On the background of collapsed lung only the main and lobar bronchi and pleural space are ventilated. The oxygenation of blood in collapsed lungs does not occur, therefore the shunting of a venous blood arise.

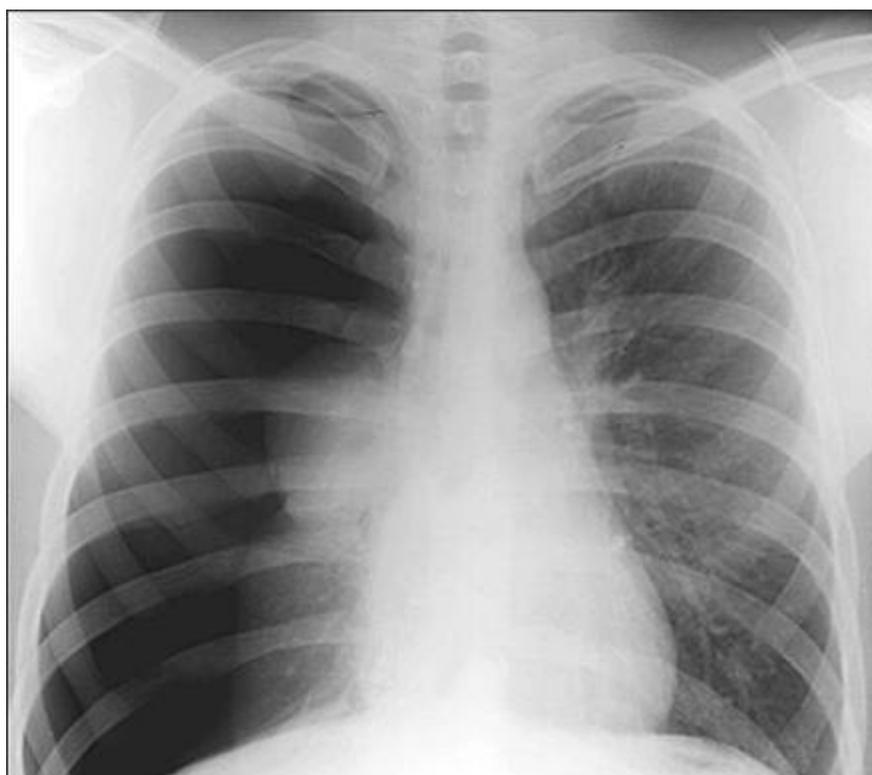

The chest pain is more characteristic manifestation for trauma with the damage of ribs, however pulmonary collapse also can associate with a pain syndrome. Nevertheless the patients promptly adapt for it and the

dyspnea finally remains the basic clinical manifestation of such complication.

On the background of severe trauma of the chest the signs of damage dominate in clinical manifestation on inappreciable entry of air in a pleural space. Pneumothorax mostly revealed during X-ray examination. Progressing of air entry in a pleural space and pulmonary collapse cause the respiratory lag on affected side. By palpation the vocal fremitus is absent. It indicates the origin of the complication – rib fracture.

Percussion obtains bandbox sound, or pulmonary sound with tympanitis. By auscultation - weak or absent breathing sounds, sometimes – amphoric respiration. The expressiveness of clinical pattern depends on degree of a pulmonary collapse.

Pulmonary atelectasis and presence of air in a pleural space are the X-ray findings that enable to establish the final diagnosis.

Right-side pneumothorax

The diagnostic program

1. Complaints and history of the disease.

The presentation of patients with pneumothorax varies depending on the type of

pneumothorax.

Spontaneous and iatrogenic pneumothorax

Despite descriptions of Valsalva maneuvers and increased intrathoracic pressures as inciting factors, spontaneous pneumothorax usually develops at rest. By definition, spontaneous pneumothorax is not associated with trauma or stress. Symptoms of iatrogenic pneumothorax are similar to those of a spontaneous pneumothorax and, depend on the age of the patient, the presence of underlying lung disease, and the extent of the pneumothorax.

Until a bleb ruptures and causes pneumothorax, no clinical signs or symptoms are present in primary spontaneous pneumothorax (PSP). Young and otherwise healthy patients can tolerate the main physiologic consequences of a decrease in vital capacity and partial pressure of oxygen fairly well, with minimal changes in vital signs and symptoms, but those with underlying lung disease may have respiratory distress. The most common underlying abnormality in secondary spontaneous pneumothorax is chronic obstructive pulmonary disease (COPD), and cystic fibrosis carries one of the highest associations, with more than 20% reporting spontaneous pneumothorax.

In one series, acute onset of chest pain and shortness of breath were present in all patients in one series; typically, both symptoms are present in 64-85% of patients. The chest pain is described as severe and/or stabbing, radiates to the ipsilateral shoulder and increases with inspiration (pleuritic). In PSP, chest often improves over the first 24 hours, even without resolution of the underlying air accumulation. Well-tolerated primary pneumothorax can take 12 weeks to resolve. In secondary pneumothorax (SSP), the chest pain is more likely to persist with more significant clinical symptoms.

Shortness of breath/dyspnea in PSP is generally of sudden onset and tends to be more severe with secondary spontaneous pneumothoraces (SSPs) because of decreased lung reserve. Anxiety, cough, and vague presenting symptoms (eg, general malaise, fatigue) are less commonly observed.

A history of previous pneumothorax is important, as recurrence is common, with rates reported between 15% and 40%. Up to 15% of recurrences can be on the contralateral side. Secondary pneumothoraces are often more likely to recur, with cystic fibrosis carrying the highest recurrence rates at 68-90%. No study has shown that the number or size of blebs and bullae found in the lung can be used to predict recurrence.

Tension pneumothorax

Signs and symptoms of tension pneumothorax are usually more impressive than those seen with a simple pneumothorax, and clinical interpretation of these is crucial for diagnosing

and treating the condition. Unlike the obvious patient presentations oftentimes used in medical training courses to describe a tension pneumothorax, actual case reports include descriptions of the diagnosis of the condition being missed or delayed because of subtle presentations that do not always present with the classically described clinical findings of this condition.

Symptoms of tension pneumothorax may include chest pain (90%), dyspnea (80%), anxiety, fatigue, or acute epigastric pain (a rare finding).

2. Physical examination.

The general appearance of the patient with pneumothorax may vary from asymptomatic to respiratory distress. It may include diaphoresis, splinting chest wall to relieve pleuritic pain, and cyanosis (in the case of tension pneumothorax). Findings on lung auscultation also vary depending on the extent of the pneumothorax. Affected patients may also reveal altered mental status changes, including decreased alertness and/or consciousness (a rare finding).

Respiratory findings may include the following:

- Respiratory distress (considered a universal finding) or respiratory arrest
- Tachypnea (or bradypnea as a preterminal event)
- Asymmetric lung expansion: A mediastinal and tracheal shift to the contralateral side can occur with a large tension pneumothorax.
- Distant or absent breath sounds: Unilaterally decreased or absent lung sounds is a common finding, but decreased air entry may be absent even in an advanced state of the disease.
- Lung sounds transmitted from the unaffected hemithorax are minimal with auscultation at the midaxillary line
- Hyperresonance on percussion: This is a rare finding and may be absent even in an advanced state of the disease.
- Decreased tactile fremitus

Adventitious lung sounds (crackles, wheeze; an ipsilateral finding)

- Cardiovascular findings may include the following:
- Tachycardia: This is the most common finding. If the heart rate is faster than 135 beats per minute (bpm), tension pneumothorax is likely.
- Pulsus paradoxus
- Hypotension: This should be considered as an inconsistently present finding; although hypotension is typically considered a key sign of a tension pneumothorax, studies suggest that hypotension can be delayed until its

appearance immediately precedes cardiovascular collapse.

- Jugular venous distention: This is generally seen in tension pneumothorax, although it may be absent if hypotension is severe.
- Cardiac apical displacement: This is a rare finding.

3. Chest X-radiography in 2 planes.

Portable chest radiography should always be included in the initial radiographic evaluation of major trauma, as significant chest injuries carry an estimated 10-50% risk of associated pneumothorax. Chest computed tomography (CT) scanning should always be performed for significant chest injuries, because they carry an estimated risk of associated pneumothorax as high as 50% and about half of these pneumothoraces may be occult.

When evaluating the chest radiograph for pneumothorax, assess rotation, which can obscure a pneumothorax and mimic a mediastinal shift. Compare the symmetry and shape of the clavicles, and look at the relative lengths of the ribs in the middle lung fields on each side on the anteroposterior (AP) or posteroanterior (PA) views. On an image with rotation, the ribs on each side often have unequal lengths.

In a nonloculated pneumothorax, air rises to the nondependent portion of the pleural cavity. Therefore, carefully examine the apices of an upright chest radiograph, and scrutinize the costophrenic and cardiophrenic angles on a supine chest radiograph.

Finding of pneumothorax on chest radiographs may include the following:

- A linear shadow of visceral pleura with lack of lung markings peripheral to the shadow may be observed, indicating collapsed lung.
- An ipsilateral lung edge may be seen parallel to the chest wall.
- In supine patients, deep sulcus sign (very dark and deep costophrenic angle) with radiolucency along costophrenic sulcus may help to identify occult pneumothorax. The anterior costophrenic recess becomes the highest point in the hemithorax, resulting in an unusually sharp definition of the anterior diaphragmatic surface due to gas collection and a depressed costophrenic angle
- Small pleural effusions commonly are present and increase in size if the pneumothorax does not reexpand.
- Mediastinal shift toward the contralateral lung may also be apparent.
- Airway or parenchymal abnormalities in the contralateral lung suggest causes of secondary pneumothorax. Evaluation of the parenchyma in the collapsed lung is less reliable.

Although expiratory images are thought to better depict subtle pneumothoraces (the volume of the pneumothorax is constant and hence proportionally higher on expiratory images), a randomized controlled trial revealed no difference in the ability of radiologists to detect pneumothoraces on inspiratory and expiratory images after procedures with the potential to cause pneumothoraces.

4. [Thoracentesis](#).
5. ECG.
6. Chest CT Scanning

Computed tomography (CT) scanning is the most reliable imaging study for the diagnosis of pneumothorax, but it is not recommended for routine use in pneumothorax. This imaging modality can help to accomplish the following:

- Distinguish between a large bulla and a pneumothorax
- Indicate underlying emphysema or emphysemalike changes (ELCs)
- Determine the exact size of the pneumothorax, especially if it is small
- Confirm the diagnosis of pneumothorax in patients with head trauma who are mechanically ventilated
- Detect occult/small pneumothoraces and pneumomediastinum (although the clinical significance of these occult pneumothoraces is unclear, particularly in the stable nonintubated patient)

CT scanning is widely used in actual clinical practice to assess the possibility of associated concurrent pulmonary disease because of the inherent superiority of CT scans to visualize the details of lung parenchyma and pleura, as can be seen in the images below.

When performed on primary spontaneous pneumothorax patients, CT detects multiple blebs and bullae in the setting of negative chest radiographic findings. This may not impact management, as there has been no correlation between number of blebs and recurrence. However, CT scanning may have a role in secondary spontaneous pneumothorax, especially to differentiate from giant bullous emphysema.

CT scanning can detect occult pneumothorax in patients who will require mechanical ventilation in trauma and emergency surgery settings. This modality has also been shown to be more sensitive than radiography for hemothorax and pulmonary contusion.

Collapse of the lung, air in the pleural cavity, and deviation of mediastinal structures are present in tension pneumothorax.

Treatment

A chest trauma, which complicated by pneumothorax with a partial pulmonary collapse (to 1/3 of volume) is indication to aspiration of air by means of thoracentesis. The cases, if the negative pressure in a pleural space is not obtained, and also subtotal, and total pneumothorax require closed [drainage of a pleural space](#).

Under the local anesthesia by solution of novocaine in II intercostal space in the midclavicular line by means of a trocar in a pleural space inserted a plastic tube, which fixed to skin. The drainage connects to [aspirative system](#) or according to method of Bulau. In the majority of patients the pneumothorax liquidates in some hours, or during 1-2 days.

The absence of effect (incomplete expansion of lung) of active aspiration, and also valvular closed pneumothorax is the indications to operative management – suturing of the pulmonary wound. In some cases a segmental resection of lung, or lobectomy is carried out.

Emergent Needle Decompression

Tension pneumothorax is a life-threatening condition that demands urgent management. If this diagnosis is suspected, do not delay treatment in the interest of confirming the diagnosis (ie, before radiologic evaluation).

The basic principle of emergent needle decompression is to introduce a catheter into the pleural space, thus producing a pathway for the air to escape and relieving the built-up pressure. Although this procedure is not the definitive treatment for tension pneumothorax, emergent needle decompression does arrest its progression and serves to restore cardiopulmonary function slightly. Needle length in persons with large pectoral muscles may be an issue, and long needles or angiocatheters may be necessary.

Immediately place the patient on 100% oxygen, ventilate the patient if necessary, and evaluate the patient for evidence of respiratory compromise, hemodynamic instability, or clinical deterioration.

Essentially, a large-bore (16 or 18 gauge) angiocatheter is introduced in the midclavicular line at the second intercostal space. Use large-bore catheters, because hemothorax can be associated with pneumothorax, and the patient may, therefore, require immediate intravenous (IV) infusion. Upright positioning, if not inappropriate due to cervical spine or trauma concerns, may be beneficial. This serves as a bridge until the definitive

treatment of tube thoracostomy. The catheter is left in place until the chest tube is placed.

The procedure is as follows:

- Locate the anatomic landmarks and quickly prepare the area to be punctured with an iodine-based solution (eg, Betadine).
- Insert a large-bore needle with a catheter into the second intercostal space, just superior to the third rib at the midclavicular line, 1-2 cm from the sternal edge (ie, to avoid injury to the internal thoracic artery). Use a catheter or needle >5 cm long, and hold it perpendicular to the chest wall when inserting; however, note that some patients may have a chest wall thickness greater than 5 cm, and failure for the symptoms to resolve may be attributed to inadequate needle length.[1, 2, 3]
- Once the needle is in the pleural space, listen for the hissing sound of air escaping to confirm the diagnosis of tension pneumothorax (note this finding on the patient's chart). In an area with high ambient noise, the escape of air may not be detected. Remove the needle while leaving the catheter in place.
- Secure the catheter in place, and install a flutter valve.

After needle decompression, immediately begin preparation to insert a thoracostomy tube. Then, reassess the patient, paying careful attention to the ABCs (ie, airway, breathing, circulation) of trauma management.

Needle Aspiration

Nonemergent needle aspiration can be used to treat a small primary spontaneous pneumothorax (PSP) or an iatrogenic pneumothorax.

The procedure is as follows:

- Palpate the rib and intercostal space intended for needle aspiration. For needle aspiration, the anterior approach at the second or third intercostal space at the midclavicular line or a lateral approach at the fifth or sixth intercostal space at the midaxillary line is appropriate. For catheter aspiration, the lateral approach is preferred.
- Prepare the skin with povidone-iodine (Betadine), alcohol scrubs, or both, and cover with sterile drapes.
- Instill a local anesthetic (eg, 1% Xylocaine solution) to skin and soft tissue down to the pleura, directing the needle over the top of the rib into the desired

intercostal space.

- Insert a large-bore Angiocath (14-gauge in an adult, 18- or 20-gauge in an infant) or ready-to-use aspiration kit into the chosen intercostal space over the top of the rib and perpendicular to the chest wall.
- For simple needle aspiration, withdraw air once the pleural cavity is entered, and when resistance is felt, withdraw the needle.
- For catheter aspiration, once the pleural cavity is entered, a soft pigtail catheter is advanced over the needle into the pleural space. A scalpel may be necessary to enlarge the entry site at the skin. Remove the needle once the pleural cavity is entered, and attach the catheter to a 3-way stopcock and large syringe (eg, 60-mL syringe) to evacuate air.
- When no more air can be aspirated (discontinue if resistance is felt, if the patient coughs excessively, or if more than 2.5 L is aspirated) or the patient suddenly coughs, the lung most likely has reexpanded.
- Close the stopcock, and secure the catheter to the chest wall.
- Obtain a chest radiograph to assess the degree of success, and obtain another radiograph 4 hours later to confirm the absence of recurring accumulation.
- If no recurrence is present, remove the catheter and massage the insertion site with sterile gauze to seal the channel into the pleural space.
- Discharge the patient with appropriate return instructions. (Some authors suggest observation for an additional 2 h after catheter removal.)
- If the pneumothorax persists, attach a Heimlich valve or a water seal and admit the patient.

Potential complications associated with needle aspiration includes pneumothorax (with potential to later tension pneumothorax), cardiac tamponade, hemorrhage (which can be life threatening), loculated intrapleural hematoma, atelectasis, pneumonia, arterial air embolism (when needle thoracostomy is performed and no tension pneumothorax is present), and pain to the patient.

Tube Thoracostomy

Tube thoracostomy is the definitive treatment for secondary spontaneous pneumothorax (SSP) (see the following image) and tension pneumothorax. Needle decompression mandates an immediate follow up with a tube thoracostomy.

The procedure is as follows:

- If the patient is hemodynamically stable, consider conscious sedation with careful titration of a short-acting narcotic and benzodiazepine.
- Place the patient in a 30-60° reverse Trendelenburg position.
- Scrub the site (centered around the fifth or sixth rib in the midaxillary line) with povidone-iodine (Betadine), alcohol, or both.
- Locally anesthetize the site with lidocaine. (Use a generous amount, and anesthetize all the way down to the pleura.)
- Create a 3- to 4-cm horizontal incision over the fifth or sixth rib in the midaxillary line.
- Use a curved hemostat, and dissect (in a controlled manner) through the soft tissue and down to the rib.
- Push the hemostat just over the superior portion of the rib, avoiding the intercostal neurovascular bundle that runs under the inferior portion of the next most superior rib. Then, puncture the intercostal muscles and parietal pleura. Spread the hemostat wide to create an adequate opening.
- Maintain the intrapleural position by inserting a finger along side of the hemostat. Assess the presence and location of pulmonary adhesions. Sweep the finger in all directions, and feel for the diaphragm and possible intra-abdominal structures. Remove the hemostat. To avoid losing the desired tract, some authors recommend keeping the finger in place until the tube is inserted.
- Insert the chest tube over the finger into the pleural space. A clamp may suffice for guiding the thoracostomy tube into place on the proximal end.
- Direct the chest tube posteriorly, and insert it until it is at least 5 cm beyond the last hole in the tube.
- Look for condensation in the tube as a sign of correct placement and air evacuation.
- Attach the tube to a water seal and vacuum device (eg, Pleur-Evac). Look for respiratory variation of the water seal and bubbling of air through the water seal. Document the amount of blood or other fluids drained.
- Connect the thoracostomy tube to an underwater seal apparatus and suction.
- Suture the tube in place, dress the wound, and tape the tube to the chest. Cover the site with Vaseline-impregnated gauze, and apply a suitable dressing. A variety

of anchoring and closure techniques exist, all of which are probably equivalent

- Obtain a follow-up chest x-ray to assess tube positioning and lung reexpansion.

Complications of tube thoracostomy include death, injury to lung or mediastinum, hemorrhage (usually from intercostal artery injury), neurovascular bundle injury, infection, bronchopleural fistula, and subcutaneous or intraperitoneal tube placement.

Indications for Surgical Intervention

- Surgical decompression (vacuum-assisted thoracostomy [VATS], open thoracotomy, etc) is indicated for the following:
 - Persistent air leak for longer than 5-7 days with a chest tube in place
 - Recurrent, ipsilateral pneumothorax
 - Contralateral or bilateral pneumothorax
 - First-time presentation in a patient with a high-risk occupation (eg, diver, pilot)
 - Patients with acquired immunodeficiency syndrome (AIDS) (often because of extensive underlying necrosis)
 - Unacceptable risk of recurrent pneumothorax for patients with plans for extended stays at remote sites
 - Lymphangiomyomatosis, a condition causing a high risk of pneumothorax.

HEMOTHORAX

Accumulation of blood within the chest, or hemothorax, is a relatively common problem, most often resulting from injury to intrathoracic structures or the chest wall. Hemothorax unrelated to trauma is considerably less common and can result from various causes. Prompt identification and treatment of traumatic hemothorax is an essential part of the care of the injured patient. In cases of hemothorax unrelated to trauma, a careful investigation for the underlying source must be performed while treatment is occurring.

Pathophysiology

Bleeding into the pleural space can occur with virtually any disruption of the tissues of the chest wall and pleura or the intrathoracic structures.

The physiologic response to the development of a hemothorax is manifested in 2 major areas: hemodynamic and respiratory. The degree of hemodynamic response is determined by the amount and rapidity of blood loss.

Normal respiratory movement may be hampered by the space-occupying effect of a large accumulation of blood within the pleural space. In trauma cases, abnormalities of ventilation and oxygenation may result, especially if associated with injuries to the chest wall. In some cases of nontraumatic origin, especially those associated with pneumothorax and a limited amount of bleeding, respiratory symptoms may predominate.

Hemodynamic changes vary depending on the amount of bleeding and the rapidity of blood loss. Blood loss of up to 750 mL in a 70-kg man should cause no significant hemodynamic change. Loss of 750-1500 mL in the same individual will cause the early symptoms of shock, ie, tachycardia, tachypnea, and a decrease in pulse pressure.

Significant signs of shock with signs of poor perfusion occur with loss of blood volume of 30% or more (1500-2000 mL). Because the pleural cavity of a 70-kg man can hold 4 or more liters of blood, exsanguinating hemorrhage can occur without external evidence of blood loss.

Blood occupying the pleural cavity takes up space that the lung would fill in normal respiratory excursion. A large enough collection causes the patient to complain of dyspnea and may produce the clinical finding of tachypnea. The volume of blood required to produce these symptoms in a given individual varies depending on a number of factors, including organs injured, severity of injury, and underlying pulmonary and cardiac reserve.

Dyspnea is a common symptom in cases in which hemothorax develops in an insidious manner, such as those secondary to metastatic disease. Blood loss in such cases is not acute as

to produce a visible hemodynamic response, and dyspnea is often the predominant complaint.

Two pathologic states are associated with the later stages of hemothorax. These include empyema and fibrothorax.

Empyema results from bacterial contamination of the retained hemothorax. If undetected or improperly treated, this can lead to bacteremia and septic shock.

Fibrothorax results when fibrin deposition develops in an organized hemothorax and coats both the parietal and visceral pleural surfaces, trapping the lung. The lung is fixed in position by this adhesive process and is unable to fully expand. Persistent atelectasis of portions of the lung and reduced pulmonary function result from this process.

Classification

I. According to extent:

1. Unilateral.
2. Bilateral.

II. According to degree of hemorrhage:

1. Small (the loss less 10 % of volume of circulating blood).
2. Moderate (loss of 10-20 % of volume of circulating blood).
3. Great (loss of 20-40 % of volume of circulating blood).
4. Total (exceeds 40 % of volume of circulating blood).

III. According to duration of bleeding:

1. With persistent hemorrhage.
2. With the stopped bleeding.

IV. According to the presence of clots in a pleural space:

1. Coagulated.
2. No- coagulated.

V. According to the presence of infection:

1. Not infected.
2. Infected (suppurative).

Symptomatology and clinical course

If hemothorax is the complication of blunt chest trauma, the clinical manifestations depend on the gravity of trauma and degree of hemorrhage. Also hemothorax by itself results in pulmonary compression and shift of mediastinum.

In case of **small hemothorax** clinical manifestations of hemorrhage are slightly expressed or absent at all.

Dyspnea, cough, general malaise and dizziness are obvious in **moderate hemothorax**. The skin is pale. The hemodynamic disturbances – tachycardia and decreased arterial pressure are observed.

The **great and total hemothorax** are associated with extremely grave condition. The patients are troubled with expressed general malaise, dizziness, dyspnea and difficult breathing. In some cases they enter medical hospitals in a terminal state. The skin is sharply pale. The peripheral pulse impaired or absent. Tachycardia, weak cardiac tones, low arterial pressure are obvious.

By percussion the dullness is revealed. On auscultation - the breathing over the site of hemothorax is sharply diminished or is not heard.

The X-ray picture of hemothorax is rather specific. The intensive homogeneous shadow on the side of the lesion with oblique upper contour (Damuaso' line) is observed. The costal sinus does not visualized. In small hemothorax, depending on the degree of intrapleural bleeding, the shadow observed only in the region of sinus. In moderate hemothorax it achieves a scapular angle (on the back surface) or V rib on anterior surface of the chest wall. In great hemothorax this shadow achieves III rib, and total hemothorax characterized by complete shadow of a pleural space, and in some cases – mediastinal shift to the healthy side.

Left side small hemothorax

Left side moderate hemothorax

Right side great hemothorax

Left side total hemothorax

The diagnostic program

1. Complaint and anamnesis of the disease.
2. Physical examination.

Symptoms and physical findings associated with hemothorax in trauma vary widely depending on the amount and rapidity of bleeding, the existence and severity of underlying pulmonary disease, the nature and degree of associated injuries, and the mechanism of injury.

Hemothorax is rarely a solitary finding in blunt trauma. Associated chest wall or pulmonary injuries are nearly always present.

Simple bony injuries consisting of one or multiple rib fractures are the most common blunt chest injuries. A small hemothorax may be associated with even single rib fractures but often remains unnoticed during the physical examination and even after chest radiography. Such small collections rarely need treatment.

Complex chest wall injuries are those in which either 4 or more sequential single rib fractures are present or a flail chest exists. These types of injuries are associated with a significant degree of chest wall damage and often produce large collections of blood within the pleural cavity and substantial respiratory impairment. Pulmonary contusion and pneumothorax are commonly associated injuries. Injuries resulting in laceration of intercostal or internal mammary arteries may produce a hemothorax of significant size and significant hemodynamic compromise. These vessels are the most common source of persistent bleeding from the chest after trauma.

Delayed hemothorax can occur at some interval after blunt chest trauma. In such cases, the initial evaluation, including chest radiography, reveals findings of rib fractures without any accompanying intrathoracic pathology. However, hours to days later, a hemothorax is seen. The mechanism is believed to be either rupture of a trauma-associated chest wall hematoma into the pleural space or displacement of rib fracture edges with eventual disruption of intercostal vessels during respiratory movement or coughing.

Large hemothoraces are usually related to injury of vascular structures. Disruption or laceration of major arterial or venous structures within the chest may result in massive or exsanguinating hemorrhage.

Hemodynamic manifestations associated with massive hemothorax are those of hemorrhagic shock. Symptoms can range from mild to profound, depending on the amount and rate of bleeding into the chest cavity and the nature and severity of associated injuries.

Because a large collection of blood will compress the ipsilateral lung, related respiratory manifestations include tachypnea and, in some cases, hypoxemia.

A variety of physical findings such as bruising, pain, instability or crepitus upon palpation over fractured ribs, chest wall deformity, or paradoxical chest wall movement may lead to the possibility of coexisting hemothorax in cases of blunt chest wall injury. Dullness to

percussion over a portion of the affected hemithorax is often noted and is more commonly found over the more dependent areas of the thorax if the patient is upright. Decreased or absent breath sounds upon auscultation are noted over the area of hemothorax.

3. Chest roentgenograms in 2 planes.

The upright chest radiograph is the ideal primary diagnostic study in the evaluation of hemothorax.

In the normal unscarred pleural space, a hemothorax is noted as a meniscus of fluid blunting the costophrenic angle or diaphragmatic surface and tracking up the pleural margins of the chest wall when viewed on the upright chest x-ray film. This is essentially the same chest radiographic appearance found with any pleural effusion.

In cases in which pleural scarring or symphysis is present, the collection may not be free to occupy the most dependent position within the thorax, but will fill whatever free pleural space is available. This situation may not create the classic appearance of a fluid layer on a chest x-ray film.

As much as 400-500 mL of blood is required to obliterate the costophrenic angle as seen on an upright chest radiograph.

In the acute trauma setting, the portable supine chest radiograph may be the first and only view available from which to make definitive decisions regarding therapy. The presence and size of a hemothorax is much more difficult to evaluate on supine films. As much as 1000 mL of blood may be missed when viewing a portable supine chest x-ray film. Only a general haziness of the affected hemithorax may be noted.

In blunt trauma cases, hemothorax is frequently associated with other chest injuries visible on the chest radiograph, such as rib fractures (see below), pneumothorax, or a widening of the superior mediastinum.

Additional studies such as ultrasonography or CT scan may sometimes be required for identification and quantification of a hemothorax noted on a plain chest radiograph

4. [Thoracentesis](#).
5. Investigation of a pleural content.
6. Test by Revilour-Greguar.
7. General blood analysis.

Hematocrit of pleural fluid. Measurement of the hematocrit is virtually never needed in a patient with a traumatic hemothorax.

This study may be needed for the analysis of a bloody effusion from a nontraumatic cause. In such cases, a pleural effusion with a hematocrit value of more than 50% of that of the circulating hematocrit is considered a hemothorax.

8. Biochemical blood analysis.
9. Determining of the blood group and Rh factor.

Variants of clinical course and complications

The coagulated hemothorax. The patient's late apply for medical aid or major bleeding results in formation of clots in a pleural space, and in some cases all blood, which has accumulated in a pleural space, forms by itself a major entire clot.

Depending on degree of bleeding and, consequently, size of clot, the patients complain of chest pain, which intensifies at respiration, dyspnea, general malaise, and dizziness. As a rule, on 3-5 day the fever to 37,5-38°C is observed.

The physical findings (diminishing and absence of vocal fremitus by palpation, dullness by percussion and sharply diminished or absent breathing by auscultation) suggest the presence of pathological process in a pleural space.

Chest roentgenogram reveals the intensive shadow, sometimes heterogeneous (with enlightenments and multiple levels).

The needle aspiration obtains small amount of a liquid hemolyzed blood and small bloody thrombi (according to inner diameter of the needle).

Suppurative hemothorax. The coagulated hemothorax in overwhelming majority is infected, that results in occurrence of a pleural empyema (clinical manifestations, diagnostics and treatment look in chapter " pleural empyema").

Treatment

A treatment of small hemothorax requires [needle aspiration](#) or [drainage](#) of pleural space and elimination of blood. The manipulation is carried out in VI-VII intercostal spaces in the postaxillary or scapular lines.

Total, great or moderate hemothorax with persistent bleeding (positive test by Revilour-Greguar) requires thoracotomy for liquidation of a bleeding source.

The bleeding wounds of lungs are sewed up by twist suture. If the pleural space contains liquid blood, the surgeon carries out its reinfusion. The clots are removed from pleural space.

Tube thoracostomy drainage

Tube thoracostomy drainage is the primary mode of treatment for hemothorax. In adult patients, large-bore chest tubes, usually 36-42F, should be used to achieve adequate drainage in adults. Smaller-caliber tubes are more likely to occlude. In pediatric patients, chest tube size varies with the size of the child. In patients older than 12 years, the chest tube size used is usually the same as that for adults. In smaller children, a 24-34F chest tube should be used, depending on the size of the child.

Thoracostomy tube placement for hemothorax should ideally be in the sixth or seventh intercostal space at the posterior axillary line. In the supine trauma victim, a common error in chest tube insertion is placement too anteriorly and superiorly, making complete drainage very unlikely.

After tube thoracostomy is performed, a repeat chest radiograph should always be obtained. This helps identify chest tube position, helps determine completeness of the hemothorax evacuation, and may reveal other intrathoracic pathology previously obscured by the hemothorax. If drainage is incomplete as visualized on the postthoracostomy chest radiograph, placement of a second drainage tube should be considered. Preferably, a video-assisted thoracic surgery (VATS) operative procedure should be undertaken to evacuate the pleural space.

In cases of hemopneumothorax, 2 chest tubes may be preferred, with the tube draining the pneumothorax placed in a more superior and anterior position.

Surgical exploration in cases of traumatic hemothorax should be performed in the following circumstances:

Greater than 1000 mL of blood is evacuated immediately after tube thoracostomy. This is considered a massive hemothorax.

Bleeding from the chest continues, defined as 150-200 mL/h for 2-4 hours.

Persistent blood transfusion is required to maintain hemodynamic stability.

In the majority of trauma cases requiring chest exploration, the bleeding source is from

the chest wall, most commonly intercostal or internal mammary arteries. Once identified, these can be easily controlled with suture ligatures in most cases. After control of obvious bleeding and evacuation of clot and blood, a rapid but thorough exploration of the entire chest cavity should be performed.

Unstable rib fractures found at the time of surgery may require some debridement of sharp rib edges to prevent further injury to the lung or adjacent chest wall structures. At some centers, flail segments or extensive rib fractures are stabilized with wires or other types of support in an attempt to improve postoperative chest wall mechanics.

A thoracic surgeon should be present or immediately available at the time of emergency thoracic exploration because control of bleeding from difficult areas such as the hilum of the lung, the heart, or the great vessels may require a surgeon with expertise in that field.

Adequate drainage of the chest after control of bleeding is very important. Because chest drainage tubes are placed under direct vision, the complication of retained hemothorax should occur with extreme infrequency. A minimum of 2 large-bore chest tubes should be used, with one positioned posteriorly and the other positioned anteriorly. Some surgeons prefer the addition of a right-angled chest tube positioned over the diaphragm.

The late sequelae of hemothorax, including residual clot, infected collections, and trapped lung, require additional treatment and, most often, surgical intervention.

SUBCUTANEOUS EMPHYSEMA

The cause of this complication of blunt chest trauma is the damage by edge of the broken rib of parietal and visceral pleural membranes with the following entering of air from a pulmonary tissue into a pleural space and through damaged chest wall (ruptured intercostal muscles) into subcutaneous fat.

In overwhelming majority the subcutaneous emphysema is the outcome of a valvular pneumothorax and pneumothorax in obliterated pleural space.

Classification

Subcutaneous emphysema is divided on:

1. Localized.
2. Widespread.
3. Total.

Symptomatology and clinical course

As the subcutaneous emphysema is the outcome of trauma complicated by a rib fracture and posttraumatic pneumothorax, the chief complaints are of chest pain and dyspnea, which intensify at respiration, movements and minor physical activity.

In **localized subcutaneous emphysema** the patients the complaints of the chest trauma are predominant in symptomatology. On examination observed a swelling of a chest wall in the place of damage. By palpation a subcutaneous crepitation is felt over this region. Percussion reveals a bandbox sound or tympanitis.

Auscultation of lungs over subcutaneous emphysema is usually impossible.

The **widespread and total subcutaneous emphysema** represents a serious moral problem for the patient. Owing to extent of air all over the chest, abdominal wall, neck (wide-spread emphysema), and also face, arms and legs (total emphysema), the patients has a specific appearance: swelling face, thick neck, enlargement of the chest, arms, and legs. Subcutaneous emphysema by itself usually causes no respiratory and cardiovascular disturbances. However the patients note the change of the quality of voice. By palpation the subcutaneous emphysema is felt in whole body ("crisping snow").

It is necessary to note, that in widespread and total emphysema the auscultation is impossible. However the

presence of subcutaneous emphysema at the closed trauma of the chest enables to suspect the presence of posttraumatic pneumothorax.

On the chest roentgenogram the enlightenment of a subcutaneous fat (presence of air) is observed.

Subcutaneous emphysema

The diagnostic program

1. Complaint and history of the disease.
2. Physical findings.
3. Chest X-radiography.

Treatment

Widespread and total subcutaneous emphysema requires the draining of subcutaneous space by plastic tubes in infra- and supraclavicular region, and also in the zone of the most expressed emphysema. Also performed the drainage of a pleural space.

The subcutaneous emphysema resolves depending on its extent from several days to 2-3,5 weeks.

TRAUMATIC INJURY OF TRACHEA AND MAIN BRONCHI

The isolated injuries of trachea and bronchi as the result of blunt trauma of the chest occur rarely and located mainly in a cervical part.

The main causes of tearing of trachea and bronchi are:

- 1) shearing forces, which arises at the moment of trauma owing to a sudden rise of intraluminal pressure against a closed glottis when the airway is compressed against the spine.;
- 2) compressing of a bronchial tree between a breastbone and vertebral column;
- 3) shift of lungs in sudden and rapid deceleration or acceleration of a body occurs with greater amplitude, than fixed bifurcation of trachea.

Such disruptions most often occurs as a result of vehicular impacts, falls from great heights, direct blows to the chest. In most cases disruption of trachea and bronchi are accompanied with the other visceral damages: lungs, skull and brain, heart, liver and flail chest.

Classification

I. According to degree of disruption:

1. Partial:
 - without damage of cartilaginous rings (I degree);
 - with fracture of cartilaginous rings (II degree).
2. Partial disruption of all layers (III degree).
3. Complete transverse disruption of all walls without disjunction of the of trachea, (bronchus) (IV degree).
4. Abruption with disjunction of the edges of trachea (bronchus) (V degree).

II. According to direction of rupture:

1. Longitudinal.
2. Oblique.

3. Transversal.

4. Mixed.

III. According to localization of the damage:

1. Tracheo-laryngeal.

2. Cervico-tracheal.

3. Mediastino-bronchial.

4. Bifurcational.

5. Bronchial.

IV. According to the size of injury:

1. Combined damages of trachea (bronchi) and adjacent organs.

2. Damage of trachea (bronchi) and other segments of the body.

3. Damage of a trachea (bronchi). adjacent organs and other segments of the body.

Symptomatology and clinical course

The clinical manifestations of the injury of trachea depend on the type of disruption, its degree and presence of concomitant damages.

Incomplete isolated disruption of trachea commonly manifests by cough and hemoptysis. Respiration is not disturbed as a rule.

The small disruptions are characterized by various clinics. If the hole is occluded by clot and mediastinal tissues, the signs, which had appeared earlier (cough, hemoptysis, mediastinal emphysema), can disappear. Nevertheless the repeated occurrence of cough, as a rule, leads to severe aggravation of the patient state.

Major and circular disruptions of trachea cause a grave state of the patients. They manifest except difficult breathing by such signs:

- 1) mediastinal emphysema or pneumothorax;
- 2) compression syndrome – compression and inflection of major vessels due to tension pneumothorax or mediastinal emphysema with transmission into acute cardiopulmonary failure;

- 3) hemorrhage syndrome;
- 4) aspiration syndrome, which is the outcome of bleeding into airways or aspirations of the gastric content;
- 5) traumatic shock.

The injuries of bronchi occur in the way of abruption of main bronchi or their disruption in the zone of bifurcation. In the zone of a tracheal bifurcation observed multiple (2-4) disruptions, which can be longitudinal, transversal or oblique.

Depending on the character of trauma, it is necessary to distinguish direct and secondary disruptions of bronchi. The direct injuries arise from the gunshot and knife wounds, penetration of rib fragments or other subjects in mediastinum or endoscopic manipulations.

The overwhelming majority of bronchial disruption is the part of blunt trauma of the chest. By the way, the damage of vessels of a lung root occurs in 41,3 %.

The predominant clinical signs of a bronchial disruption are the respiratory disturbance, gas syndrome, hemothysis and hemothorax. However these signs may be observed only in isolated injuries of lungs.

The patients state is grave. Rest dyspnea and acute pain behind a breastbone are the most troubling manifestations. The difficult swallowing, hoarseness, swelling face and subcutaneous crepitation are observed. Auscultatory on the side of trauma the breathing sounds are weak or absent at all.

The sequence of examination of the patients with injuries of trachea and bronchi depends on the character and gravity of trauma, clinical signs and concomitant damages, which threatening life.

If the state of the patient allows, a chest X-radiography is performed. Commonly it is possible to find out mediastinal emphysema, sometimes the sign of discontinuing of trachea.

The injuries of bronchi manifest by the distension of mediastinum and presence of air strips along its borders, and in some cases total or tension pneumothorax observed.

Final and most informative diagnostic method is the tracheobronchoscopy, which can be also the therapeutic method. However it is necessary to carry out decompression of a mediastinal emphysema and pneumothorax before such investigation.

Before examination the clots and liquid blood are aspirated from airways, then adjusted the localization and character of disruption. The incomplete disruptions are usually longitudinal and oblique and located on the line of membranous and cartilaginous part, circular – mainly in a cervical part of trachea. Except disruption of the wall, observed the absence of cartilaginous rings in this region and filled by blood parabronchial fat.

The open damages of trachea take place mainly in a cervical part and rarely - in thoracic. In all cases of neck

trauma it is necessary always suspect the opportunity of damage of trachea and esophagus.

Such variants of clinical course are distinguished:

- acute course (first 30 days after operation);
- chronic course (complication of trauma).

Acute course is divided onto three stages:

1. The initial stage (lasts during 2 days after the trauma with typical signs of disruption; the urgent resuscitation measures are required).
2. The stage of temporary compensation (lasts during 2 weeks; at this time it is possible to carry out diagnostic examination).
3. The stage of persistent compensation (lasts during 30 days; during this time a stenosis and other persistent complications of disruption of trachea and bronchi develops).

The diagnostic program

1. Complaint and the history of disease.
2. Physical findings.
3. Chest X-radiography.
4. Diagnostic [thoracentesis](#).
5. General blood and urine analyses.
6. Biochemical blood analysis.
7. Tracheobronchoscopy.
8. Tomography.

Treatment

There are primary operations in acute stage (first two days after the trauma) and late repairing operations (in 1 month after the trauma). The operation is based in resection of injured tissues, edges of bronchus with the further suturing of disruption, or wedge-like or circular resection with following anastomosis. In series of

cases lobe-, bilobe- or pneumonectomy is performed.

MEDIASTINAL EMPHYSEMA

Mediastinal emphysema is the complication of the blunt trauma of the chest, which is characterized by entering and accumulation of air in mediastinum.

The causes of mediastinal emphysema is partial (damage of a membranous part) or complete disruptions of trachea, bronchi, esophagus and in some cases – tension pneumothorax.

The entry of air in mediastinum leads to compressing of superior cava vein and right atrium, which results in the expressed discirculation.

Symptomatology and clinical course

The patients complain of difficult breathing and swallowing, pain behind breastbone, hoarseness, cough attacks. As a rule, the patient's position is forced – semi-sitting. The neck and face are thickened, cervical veins distended, the skin is cyanotic. By palpation – the crepitation of neck, face, and shoulder area. By auscultation heart tones are diminished with tachycardia.

On X-ray film on the background of enlightenment observed well-defined contour of a mediastinal pleura. If there is the damage of mediastinal pleural membrane a pneumothorax (mainly total or intense) is revealed.

Mediastinal emphysema with left-side pneumothorax

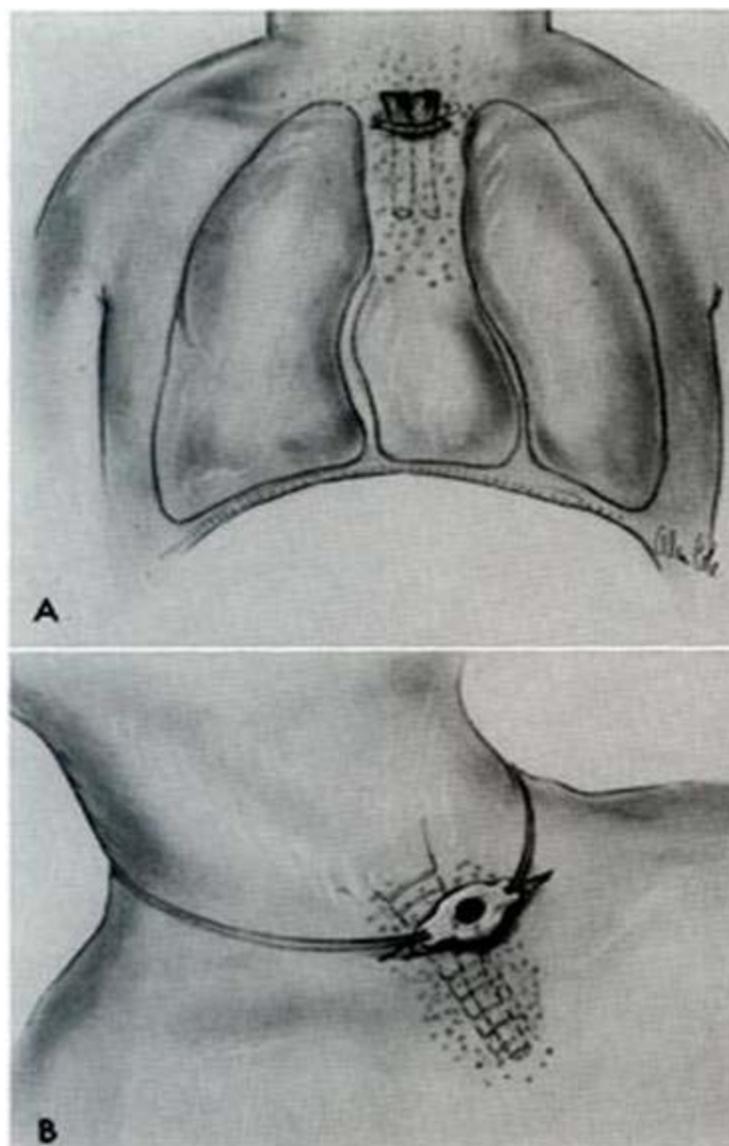

The diagnostic program

1. Complaint and history of the disease.
2. Physical findings.
3. Examination X-radiography of organs of the chest.
4. Definition of central venous pressure.
5. Control of hemodynamic data.
6. ECG.

Tactics and choice of treatment

Progressing mediastinal emphysema requires the urgent drainage of a forward mediastinum in order to prevent external cardiac tamponade.

Tension mediastinal emphysema resulting from disruption of trachea or bronchus operative management, pneumothorax, etc., requires the treatment, which is described in previous chapters.

Drainage of anterior mediastinum

SHOCK

Circulatory shock, commonly known as just shock, is a serious, life-threatening medical condition where insufficient blood flow reaches the body tissues. As the blood carries oxygen and nutrients around the body, reduced flow hinders the delivery of these components to the tissues, and can stop the tissues from functioning properly. The process of blood entering the tissues is called perfusion, so when perfusion is not occurring properly this is called a hypoperfusional (hypo = below) state.

Circulatory shock should not be confused with the emotional state of shock, as the two are not related. Medical shock is a life-threatening medical emergency and one of the most common causes of death for critically-ill people. Shock can have a variety of effects, all with similar outcomes, but all relate to a problem with the body's circulatory system. For example,

shock may lead to hypoxemia (a lack of oxygen in arterial blood) or cardiac arrest (the heart stopping)

Fig. Classes of hemorrhagic shock

- **Class I hemorrhage (loss of 0-15%)**
 - Little tachycardia
 - Usually no significant change in BP, pulse pressure, respiratory rate
- **Class II hemorrhage (loss of 15-30%)**
 - HR >100 beats per minute, tachypnea, decreased pulse pressure
- **Class III hemorrhage (loss of 30-40%)**
 - Marked tachycardia and tachypnea, decreased systolic BP, oliguria
- **Class IV hemorrhage (loss of >40%)**
 - Marked tachycardia and decreased systolic BP, narrowed pulse pressure, markedly decreased (or no) urinary output
 - Immediately life threatening

Effects of inadequate perfusion on cell function.

There are four stages of shock. As it is a complex and continuous condition there is no sudden transition from one stage to the next.

Initial

During this stage, the hypoperfused state causes hypoxia, leading to the mitochondria being unable to produce adenosine triphosphate (ATP). Due to this lack of oxygen, the cell membranes become damaged, they become leaky to extra-cellular fluid, and the cells perform anaerobic respiration. This causes a build-up of lactic and pyruvic acid which results in systemic metabolic acidosis. The process of removing these compounds from the cells by the liver requires oxygen, which is absent.

Compensatory (Compensating)

This stage is characterised by the body employing physiological mechanisms, including neural, hormonal and bio-chemical mechanisms in an attempt to reverse the condition. As a result of the acidosis, the person will begin to hyperventilate in order to rid the body of carbon dioxide (CO₂). CO₂ indirectly acts to acidify the blood and by removing it the body is attempting to raise the pH of the blood. The baroreceptors in the arteries detect the resulting hypotension, and cause the release of adrenaline and noradrenaline.

- Baroreceptor reflexes
- Circulating vasoconstrictors
- Chemoreceptor reflexes
- Reabsorption of tissue fluids
- Renal reabsorption of sodium and water
- Activation of thirst mechanisms
- Cerebral ischemia
- Hemapoiesis

Fig. Compensatory mechanisms

Noradrenaline causes predominately vasoconstriction with a mild increase in heart rate, whereas adrenaline predominately causes an increase in heart rate with a small effect on the vascular tone; the combined effect results in an increase in blood pressure. Renin-angiotensin axis is activated and arginine vasopressin is released to conserve fluid via the kidneys.

Also, these hormones cause the vasoconstriction of the kidneys, gastrointestinal tract, and other organs to divert blood to the heart, lungs and brain. The lack of blood to the renal system causes the characteristic low urine production. However the effects of the Renin-angiotensin axis take time and are of little importance to the immediate homeostatic mediation of shock .

Progressive (Decompensating)

Should the cause of the crisis not be successfully treated, the shock will proceed to the progressive stage and the compensatory mechanisms begin to fail. Due to the decreased perfusion of the cells, sodium ions build up within while potassium ions leak out. As anaerobic metabolism continues, increasing the body's metabolic acidosis, the arteriolar smooth muscle and precapillary sphincters relax such that blood remains in the capillaries[1]. Due to this, the hydrostatic pressure will increase and, combined with histamine release, this will lead to leakage of fluid and protein into the surrounding tissues. As this fluid is lost, the blood concentration and viscosity increase, causing sludging of the micro-circulation. The prolonged vasoconstriction will also cause the vital organs to be compromised due to reduced

perfusion[1]. If the bowel becomes sufficiently ischemic, bacteria may enter the blood stream, resulting in the increased complication of endotoxic shock[1].

Refractory (Irreversible)

At this stage, the vital organs have failed and the shock can no longer be reversed. Brain damage and cell death have occurred. Death will occur imminently.

A medical emergency is an injury or illness that is acute and poses an immediate risk to a person's life or long term health. These emergencies may require assistance from another person, who should ideally be suitably qualified to do so, although some of these emergencies can be dealt with by the victim themselves. Dependent on the severity of the emergency, and the quality of any treatment given, it may require the involvement of multiple levels of care, from a first aider to an emergency physician through to specialist surgeons.

Any response to an emergency medical situation will depend strongly on the situation, the patient involved and availability of resources to help them. It will also vary depending on whether the emergency occurs whilst in hospital under medical care, or outside of medical care (for instance, in the street or alone at home).

For emergencies starting outside of medical care, a key component of providing proper care is to summon the emergency medical services (usually an ambulance), by calling for help using the appropriate local emergency telephone number, such as 999, 911, 112 or 000 or 111. After determining that the incident is a medical emergency (as opposed to, for example, a police call), the emergency dispatchers will generally run through a questioning system such as AMPDS in order to assess the priority level of the call, along with the caller's name and location.

Those trained to perform first aid can act within the bounds of the knowledge they have, whilst awaiting the next level of definitive care. Those who are not able to perform first aid can also assist by remaining calm and staying with the injured or ill person. A common complaint of emergency service personnel is the propensity of people to crowd around the scene of victim, as it is generally unhelpful, making the patient more stressed, and obstructing the smooth working of the emergency services. If possible, first responders should designate a specific person to ensure that the emergency services are called. Another bystander should be sent to wait for their arrival and direct them to the proper location. Additional bystanders can be helpful in ensuring that crowds are moved away from the ill or injured patient, allowing the responder adequate space to work.

Many states of the USA have "Good Samaritan Laws" which protect civilian responders who choose to assist in an emergency. Responders acting within the scope of their knowledge

and training as a "reasonable person" in the same situation would act are often immune to liability in emergency situations. Usually, once care has begun, a first responder or first aid provider may not leave the patient or terminate care until a responder of equal or higher training (e.g., fire department or emergency medical technicians) assumes care. This can constitute abandonment of the patient, and may subject the responder to legal liability. Care must be continued until the patient is transferred to a higher level of care, the situation becomes too unsafe to continue, or the responder is physically unable to continue due to exhaustion or hazards.

The principles of the chain of survival apply to medical emergencies where the patient has an absence of breathing and heartbeat. This involves the four stages of Early access, Early CPR, Early defibrillation and Early advanced life support

Unless the situation is particularly hazardous, and is likely to further endanger the patient, evacuating an injured victim requires special skills, and should be left to the professionals of the emergency medical and fire service.

Within hospital settings, an adequate staff is generally present to deal with the average emergency situation. Emergency medicine physicians have training to deal with most medical emergencies, and maintain CPR and ACLS certifications. In disasters or complex emergencies, most hospitals have protocols to summon on-site and off-site staff rapidly.

Both emergency room and inpatient medical emergencies follow the basic protocol of Advanced Cardiac Life Support. Irrespective of the nature of the emergency, adequate blood pressure and oxygenation are required before the cause of the emergency can be eliminated. Possible exceptions include the clamping of arteries in severe hemorrhage.

While the golden hour (medicine) is a trauma treatment concept, two emergency medical conditions have well-documented time-critical treatment considerations: stroke and myocardial infarction (heart attack). In the case of stroke, there is a window of three hours within which the benefit of clot-busting drugs outweighs the risk of major bleeding. In the case of a heart attack, rapid stabilization of fatal arrhythmias can prevent sudden cardiac death. In addition, there is a direct relationship between time-to-treatment and the success of reperfusion (restoration of blood flow to the heart), including a time dependent reduction in the mortality and morbidity. In 1972 Hinshaw and Cox suggested the following classification which is still used today.[2] It uses four types of shock: hypovolemic, cardiogenic, distributive and obstructive shock:[3][4][5][8][10]

Hypovolemic shock – This is the most common type of shock and based on insufficient circulating volume. Its primary cause is loss of fluid from the circulation from either an internal

or external source. An internal source may be haemorrhage. External causes may include extensive bleeding, high output fistulae or severe burns.

DIAPHRAGMATIC HERNIA. DISEASE OF MEDIASTINUM

DIAPHRAGMATIC HERNIAS

Diaphragmatic hernia represents herniation of abdominal organs through natural openings of diaphragm, its weak places or ruptures.

A hiatal hernia occurs when a portion of the stomach prolapses through the diaphragmatic esophageal hiatus. Although the existence of hiatal hernia has been described in earlier medical literature, it has come under scrutiny only in the last century or so because of its association with gastroesophageal reflux disease (GERD) and its complications. There is also an association between obesity and the presence of hiatal hernia. By far, most hiatal hernias are asymptomatic and are discovered incidentally. On rare occasion, a life-threatening complication, such as gastric volvulus or strangulation, may present acutely.

Etiology and pathogenesis

The cause of occurrence of congenital hernia is the disturbance of embryogenesis with transformation in anomaly of diaphragm. The acquired diaphragmatic hernia more often arise owing to age-dependent involution of diaphragm, its ptosis in the people with a mainly sedentary mode of life, increase of intraperitoneal pressure, obesity, cough, overfeeding, constipation, meteorism and pregnancy. The cause of sliding hernias can be draw of esophagus upward in reflux esophagitis owing to intensive contraction of its longitudinal musculature.

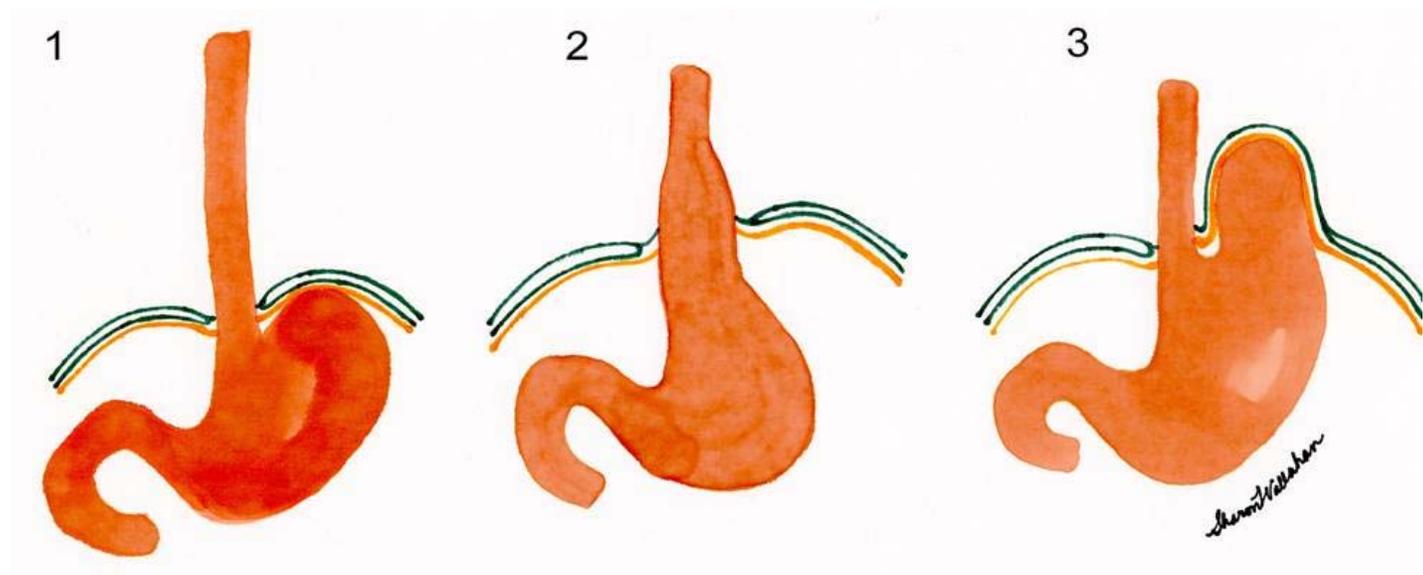

Predisposing factors include the following:

- Muscle weakening and loss of elasticity as people age is thought to predispose to hiatus hernia, based on the increasing prevalence in older people. With decreasing tissue elasticity, the gastric cardia may not return to its normal position below the diaphragmatic hiatus following a normal swallow. Loss of muscle tone around the diaphragmatic opening also may make it more patulous.
- Hiatal hernias are more common in women. This may relate to the intra-abdominal forces exerted in pregnancy.
- Burkitt et al suggest that the Western, fiber-depleted diet leads to a state of chronic constipation and straining during bowel movement, which might explain the higher incidence of this condition in Western countries.
- Obesity predisposes to hiatus hernia because of increased abdominal pressure.
- Conditions such as chronic esophagitis may cause shortening of the esophagus by causing fibrosis of the longitudinal muscles and, therefore, predispose to hiatal hernia. However, which comes first, the hiatal hernia worsening the reflux or the reflux-induced shortening of the esophagus, remains unknown.
- The presence of abdominal ascites also is associated with hiatal hernias.

Diaphragmatic hernias may be congenital or acquired. Acquired hiatal hernias are divided further into nontraumatic and traumatic hernias. The most common types of hernias are those acquired in a nontraumatic fashion. Hernias acquired in a nontraumatic fashion are divided into 2 types, (1) sliding hiatal hernia and (2) paraesophageal hiatal hernia. A mixed variety with coexisting sliding and paraesophageal components is possible.

- Sliding hiatal hernia by far is the most common type of hiatal hernia. It occurs when the gastroesophageal junction, along with a portion of the stomach, migrates into the mediastinum through the esophageal hiatus (see the image below). The majority of patients with demonstrated hiatal hernias are asymptomatic. This type of hernia interferes with the reflux barrier mechanism in several ways. As the LES moves into the chest, it no longer is exposed to positive intra-abdominal pressure and, therefore, is less effective as a sphincter. In fact, the sphincter moves into an area of low pressure, which interferes with the sphincter activity. In addition, the widening hiatus affects the competence of the diaphragmatic crura. The angle of His is lost, making regurgitation of gastric contents more likely. These changes not only predispose to reflux of gastric contents into the esophagus, but also prolong the acid contact time with the epithelium of the esophagus.

In paraesophageal hernia, also called rolling-type hiatal hernia, the widened hiatus permits the fundus of the stomach to protrude into the chest, anterior and lateral to the body of the esophagus; however, the gastroesophageal junction remains below the diaphragm (see Figure 3 of the image above). This causes the stomach to rotate in a counter-clockwise direction. As the hiatus widens, increasing amounts of the greater curvature of the stomach and, sometimes, the gastric-colic omentum, follow. The fundus eventually comes to lie above the gastroesophageal junction, with the pylorus being pulled towards the diaphragmatic hiatus. In this type of hernia, the anatomic relation of the stomach to the lower end of the esophagus (angle of His) tends to remain unchanged, so gross acid reflux does not occur.

1– norm, 2 – sliding hiatal hernia, 3 – paraesophageal hernia

Pathology

The esophagus passes through the diaphragmatic hiatus in the crural part of the diaphragm to reach the stomach. The diaphragmatic hiatus itself is approximately 2 cm in length and chiefly consists of musculotendinous slips of the right and left diaphragmatic crura arising from either side of the spine and passing around the esophagus before inserting into the central tendon of the diaphragm. The size of the hiatus is not fixed, but narrows whenever intra-abdominal pressure rises, such as when lifting weights or coughing.

The lower esophageal sphincter (LES) is an area of smooth muscle approximately 2.5-4.5 cm in length. The upper part of the sphincter normally lies within the diaphragmatic hiatus, while the lower section normally is intra-abdominal. At this level, the visceral peritoneum and the phrenoesophageal ligament cover the esophagus. The phrenoesophageal ligament is a fibrous layer of connective tissue arising from the crura, and it maintains the LES within the abdominal cavity. The A-ring is an indentation sometimes seen on barium studies, and it marks the upper part of the LES. Just below this is a slightly dilated part of the esophagus, forming the vestibule. A second ring, the B-ring, may be seen just distal to the vestibule, and it approximates the Z-line or squamocolumnar junction. The presence of a B-ring confirms the diagnosis of a hiatal hernia. Occasionally, the B-ring also is called the Schatzki ring.

Any sudden increase in intra-abdominal pressure also acts on the portion of the LES below the diaphragm to increase the sphincter pressure. An acute angle, the angle of His, is formed between the cardia of the stomach and the distal esophagus and functions as a flap at the gastroesophageal junction and helps prevent reflux of gastric contents into the esophagus (see the image below).

The gastroesophageal junction acts as a barrier to prevent reflux of contents from the stomach into the esophagus by a

combination of mechanisms forming the antireflux barrier. The components of this barrier include the diaphragmatic crura, the LES baseline pressure and intra-abdominal segment, and the angle of His. The presence of a hiatal hernia compromises this reflux barrier not only in terms of reduced LES pressure but also reduced esophageal acid clearance. Patients with hiatal hernias also have longer transient LES relaxation episodes particularly at night time. These factors increase the esophageal mucosa acid contact time predisposing to esophagitis and related complications.

Frequency

Hiatal hernias are more common in Western countries. The frequency of hiatus hernia increases with age, from 10% in patients younger than 40 years to 70% in patients older than 70 years.

Paraesophageal hernias generally tend to enlarge with time, and sometimes the entire stomach is found within the chest. The risk of these hernias becoming incarcerated, leading to strangulation or perforation, is approximately 5%. This complication is potentially lethal, and surgical intervention is necessary. Because of the high mortality associated with this condition, elective repair often is advised wherever a paraesophageal hernia is found.

Classification

There are such types of hernia:

- 1) congenital;
- 2) acquired;
- 3) posttraumatic;
- 4) true;
- 5) false.

A. Diaphragmatic hernia.

I. [Sliding](#) (axial) diaphragmatic hernia:

- 1) esophageal;
- 2) cardial;
- 3) cardiofundal.

II. Diaphragmatic hernia of [paraesophageal](#) type:

- 1) fundal;
- 2) antral;
- 3) intestinal (small and large intestine);
- 4) combined intestinal-gastric hernias;
- 5) epiploic.

III. Huge diaphragmatic hernia:

- 1) subtotal gastric;
- 2) total gastric.

IV. A short esophagus:

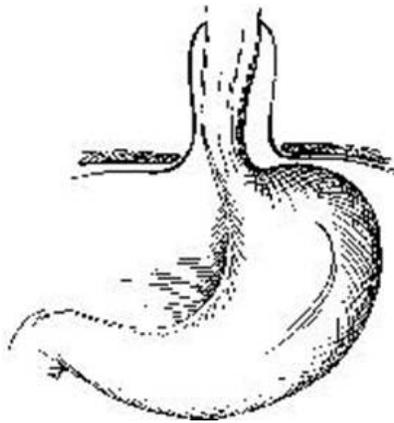

- 1) acquired short esophagus;
- 2) congenital short esophagus (thoracic stomach).

B. Parasternal hernias:

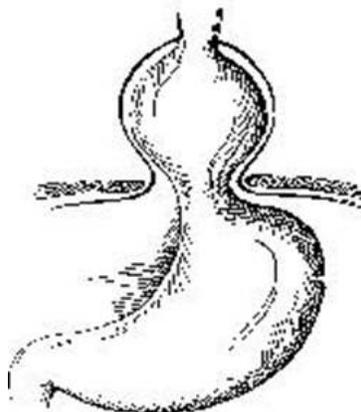

- 1) retrosternal;
- 2) retrocostosternal.

C. Lumbocostal diaphragmatic hernias.

D. Hernia of atypical localization.

Esophageal hernias:

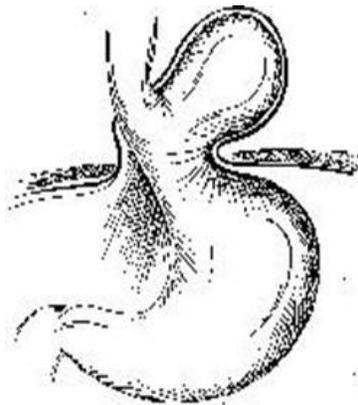

Esophageal

Cardiofundal

Mixed paraesophageal

Paraesophageal fundal

Symptomatology and clinical course

The predominant manifestations resulting from sliding diaphragmatic hernia (about 90 % of diaphragmatic hernias) are the signs of gastroesophageal reflux. It is characterized by the **pain behind breastbone** or epigastric region. It more often appears in supine position after meal or after intensive physical exertion.

Heartburn is the second according to the frequency sign and caused by the injury of esophageal mucosa by gastric juice as a result in turn of gastroesophageal reflux.

Belching by air, as a rule, observed, which commonly results in pain relief and decrease of arching feeling in epigastric region.

Regurgitation arises owing to gastroesophageal reflux, which reaches pharynx and oral cavity. More often observed regurgitation by gastric acid or bitter liquid or food.

The sign of **"lacing shoes"** is expressed when the patient bends down after liquid food, and the latter is partially poured out into the mouth. It is caused by incompetence of the lower esophageal sphincter (gastroesophageal junction).

Nausea and vomiting are rare. The latter some patients cause by themselves to achieve some relief.

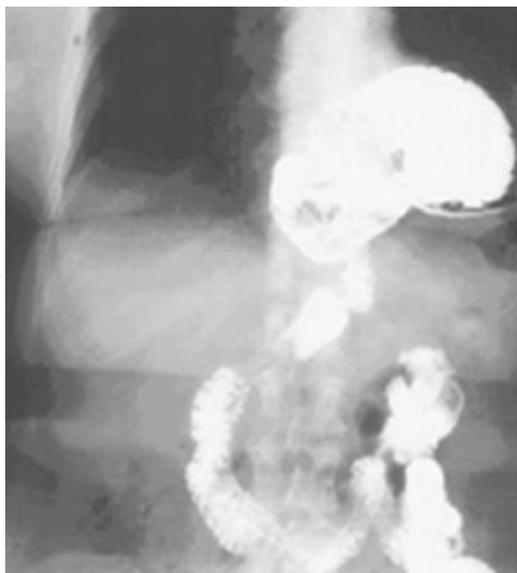

Dysphagia is rarely observed. More often it is the outcome of complications of diaphragmatic hernia (esophageal stricture, malignancy).

Roentgenological signs: 1) the sign of "bell"; 2) blunt His angle; 3) lack of air bubble of the stomach.

Sliding diaphragmatic hernia

The clinical manifestations of paraesophageal, retrosternal or lumbocostal hernias basically depend on the character of organs, which the hernial sac contents, and their compressing by hernial ring. Sometimes the clinical course even of major hernias is asymptomatic, and they are occasionally found out during X-ray examinations. For the first time the disease can manifest under the influence of physical exertion, trauma, pregnancy, labors etc.

Paraesophageal hernia

Variants of clinical course and complications

The sliding hiatal hernia commonly has typical clinical course and rather rich symptomatology, which enable to establish the diagnosis with a great degree of probability. Nevertheless occasionally gastroesophageal reflux as the sequel of a sliding hiatal hernia can result in misdiagnostics (stenocardia, acute cholelithiasis etc.).

The most often complications of sliding diaphragmatic hernia are gastric bleeding, peptic stricture of esophagus and malignancy.

The causes of the bleeding can be erosion and ulcers of stomach, which result from compression of the organ in esophageal hiatus. More often observed small bleeding, but at long-stand recurrent course they result in chronic anemia. The profuse bleeding arise rarely. The strangulation of a sliding diaphragmatic hernia never occurs.

Nevertheless for diaphragmatic hernias of other locations the most dangerous complication is naturally strangulation. Such pathology manifests by the signs of s strangulation intestinal obstruction. However the correct diagnosis frequently possible to establish only during operation.

The diagnostic program

1. Anamnesis and physical findings.

Hiatal hernias are relatively common and, in themselves, do not cause symptoms. For this reason, most people with hiatal hernias are asymptomatic. Hiatal hernias may predispose to reflux or worsen existing reflux in a minority of individuals. Physicians should resist the temptation to label hiatal hernia as a disease.

Patients can have reflux without a demonstrable hiatal hernia. When a hernia is present in a patient with symptomatic GERD, the hernia may worsen symptoms for several reasons, including the hiatal hernia acting as a fluid trap for gastric reflux and increasing the acid contact time in the esophagus. In addition, with a hiatal hernia, episodes of transient relaxation of the LES are more frequent and the length of the high-pressure zone is reduced. The main symptoms of a sliding hiatal hernia are those associated with reflux and its complications.

No clear correlation exists between the size of a hiatal hernia and the severity of the symptoms. A very large hiatal hernia may be present with no symptoms at all. Some complications are specific for a hiatal hernia.

- Esophageal complications
 - By far, the majority of hiatal hernias are asymptomatic.
 - Often, patients are left with the impression that they have a disease when a hiatal hernia is diagnosed.
 - In rare cases, however, a hiatal hernia may be responsible for intermittent bleeding from associated esophagitis, erosions (Cameron ulcers), or a discrete esophageal ulcer, leading to iron-deficiency anemia. The prevalence of large hiatal hernias in patients with iron deficiency anemia is 6-7%. This particular complication is more likely in patients who are bed-bound or those who take nonsteroidal anti-inflammatory drugs. Massive bleeding is rare.
- Nonesophageal complications
 - Incarceration of a hiatal hernia is rare and is observed only with paraesophageal hernia.
 - When this occurs, it can present abruptly, with a sudden onset of vomiting and pain, sometimes requiring immediate operative intervention.

2. X-radiography of chest and abdomen.

Although a chest radiograph may reveal a large hiatal hernia (see the first image below), and many incidentally diagnosed hiatal hernias are discovered in this manner, a barium study of the esophagus helps establish the diagnosis with greater accuracy (see the second image below).

Typical findings include an outpouching of barium at the lower end of the esophagus, a wide hiatus through which gastric folds are seen in continuum with those in the stomach, and, occasionally, free reflux of barium.

A barium study helps distinguish a sliding from a paraesophageal hernia (see the images below).

In rare cases, the entire stomach may herniate into the chest

The stomach may then undergo volvulus (see the image below) and subsequent incarceration and strangulation.

3. Esophagogastrosocopy with biopsy and histological investigation.

Hiatal hernia is diagnosed easily using upper gastrointestinal endoscopy.

The diagnosis of a hiatal hernia actually is incidental, and endoscopy is used to diagnose complications such as erosive

esophagitis, ulcers in the hiatal hernia, Barrett esophagus, or tumor.

A hiatal hernia is confirmed when the endoscope is about to enter the stomach or on retrograde view once inside the stomach (see the image below). If any doubt remains, the patient may be asked to sniff through the nose, which causes the diaphragmatic crura to approximate, seen as a pinch, closing the lumen.

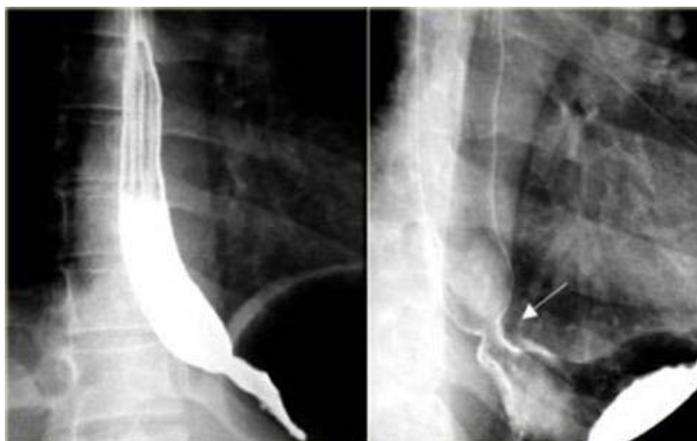

Endoscopy also permits biopsy of any abnormal or suspicious area.

Esophageal manometry has a low sensitivity for diagnosing hiatal hernia, as compared to endoscopy, and is therefore not appropriate in helping to establish a diagnosis.

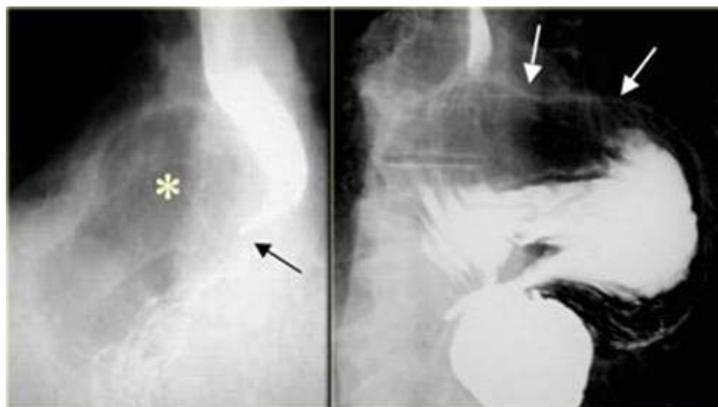

4. Contrast X-radiography of esophagus and stomach in three positions: upward, supine and upside-down position.

5. General blood and urine analyses.

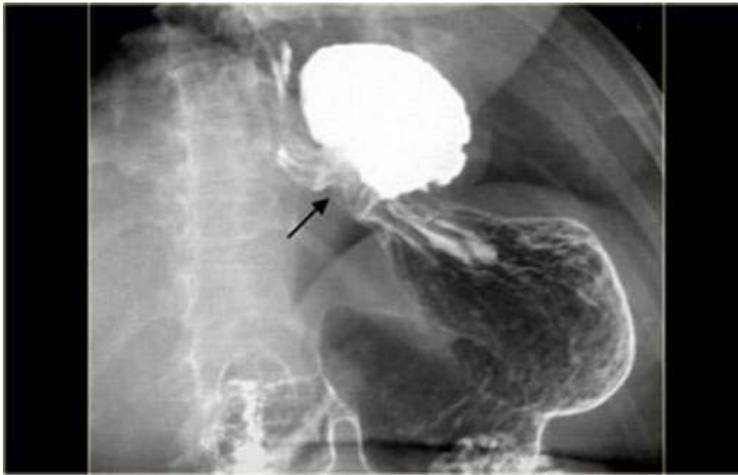

6. Coagulogram.

Sliding hernia

Paraesophageal hernia

Mixed hernia

Differential diagnostics

Stenocardia. Diaphragmatic hernias frequently cause the pain, which character not only the patient, but also doctor can identify as anginal. However in diaphragmatic hernia the pain more often is vague, spread to the stomach region and depends on body position. The pain, as a rule, arises in supine position and disappears, if the patient upward. More often it spreads to the right and anginal vice versa to the left. In diaphragmatic hernia the ECG can manifest the coronary failure, nevertheless standing up, owing to the stop of strangulation leads to disappearance of these pathological sings. The pain caused by diaphragmatic hernia does not relieve after nitroglycerin. In this case more effective and prompt is atropine.

Peptic ulcer. The pain in gastric and duodenal ulcer frequently localized in epigastric region with irradiation in the left or right hypochondrium. Nevertheless, it is characterized by periodicity, which caused by meal and disappears after the usage of soda.

Lung atelectasis, pleurisy, pneumonia are also should be differentiated with diaphragmatic hernia. Thus it is always necessary to remember, that the extrapulmonary shadow of supradiaphragmatic disposed hernia on a plain roentgenogram can resemble intrapulmonary. For correct diagnosis it is possible to recommend polypositional X-radiography, contrast roentgenography of esophagus and stomach.

Hypochromic anemia frequently associated due to repeated or permanent small bleedings. They are caused by a regional destruction a gastric mucosa. In the females of senior age if it is fail to explain genesis of the revealed anemia, it is necessary to think about the opportunity of diaphragmatic hernia and carry out appropriate X-ray examination.

Tactics and choice of treatment

The medical tactics toward diaphragmatic hernias of different localization essentially differs.

In case of sliding hiatal hernia the method of a choice is the **conservative therapy**:

- 1) the diet the same, as in peptic ulcer;

An appropriate diet maintains an ideal body mass index. Obesity predisposes to reflux disease. Burkitt et al suggest that the Western, fiber-depleted diet leads to a state of chronic constipation and straining during bowel movement, which would explain the higher incidence of this condition in Western countries.

- 2) position of the patient during sleeping – with elevated upside, during exacerbation – sedentary;
- 3) suppression of gastric secretion by administering of H₂-blockers;
- 4) neutralization of gastric acid;

- 5) intensifying of evacuation of the food from stomach;
- 6) avoidance of constipation;
- 7) anesthetics and sedative agents.

The indication for surgical treatment of sliding diaphragmatic hernia is the considerable expression of clinical signs, diminish of patient's working capacity, fail of conservative treatment, bleeding, peptic stricture, malignancy.

When hiatal hernias are symptomatic, acid reflux usually produces the symptoms. If the hernia itself is causing chest discomfort or other symptoms, surgery may be necessary.

When symptoms are due to GERD, the goals of treatment include prevention of reflux of gastric contents, improved esophageal clearance, and reduction in acid production. This is achieved in the majority of patients by a combination of the following:

- Modifying lifestyle factors
- Neutralizing acid or inhibiting acid production
- Enhancing esophageal and gastric motility

The treatment of GERD is beyond the scope of this article and is discussed in Gastroesophageal Reflux Disease.

Large hiatal hernias may cause iron deficiency anemia regardless of whether Cameron ulcers are present. This anemia responds well to PPI therapy with surgery offering no clear advantage over medical therapy.

Surgical treatment. Upper median laparotomy is mainly used. Nevertheless some surgeons prefer transthoracic accesses.

A patient with a large hiatal hernia may experience vague intermittent chest discomfort or pain. The paraesophageal hernia may strangulate and frequently is operated on prophylactically to prevent this complication. Paraesophageal hernias may present in infants or adults as a potentially life-threatening complication of strangulation, and prompt surgical repair is key. When found in asymptomatic individuals, laparoscopic repair is often undertaken, with large defects in the diaphragm being closed with mesh.

Surgery is necessary only in the minority of patients with complications of GERD despite aggressive treatment with proton pump inhibitors (PPIs). Because only a minority of patients with hiatal hernia have any problems, this represents a very small proportion of patients with sliding hiatal hernia; most patients with problems are managed medically.

By far, the majority of patients who would have undergone surgery in the past are managed successfully today with PPIs. However, young patients with severe or recurrent complications of GERD, such as strictures, ulcers, and bleeding, who cannot afford lifelong PPI treatment or would prefer to avoid taking medications long term, may be surgical candidates.

Another group of patients who are surgical candidates are those with pulmonary complications, in particular, asthma, recurrent aspiration pneumonia, chronic cough, or hoarseness linked to reflux disease.

Three major types of surgical procedures correct gastroesophageal reflux and repair the hernia in the process. They can be performed by open laparotomy or with laparoscopic approaches, which currently are being employed more frequently.

· Nissen fundoplication

○ The Nissen fundoplication performed laparoscopically has gained popularity because of its lower morbidity and shorter hospital stay compared to the open procedure performed previously. Although a relatively high incidence of postoperative complications, such as dysphagia and gas bloating, are reported, DeMeester and Peters[7] have shown that placing a larger bougie in the esophagus during this procedure, along with a shorter wrap and more complete mobilization of the stomach, have markedly reduced postoperative complications.[8, 9]

○ This procedure involves a 360° fundic wrap around the gastroesophageal junction. The diaphragmatic hiatus also is repaired.

○ A transthoracic approach may be used in patients who have had a previous Nissen wrap or those who have an irreducible hernia.

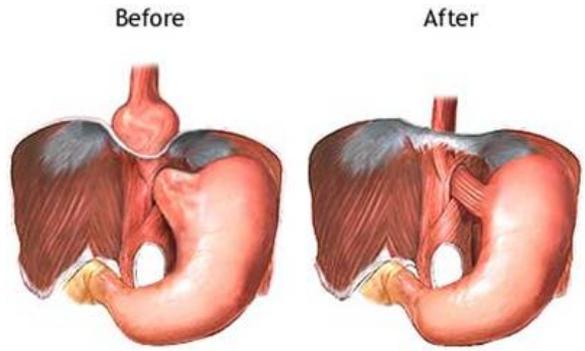

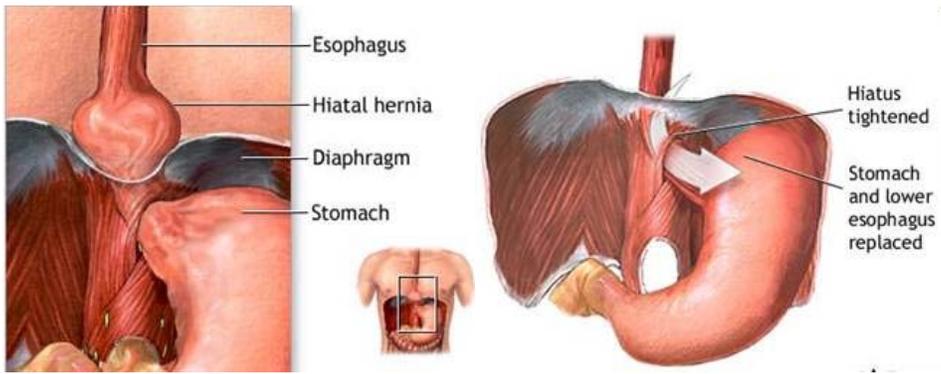

- The Toupet procedure is a variant of the Nissen wrap and involves a 180° wrap in an attempt to lessen the likelihood of postoperative dysphagia.
- Belsey (Mark IV) fundoplication: This operation involves a 270° wrap in an attempt to reduce the incidence of gas bloating and postoperative dysphagia. It also is preferred when minimal esophageal dysmotility is suspected. To complete this operation, the left and right crura of the diaphragm are approximated.
- Hill repair: In this procedure, the cardia of the stomach is anchored to the posterior abdominal areas, such as the medial arcuate ligament. This also has the effect of augmenting the angle of His and thus strengthening the antireflux mechanism.
- The antireflux procedures discussed above offer relief of symptoms in 80-90% of patients. In most cases, the procedure of choice is the one with which the surgeon is most familiar. These procedures carry low mortality and morbidity rates, lower than 15-20%. DeMeester et al found the Nissen procedure superior to the Belsey and Hill repairs with regard to symptom relief and prevention of reflux postoperatively (as judged by pH monitoring). Good long-term results have been reported for antireflux surgery, with adequate control of reflux in the range of 80% at 10 years.
- Most patients with a paraesophageal hernia remain asymptomatic. In this type of hernia, symptoms from acid reflux usually do not occur. Instead, the most common symptom is epigastric or substernal pain. Some patients complain of substernal fullness, nausea, and dysphagia.
 - A significant proportion of patients with this type of hernia develop incarceration of the hernia and possible gastric volvulus, which can lead to perforation.
 - If perforation occurs, the mortality rate is high. Because of this, many surgeons advise elective repair when the diagnosis is made.
 - The goal of surgery is to remove the hernia sac and close the abnormally wide esophageal hiatus.
 - Some surgeons then tack the stomach down in the abdomen to prevent it from migrating upwards again, or, they perform a temporary gastrostomy to help decompress the stomach and anchor it in place in the abdominal cavity.

Stages of the operation:

1. Drawing of the stomach into abdominal cavity by disjunction of adhesions in the region of its cardiac part, esophagus, excision of hernial sac.
2. The plastics of esophageal hiatus of diaphragm (cruroplasty). The most widespread cruroplasty by Hill and narrowing of esophageal ring according to Garrington.
3. Elimination of valvular failure of esophagocardial junction. The purpose of operation is to prevent gastroesophageal reflux by means of formation of His angle and esophagocardial valve. Also Nissen fundoplication is applied.
4. Gastropexia – fixation of gastric wall to parietal peritoneum.

Another tactics is applied in the patients with paraesophageal, parasternal and lumbocostal hernias. The method of choice is the surgery. Such tactics is explained by the hazard of strangulation. The essence of the operation consists of drawing down of hernial content (stomach, intestine, omentum) into abdominal cavity, removing of hernial sac and liquidation (suturing) of hernial ring.

Steps of cruroplastic

DIAPHRAGMATIC RELAXATION (DIAPHRAGMATIC EVENTRATION)

The term "diaphragmatic relaxation " was used for the first time in 1906 by Witting. It means a relaxation of diaphragm, its high standing and displacement upward of abdominal organs.

The term 'diaphragmatic eventration' is used in common practice to describe a condition of relaxation of the diaphragmatic dome. It may present at birth as a congenital condition due to a defect of diaphragmatic development or in a later stage of life as an acquired condition ('acquired diaphragmatic paralysis' or 'acquired diaphragmatic elevation').

Etiology and pathogenesis

The cause of the disease is the congenital or acquired decrease of diaphragmatic resistance, which during elevation of intraperitoneal pressure results in its outpouching. The great importance in the development of acquired relaxation belongs to the damage of diaphragmatic nerve. The cause of the latter could be inflammatory processes in chest and abdominal cavity, intoxication, poisoning, operations on chest organs and birth injury.

Pathology

In congenital form of a diaphragmatic relaxation revealed muscular aplasia, in acquired – atrophy of muscular fibers.

Classification

- 1) Complete: left-side, right-side;
- 2) Incomplete: anterior, posterior, restricted (partial).

Symptomatology and clinical course

Minor manifestation or asymptomatic course characterizes diaphragmatic relaxation. Therefrom, it is always necessary to thoroughly analyze the occurrence of multiple signs from the organs of digestive, respiratory and cardiovascular system. The clinical symptomatology basically depends on dysfunction of the diaphragm by itself and organs, which adjoin to it both in chest, and in abdominal cavity. In left-side diaphragmatic relaxation the asymptomatic course rarely occurs.

General symptomatology. The patients with diaphragmatic relaxation can feel a pain of different character, localization and intensity. The pain syndrome frequently results from gastric inflection or compression of vessels and nerves by filled stomach. Inflection of vascular bundles of pancreas, lien, kidneys, mesentery of small and large intestines as a result of shift of abdominal organs also contribute to the development of pain syndrome. Frequently patients complain of general weakness and loss of weight.

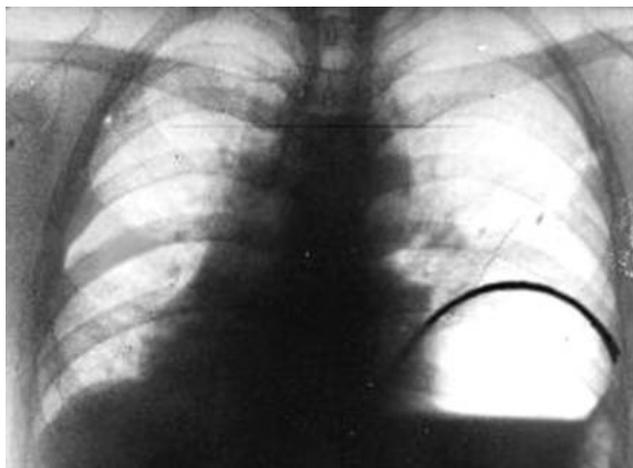

Gastrointestinal symptomatology. Dysphagia almost always arises as a result of inflection of abdominal part of esophagus. The heaviness after meal should be caused by atony of stomach and its evacuation dysfunction. Ulceration and erosive gastritis, which occurs in some patients, are the outcome of a regional ischemia from gastric inflection or torsion. Chronic constipation is basically caused by disturbance of massage influence of the diaphragm on intestine. Meanwhile heartburn, belching, nausea, vomiting and meteorism also observed.

A phrenocardiac Uden-Ramcheld's syndrome represents **cardiopulmonary signs**. It is characterized by dyspnea, discomfort in the region of heart, anginal pain, extrasystole and ECG changes (elongation of P wave, PQ interval and complex QRS).

Respiratory disturbances result from dynamic dysfunction of the diaphragm. The high standing of the diaphragm leads to compression of lung on the side of lesion and disturbed ventilation of the lower part. It causes the diminishing of vital capacity of the lungs and development of dyspnea.

Roentgenologically revealed the high standing of diaphragmatic dome (to II-III intercostal space), restriction of its excursion and reduce of the inferior

pulmonary field. Frequently observed the mediastinal shift to the opposite side. The contrast X-radiography of esophagogastric junction can find out the inflection of abdominal part of esophagus. The X-ray examination enables to establish the diagnosis with a high degree of reliability.

Diaphragmatic relaxation

Variants of clinical course and complications

Asymptomatic course of diaphragmatic relaxation in the majority of patients has caused interpretation of this pathology as "innocent disease". Nevertheless the shift and rotation of heart can cause the heart failures, and the restriction of pulmonary excursion sometimes leads to chronic pneumonia. The gastric inflection frequently may result in disturbance of the valvular mechanism of esophagogastric junction and occurrence of reflux esophagitis.

The diagnostic program

1. Anamnesis and physical findings.
2. Plain chest X-radiography.
3. Esophagogastroduodenoscopy.
4. Roentgenoscopy of esophagus and gastrointestinal tract.
5. General blood and urine analyses.

Differential diagnostics

Diaphragmatic elevation is the secondary high standing, which can arise as a result of ascites, pregnancy, expressed meteorism, peritonitis, tumours of abdomen, splenomegaly or megacolon.

Pneumothorax, pyopneumothorax, pleurisy. Such misdiagnostics in the patients with diaphragmatic relaxation frequently caused by chest pain, cough, dullness and tympanic sound revealed at percussion, and weak breathing at auscultation. Chest X-radiography rather contributes to exact diagnostics.

Diaphragmatic hernia. The differential diagnosis of diaphragmatic relaxation with this pathology is the most difficult. Nevertheless it has the important practical value, because the threat of strangulation of diaphragmatic hernia requires an active surgical tactics. During the establishment of the diagnosis it is always necessary to remember, that clinical manifestation of diaphragmatic hernia more expressed. However, the sharp inflection of abdominal organs in the patients with diaphragmatic relaxation also can associate with severe pain, which resembles strangulation. Thereafter, a reliably

differentiation of these diseases is possible only after a goal-oriented X-ray examination.

Cancer of esophagus and cardial part of stomach. A sharp gastric shift upward with inflection of abdominal part of esophagus can lead to dysphagia, substernal pain, disturbance of digestion, considerable loss of weight etc. For differential diagnostics applied a contrast X-ray examination of esophagus and stomach.

In difficult for differential diagnostics cases a pneumoperitoneum with further X-ray examination is performed. This method allows with a major degree of reliability to establish the diagnosis of diaphragmatic relaxation.

Tactics and choice of treatment

In most cases the asymptomatic course of diaphragmatic relaxation requires no special treatment.

Conservative therapy applied at presence of symptomatology:

- 1) avoidance of physical exertions, which increases intraperitoneal pressure;
- 2) diet – eating by small portions and exception of food, which form waste and gases;
- 3) therapeutic gymnastics for improving of intestinal function and decrease of the patient's weight;
- 4) symptomatic therapy for regulation of cardiovascular and respiratory systems.

The indication for operation: gastric torsion or severe cardiorespiratory dysfunction. If clinical manifestations are absent, the surgical treatment can be recommended only for women with further pregnancy and labors, because these conditions cause a sharp increase of intraperitoneal pressure with further shift of the diaphragm and abdominal organs.

Surgical treatment. By means of a lateral access in VII intercostal space a [phrenoplasty](#) is performed, which consist of incision of diaphragm from costal edge to esophageal ring with following diaphragmatic duplication.

ACUTE MEDIASTITIS

Acute mediastinitis is a purulent inflammation of mediastinum.

Etiology and pathogenesis

The penetration of pathogenic agents into mediastinum can result from perforation and chemical burns of esophagus; injuries of trachea, bronchi, operations on mediastinal organs and lungs. Also is possible the contamination from neck fat tissue and tracheobronchial lymph nodes.

Classification of mediastinitis

According to localization:

- 1) anterior;
- 2) posterior;
- 3) superior;
- 4) medial;
- 5) inferior.

According to pathogenesis:

- 1) primary;
- 2) secondary.

According to the clinical course:

- 1) acute: purulent, aseptic;
- 2) chronic.

According to the character of infection:

- 1) nonspecific;
- 2) specific.

Symptomatology and clinical course

The clinical manifestation of acute mediastinitis is characterized by prompt progressing course, dependence on extent of the process, gravity of infection and peculiarities of underlying disease.

Body temperature raises up to 39-40°C and of hectic character, the patients complain of dyspnea, cyanosis, fever and profuse sweating.

The local symptomatology of the disease depends on location of the process and involvement of esophagus, trachea, heart, n. vagus, n. phrenicus, n. recurrens, tr. sympaticus.

Also is possible dysphagia, dyspnea, constant cough, hoarseness, change of cardiac rhythm.

On percussion revealed a mediastinal widening, on auscultation – weak cardiac tones.

X-ray examination. The method of X-ray examination should be chosen according to the cause of occurrence of acute mediastinitis. If the disease is

caused by cervical phlegmon the X-radiography examination should be restricted only by chest X-ray film in three plains. In such situations observed widening of mediastinum, shadowing of its anterior part and shift of trachea. Compression of esophagus revealed by barium swallow.

The contrast X-ray examination of esophagus after its iatrogenic perforation it is possible to see penetration of barium into mediastinum, shadowing and widening of its consequent parts. Fibresophagoscopy as the method of diagnostics of esophageal perforation is not recommended due to pneumatic pressure during this manipulation.

Variants of clinical course and complications

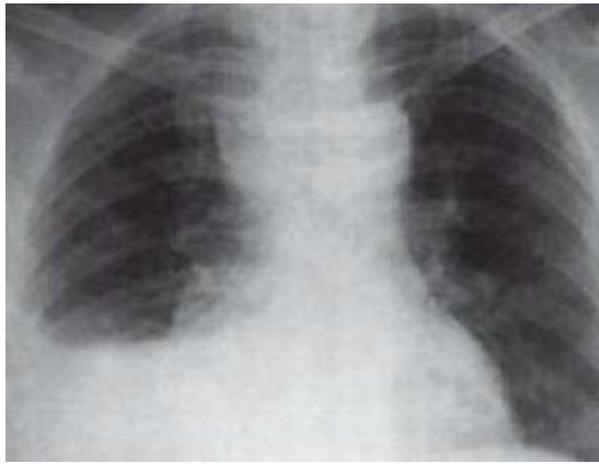

According to the features of clinical symptomatology, acute mediastinitis is divided into anterior and posterior mediastinites.

Anterior mediastinitis	Posterior mediastinitis
Throbbing substernal pain	Throbbing chest pain with irradiation in interscapular region
Intensifying of pain during percussion of breast bone	Intensifying of pain during vertebral pressing
Intensifying of pain when head is unbent back	Intensifying of pain at swallowing
Occurrence of swelling in the region of jugular fossa	Swelling above clavicle
Signs of compression of superior vena cava	Sign of compression of azygos and hemiazygos veins (distended intercostal veins, pleural effusion)

The most often complications of acute mediastinitis are: pyopneumothorax, which has arisen after the abscess discharge into pleural space, pleural empyema, purulent pericarditis, erosive bleeding and lung abscesses.

The diagnostic program

1. Complaint and history of the disease.
2. Physical findings.
3. Chest X-ray examination.
4. Contrast esophagography.
5. ECG.
6. Fibrobronchoscopy.

Acute mediastinitis

Differential diagnostics

Acute mediastinitis requires express differential diagnostics.

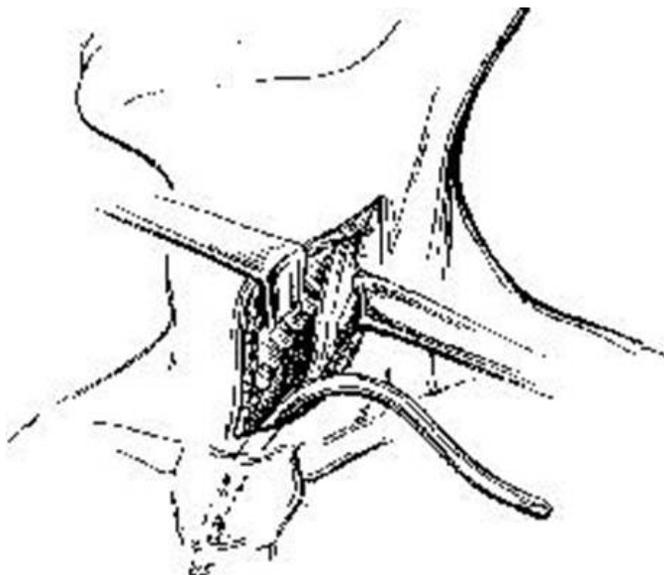

Acute pneumonia, as a rule, is the outcome of catarrhal factor, which evidence is showed by the patients. Besides, more long duration, high temperature, and cough with expectoration of mucopurulent sputum characterize the pneumonia; on auscultation –fine bubbling wet rales on the side of lesion and infiltration of pulmonary tissue at chest X-ray examination. All these findings enable to confirm or to rule out pneumonia.

Exsudative pleurisy mostly arises as the result of complication of pleuropneumonia. The process lasts, as a rule, 5-7 days. The most typical manifestations are cough and chest pain on the side of lesion, which intensifies at deep breathing. Percussion reveals a shortening of percussion sound. On auscultation – weak breathing sounds and pleural friction rub. The presence of intensive homogeneous shadow with oblique upper contour on chest X-radiography and also thoracentesis confirm the diagnosis of pleurisy.

Exsudative pericarditis. It most often results from rheumatic lesion of heart, acute myocardial infarction or polyserositis. Dyspnea, pain, heavy feeling behind breastbone, general malaise, forced sedentary patient's position are the chief signs of pericarditis. On X-ray films observed a trapezoid shape of heart, and on ECG – diminished waves. Puncture of the pericardium with obtaining of exudate finally confirms the diagnosis.

Tactics and choice of treatment

The treatment of mediastinitis is only surgical. Its character and volume significantly depend on the cause, location and extent of purulent process. Established perforation of esophagus, trachea or bronchus requires an urgent operation. The foreign bodies thus removed, and operation ends by drainage. If the process located in anterosuperior mediastinum used a cervical mediastinotomy.

Cervical mediastinotomy

Nevertheless cervical mediastinotomy is insufficient at low localization of the process. In such cases performed anterior mediastinotomy. Meanwhile, isolated posterior mediastinitis is the indication for drainage by means of posterior extrapleural mediastinotomy.

In postoperative period is necessary application of intensive antibacterial, antiinflammatory and detoxycation therapy, and also treatment direct on the increase of immunological resistance of the organism. The mortality after such operative approaches has been 26-36 %, and after conservative treatment – about 70 %.

MEDIASTINAL TUMORS

The mediastinal tumors include true tumours, cyst and masses.

Classification of tumours

1. Neurogenic tumours:

- a) ganglioneuroma;
- b) neurinoma;
- c) neurogenic sarcoma;
- d) neuroblastoma;
- e) sympathoblastoma.

2. Mesenchymal tumours:

- a) fibroma;
- b) lipoma;
- c) hemangioma;
- d) fibrosarcoma;
- e) liposarcoma;
- f) angiosarcoma.

3. Tumours originated from reticular tissue of lymph nodes:

- a) lymphosarcoma;
- b) reticulosarcoma;
- c) lymphogranulomatosis.

4. Tumour originated from thymus (thymoma), and thyroid gland (substernal, intrathoracic goiter).

5. Germ cell tumours:

- a) dermoid cyst;
- b) teratoma;
- c) mediastinal seminoma;
- d) choriocarcinoma.

6. True mediastinal cysts:

- a) mesothelial cyst;
- b) pericardial diverticula;
- c) bronchogenic cyst;
- d) enteric cyst.

7. Parasitogenic (echinococcal) cysts.

Symptomatology and clinical course

On early stages of the development the tumours are almost asymptomatic, and 40 % of mediastinal neoplasms are revealed at preventive chest X-ray examination. The patients most often complain of chest pain. The intensity of pain depends on degree of tumour compression or growth into nervous structures. In malignant growth the pain has more intensive character, than in benign. Frequently the pain precedes by feeling of heaviness, discomfort and foreign body in chest. Sometimes observed dyspnea caused by compression of airways, and major vessels both of anterior, and posterior mediastinum.

Owing to compression of the lumen of superior vena cava the syndrome of superior vena cava develops, which manifest by cyanosis of face, neck and upper half of chest, distend cervical veins, edema and dyspnea. Resulting from the rise of blood pressure and disruption of venous walls, the nasal, esophageal and pulmonary bleedings develop. As the characteristic features considered headache, loss of consciousness and hallucinations. In overwhelming cases superior vena cava syndrome results from malignant tumours of lungs and mediastinum. Only in 5-7 % of patients they are benign.

The basic method of diagnostics is a complex X-ray examination: roentgenoscopy, polypositional X-radiography, tomography, computer tomography. The examination should be start from roentgenoscopy in different plains (multiaxial roentgenoscopy). It gives the possibility to find out a pathological shadow, its location, shape, size, mobility, intensity, contours and to reveal the presence or lack of pulsation of walls. Computer tomography is also a high-grade method of diagnostics. It helps to receive the image of transversal plain of chest at any level, to confirm the location of mediastinal tumour and its communication with adjacent organs. In suspicion on a vascular nature of the process, angiography is used. It enables to rule out aneurysm of heart, aorta and its branches, reveal compression of superior vena cava and growth of the tumour into major arterial trunks.

If it is necessary to differentiate the tumour from cyst and reveal its different deposits, it is expedient to apply ultrasonic examination (sonography).

With the purpose of improvement of localization, size of mass, its communication with mediastinal organs performed pneumomediastinography (X-radiography of mediastinum with introducing of oxygen or air). For pneumomediastinography, depending on tumour locating the gas is introduced through a puncture above jugular incisure of breastbone, under xyphoid process or parasternally. Thus gas at first is spread in anterior mediastinum, and in 45-60 min. penetrates in posterior. The introduced gas achieves a good visualization of tumour contours and its growth into adjacent organs. Sometimes an artificial pneumothorax is performed on the affected side. In such patients collapse of lung gives the opportunity to differentiate pulmonary tumour from mediastinal tumours and cysts.

For morphological verification of the tumour applied such additional methods:

- thoracoscopy, which allows to examine a pleural space, to take biopsy from mediastinal lymph nodes or tumour;
- mediastinoscopy (through a small incision above the breastbone exposed trachea, and along its position performed the canal in anterior mediastinum with following insertion of a special endoscope) enables to examine anterior mediastinum, and take a biopsy from lymph nodes and tumour;
- transthoracic aspiration biopsy is performed if tumour is located near chest wall;
- transbronchial puncture of lymph nodes is carried out during bronchoscopy.

During diagnostics of mediastinal neoplasms applied according to indications bronchography, esophagography and pneumoperitoneum.

Variants of clinical course and complications

Neurogenic tumours are the most common neoplasms of mediastinum, which occur in 20 % among the tumours of this location. There arise in any age and more often benign. Their predominant localization is the posterior mediastinum. The origin of such tumours could be nervous trunks, ganglions and other nervous structures of mediastinum. From the cells of sympathetic nervous trunk arise ganglioneuromas, neuroblastomas and sympathoblastomas.

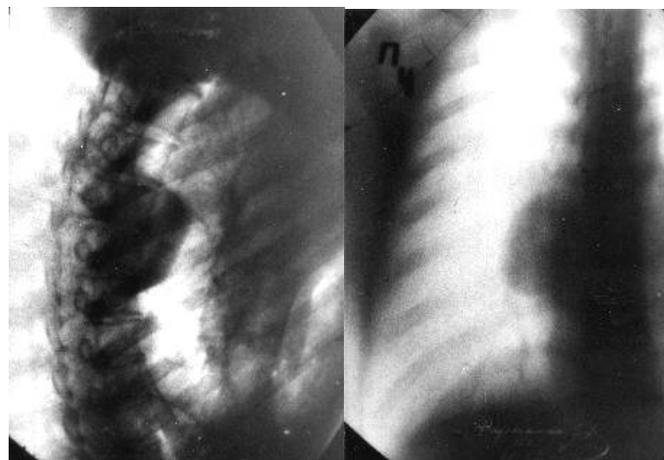

[Slide](#)

The tumours, which arise from peripheral nerves are represent by neuromas and neurofibromas. The paragangliomas and mediastinal pheochromocytoma develop from chemoceptor cells of and according to the structure resemble the tumours of sinocarotid zone. They frequently produce hormones, and manifests by hypertension with often crises. In half of patients these tumours are malignant.

Neurogenic sarcoma is a malignant tumour of nervous sheath. It is usually solitary, or in association with von Recklinhausen's disease.

The neurogenic tumours commonly manifest by backache, hyperalgesia, pareses and paralyzes at tumour growth through the spinal canal. The pain reaction varies from slight to severe expressed neuralgias. Frequently ganglioneuroma is asymptomatic for many years. In the clinical pattern of malignant neurogenic tumours prevail general intoxication, loss of weight and pain syndrome.

Roentgenologically in neurogenic tumour of a vertebrocostal angle observed characteristic intensive rounded shadow, with vertebral and costal usuration, rib. Frequently revealed hemorrhagic pleural effusion on the side of lesion by malignant tumour.

Ganglioneuroma

Mesenchymal tumours. According to the histological origin mesenchymal benign tumours are represented by:

- from a fibrous connecting tissue – fibroma;
- from a cartilaginous and osseous tissue - chondroma, osteochondroma, osteoblastoclastoma;
- from a spinal cord – chordoma;
- from fat tissues – lipoma, hibernoma;
- the tumours, which originate from vessels – hemangioma, lymphangioma;
- from a muscular tissue - leiomyoma, rhabdomyoma.

Lipomas are the most frequent mesenchymal benign tumours with predominant location in cardiophrenic angle.

The clinical symptomatology of these tumours is atypical. At the small sizes they are usually asymptomatic. The malignant neoplasms manifest much earlier as the result of prompt infiltrative growth of the tumour and intoxication of the organism. Nevertheless, despite the malignant character, liposarcoma can grow rather slowly with late metastatic spread.

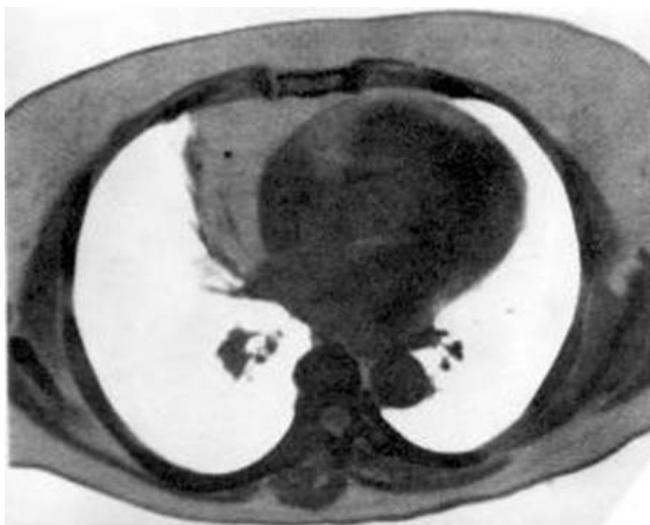

On [roentgenogram](#) such masses represented by homogeneous formations, that applies to heart shadow.

The **lymphomas** occur in 3-5 % of patients with mediastinal tumors and in 20-25 % with all malignant neoplasms of mediastinum. The lymphomas arise from mediastinal lymph nodes. Their common localization – anterior mediastinum, nevertheless lymph nodes of any part can be affected. There are three types of lymphomas: lymphosarcoma, reticulosarcoma and lymphogranulomatosis. All of them are characterized by malignant course. The initial signs of this pathology mainly caused by intoxication: malaise, subfebrile or febrile temperature with further remittent character, sweating and loss of weight. One of most typical manifestation of the disease should be considered itching of skin. Abnormally enlarged lymph nodes can compress mediastinal organs, which lead to dry cough, chest pain, and dyspnea. In lymphogranulomatosis, in contrast with other mediastinal tumours, the signs of compression are weakly expressed. It is characterized by bilateral lesion and blood changes (leukocytosis or leukopenia and elevation of erythrocyte sedimentation rate). Lymphosarcoma differs by more prompt course and considerable progression of mediastinal compression syndrome. X-ray examination, mediastinoscopy and biopsy of lymph nodes are the most valuable for diagnostics.

The **dermoid cysts and teratomas** arise owing to disturbance of embryogenesis and occur in 5-8 % of the patients with mediastinal tumors. The origin of dermoid cysts is the ectoderm, which transforms to a fibrous connecting tissue. The cystic cavity frequently contains similar to fat viscous mass of brown color with deposits of skin and hair. The teratomas arise from several germinal laminae and contain different structural tissues. They are divided on mature and immature. All mature teratomas, as a rule, are characterized by well-defined capsule, irregular rounded or oval shape, different size, and look like a cyst on slit. Immature ones look like solitary nodes, sometimes with small cavities. The structure of teratomas can include parts of glands, teeth, bones and sometimes even underdeveloped fetus. According to degree of cellular differentiation teratoma is divided on benign (80-90 %) and malignant (10-20 %). Although this disease is always congenital, it is diagnosed, mainly, in elderly age at occurrence of pain and "compression syndrome". 95 % of such cysts are located in anterior mediastinum and frequently are accompanied with cardiovascular disturbances (tachycardia, pressing pain in the region of heart). The compression of major bronchi and trachea results in occurrence of dyspnea, paroxysmal cough and hemoptysis. The infection of the tumour frequently leads to fever and increase of intoxication. The presence in sputum of hair and other tissues is considered to be the sign of bronchial fistula.

In diagnostics of teratomas the major value has a complex X-ray examination. It is possible to find out teeth, calcification of cystic capsule and its contents. Prompt growth of the tumour, disappearance of its regular contours suspects the malignancy.

Cysts of pericardium are the cavity thin-walled formations, which according to the structure resemble pericardium. They occur in 7-8 % of cases of all mediastinal tumors. Their most often location is the right cardiophrenic angle, much less often – left one. A true cyst may be single-, double- or multichamber, connected or non-connected with pericardium. The cases, when the cystic cavity communicates with the cavity of pericardium, it should be considered as diverticulum. The disease, as a rule, is asymptomatic and it is casually revealed only during prophylactic fluorography. In cases of great size of cyst the patients complain of pain in the region of heart and cardiac arrhythmia. During X-ray examination mesothelial cyst or pericardial diverticulum is observed as oval or semicircular homogeneous shadow with regular outline, which intimately applies to the shadow of heart.

Cysts of pericardium. Computer tomography

Bronchogenic and enteric cysts of mediastinum arise in the period of intrauterine development and originated from dystopic germs of bronchial or intestinal epithelium.

Bronchogenic cysts, as a rule, are single chamber, with location either in mediastinum, or in pulmonary tissue. The neighborhood of cyst with bifurcation of trachea can cause paroxysmal cough, dyspnea and respiratory disturbances. Paraesophageal location of the cyst manifests by dysphagia. The clinical manifestations of such pathology can be caused by inflammatory process in cyst or its sudden discharge into airways. If the cyst is communicated with airways, the roentgenogram reveals a fluid level, and during bronchography a contrast agent fills in the lumen of cyst. The diagnosis is possible to confirm by means of pneumomediastinography.

The enteric cyst (enterocystoma) arises from the dorsal parts of a primary intestinal tube, located more often in lower parts of posterior mediastinum and applies to esophagus. Depending on histology they are divided on esophageal, gastric and intestinal cyst. In cases, when a cystic wall is covered by gastric epithelium, which produces hydrochloric acid, an ulceration of wall, bleeding and its perforation can develop.

Frequently enteric cyst suppurates with the hazard of discharge into pleural space or pericardium, esophagus and bronchi. The most often signs of the disease is dyspnea and chest pain. Due to characteristic localization of the pathological focus in posterior mediastinum, to the right from median line, the roentgenological diagnostics is usually not difficult. In order to determine mutual relation of neoplasm to trachea, bronchi, and esophagus it is possible to apply pneumomediastinography. As there is always a danger of the development of complications, it is necessary to consider such pathology as absolute indication for operative removal.

Echinococcosis of mediastinum occurs rarely (1-2 % of all mediastinal tumors). If the parasite is of small size, the disease most often asymptomatic. The enlargement of echinococcal cyst causes pain, dyspnea, dysphagia and superior vena cava syndrome. Sometimes in such patients the cyst can discharge into bronchus or trachea. The suppuration of parasitogenic cysts is transformed into abscess and purulent mediastinitis. Roentgenological method should be considered to be predominant in the diagnostics of echinococcosis of mediastinum. The presence of homogeneous, round or oval shadow with regular outline (with further calcification) suggests echinococcosis. For confirming of the diagnosis reaction of latex-agglutination is performed. Echinococcosis of mediastinum frequently associated with anatomical lesion of lungs.

Principles of diagnostics in such situation are similar to primary mediastinal tumors.

Tactics and choice of treatment

The presence of mediastinal tumors requires surgical treatment. Expectant tactics and dynamic observation in such cases are unjustified.

In connection with a constant and substantial threat of infection, perforation and development of purulent intrapleural complications, the pericardial, bronchogenic and enteric cysts of mediastinum are the subjects to operative remove.

The operative treatment of malignant mediastinal tumors should be applied on early stages of the disease. In advanced cases it is expedient to apply antineoplastic and radiotherapy.

The benign neurogenic tumours are removed in surgical way through thoracotomy incision. If the tumour grow like a " sandglasses" a fragment of the tumour removed with following resection of vertebral arches. The malignant tumours are removed "in mass", with maximal excision of the tumour, affected ribs, paraaortic, esophageal and paratracheal lymph nodes.

SUPERIOR VENA CAVA (SVC) SYNDROME

Superior vena cava (SVC) syndrome (SVCS) is characterized by gradual, insidious compression/obstruction of the superior vena cava. Although the syndrome can be life threatening, its presentation is often associated with a gradual increase in symptomatology. For this reason, diagnosis is often delayed until significant compression of the superior vena cava has occurred.

Pathophysiology

Extrinsic compression of the superior vena cava is possible because it has a thin wall coupled with a low intravascular pressure. Because the superior vena cava is surrounded by rigid structures, it is relatively easy to compress. The low intravascular pressure also allows for the possibility of thrombus formation, such as catheter-induced thrombus.

The subsequent obstruction to flow causes an increased venous pressure, which results in interstitial edema and retrograde collateral flow.

Epidemiology

Superior vena cava syndrome is chiefly associated with malignancy. Currently, more than 90% of patients with superior vena cava syndrome have an associated malignancy as the cause. This contrasts with studies in the early 1950s in which a large proportion of cases were nonmalignant. Infectious causes (eg, syphilis, tuberculosis) have decreased because of improvements in antibiotic therapy. Of the nonmalignant causes of superior vena cava syndrome, thrombosis from central venous instrumentation (catheter, pacemaker, guidewire) is an increasingly common event, especially as these procedures become more common.

Causes

Today, the most common etiology of superior vena cava syndrome is related to malignancy.

- Prior to modern antibiotics, infectious causes including syphilis, tuberculosis, and fungi occurred with almost equal frequency.
- The most common cause of malignancy-related superior vena cava syndrome is bronchogenic carcinoma, which accounts for nearly 80% of cases.
- Lymphoma accounts for approximately 15% of cases.
- Other cases have various causes, including infectious and catheter-related etiologies. Increasingly, dialysis catheters and pacemaker leads are becoming associated with superior vena cava syndrome due to thrombosis.

Symptoms

The symptoms of SVCS are more severe if the vein becomes blocked quickly. This is because the other veins in the area do not have time to widen and take over the blood flow that cannot pass through the superior vena cava.

The most common symptoms are:

- Trouble breathing.
- Coughing.
- Swelling in the face, neck, upper body, or arms.

Less common symptoms include the following:

- Hoarse voice.
- Trouble swallowing or talking.
- Coughing up blood.
- Swollen veins in the chest or neck.
- Chest pain.
- Reddish skin color.

Laboratory Studies

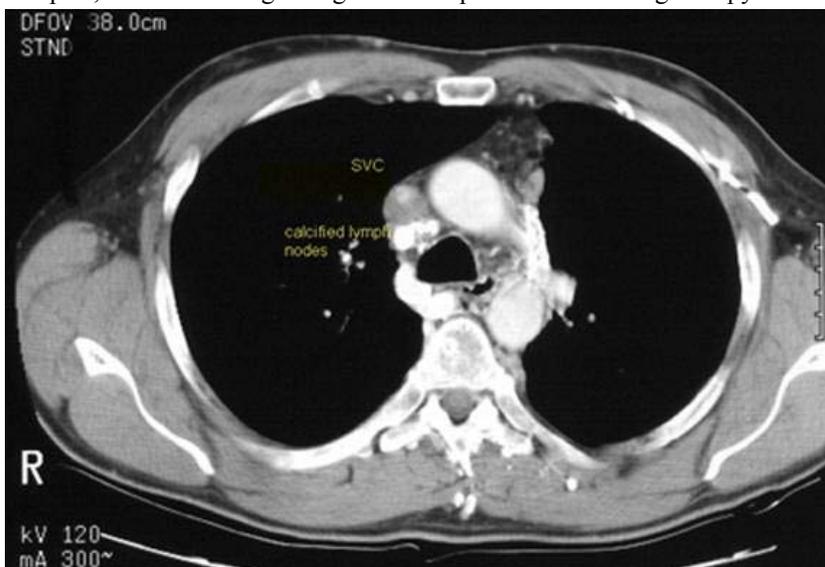

The diagnosis of superior vena cava syndrome (SVCS) is often made on clinical grounds alone, combining clinical presentation with an often-obtained history of thoracic malignancy.

Imaging Studies

Plain radiography is often helpful and reveals a mediastinal mass in most patients (as is seen in the image below).

When in doubt, venography can aid in the diagnosis, but this is usually not necessary.

Thoracic CT scanning is helpful, but the histologic diagnosis is important in initiating therapy.

Treatment

Treatment for SCVS caused by cancer depends on the following:

- The type of cancer.
- The cause of the blockage.
- How severe the symptoms are.
- The prognosis (chance of recovery).
- Whether treatment is to cure, control, or relieve the symptoms of cancer.
- The patient's wishes.

Treatment may include the following:

Watchful waiting

Watchful waiting is closely monitoring a patient's condition without giving any treatment unless symptoms appear or change.

A patient who has good blood flow through smaller veins in the area and mild symptoms may not need treatment.

The following may be used to relieve symptoms and keep the patient comfortable:

- Keeping the upper body raised higher than the lower body.
- Corticosteroids (drugs that reduce swelling).
- Diuretics (drugs that make excess fluid pass from the body in urine). Patients taking diuretics are closely watched because these drugs can cause dehydration (loss of too much fluid from the body).

Chemotherapy

Chemotherapy is the usual treatment for tumors that respond to anticancer drugs, including small cell lung cancer and lymphoma. Chemotherapy uses drugs to stop the growth of cancer cells, either by killing the cells or by stopping them from dividing. When chemotherapy is taken by mouth or injected into a vein or muscle, the drugs enter the bloodstream and can reach cancer cells throughout the body (systemic chemotherapy). When chemotherapy is placed directly into the cerebrospinal fluid, an organ, or a body cavity such as the abdomen, the drugs mainly affect cancer cells in those areas (regional chemotherapy). The way the chemotherapy is given depends on the type and stage of the cancer being treated.

Radiation therapy

If the blockage of the superior vena cava is caused by a tumor that does not usually respond to chemotherapy, radiation therapy may be given. Radiation therapy is a cancer treatment that uses high-energy x-rays or other types of radiation to kill cancer

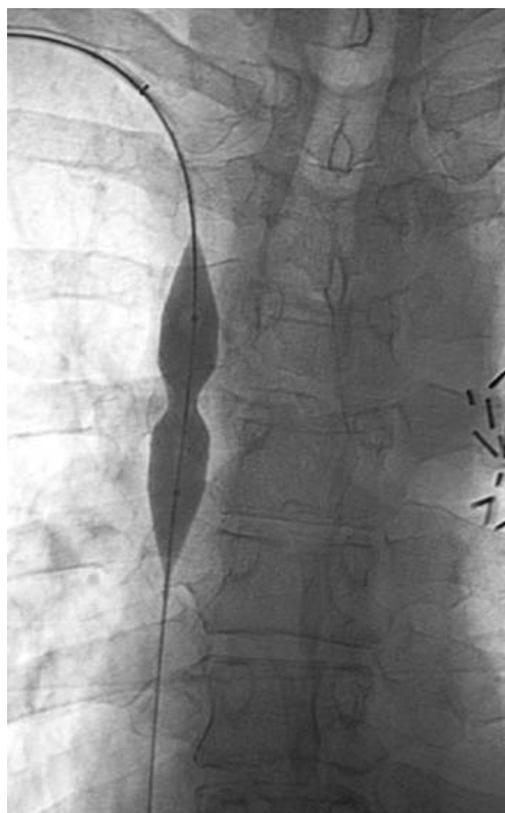

cells. External radiation therapy uses a machine outside the body to send radiation toward the cancer. The way the radiation therapy is given depends on the type and stage of the cancer being treated.

Thrombolysis

SVCS may occur when a thrombus (blood clot) forms in a partly blocked vein. Thrombolysis is a way to break up and remove blood clots. This may be done by a thrombectomy. Thrombectomy is surgery to remove the blood clot or the use of a device inserted into the vein to remove the blood clot. This may be done with or without the use of drugs to break up the clot.

Stent placement

If the superior vena cava is partly blocked by the tumor, an expandable stent (tube) may be placed inside the superior vena cava to help keep it open and allow blood to pass through. This helps most patients. Drugs to keep more blood clots from forming may also be used.

Surgery

Surgery to bypass (go around) the blocked part of the vein is sometimes used for cancer patients, but is used more often for patients without cancer.

Palliative care may be given to relieve symptoms in patients with SVCS.

Superior vena cava syndrome is serious and the symptoms can be upsetting for the patient and family. It is important that patients and family members ask questions about superior vena cava syndrome and how to treat it. This can help relieve anxiety about symptoms such as swelling, trouble swallowing, coughing, and hoarseness.

Patients with advanced cancer sometimes decide not to have any serious treatment. Palliative treatment can help keep patients comfortable by relieving symptoms to improve their quality of life.

GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD) is a condition in which the stomach contents (food or liquid) leak backwards from the stomach into the esophagus (the tube from the mouth to the stomach). This action can irritate the esophagus, causing heartburn and other symptoms.

Causes

When you eat, food passes from the throat to the stomach through the esophagus (also called the food pipe or swallowing tube). Once food is in the stomach, a ring of muscle fibers prevents food from moving backward into the esophagus. These muscle fibers are called the lower esophageal sphincter, or LES.

If this sphincter muscle doesn't close well, food, liquid, and stomach acid can leak back into the esophagus. This is called reflux or gastroesophageal reflux. Reflux may cause symptoms, or it can even damage the esophagus.

The risk factors for reflux include:

- Alcohol (possibly)
- Hiatal hernia (a condition in which part of the stomach moves above the diaphragm, which is the muscle that separates the chest and abdominal cavities)
- Obesity
- Pregnancy
- Scleroderma
- Smoking

Heartburn and gastroesophageal reflux can be brought on or made worse by pregnancy and many different medications. Such drugs include:

- Anticholinergics (e.g., for seasickness)
- Beta-blockers for high blood pressure or heart disease
- Bronchodilators for asthma
- Calcium channel blockers for high blood pressure
- Dopamine-active drugs for Parkinson's disease
- Progestin for abnormal menstrual bleeding or birth control
- Sedatives for insomnia or anxiety
- Tricyclic antidepressants

If you suspect that one of your medications may be causing heartburn, talk to your doctor. Never change or stop a medication you take regularly without talking to your doctor.

Symptoms

More common symptoms are:

- Feeling that food is stuck behind the breastbone
- Heartburn or a burning pain in the chest (under the breastbone)
- Increased by bending, stooping, lying down, or eating
- More likely or worse at night
- Relieved by antacids
- Nausea after eating

Less common symptoms are:

- Bringing food back up (regurgitation)
- Cough or wheezing
- Difficulty swallowing
- Hiccups

- Hoarseness or change in voice
- Sore throat

Exams and Tests

You may not need any tests if your symptoms are not severe.

If your symptoms are severe or they come back after you have been treated, one or more tests may help diagnose reflux or any complications:

- Esophagogastroduodenoscopy (EGD) is often used to find the cause and examine the esophagus (swallowing tube) for damage. The doctor inserts a thin tube with a camera on the end through your mouth. The tube is then passed into your esophagus, stomach, and small intestine.
- Barium swallow
- Continuous esophageal pH monitoring
- Esophageal manometry

A positive stool occult blood test may diagnose bleeding that is coming from the irritation in the esophagus, stomach, or intestines.

Treatment

You can make many lifestyle changes to help treat your symptoms. Avoid foods that cause problems for you. Making changes to your routine before you go to sleep may also help.

Avoid drugs such as aspirin, ibuprofen (Advil, Motrin), or naproxen (Aleve, Naprosyn). Take acetaminophen (Tylenol) to relieve pain. Take your medicines with plenty of water. When your doctor gives you a new medicine, remember to ask whether it will make your heartburn worse.

You may use over-the-counter antacids after meals and at bedtime, although they do not last very long. Common side effects of antacids include diarrhea or constipation.

Other over-the-counter and prescription drugs can treat GERD. They work more slowly than antacids but give you longer relief. Your pharmacist, doctor, or nurse can tell you how to take these drugs.

- Proton pump inhibitors (PPIs) decrease the amount of acid produced in your stomach
- H2 blockers (antagonists) lower the amount of acid released in the stomach

Anti-reflux operations (fundoplication and others) may be an option for patients whose symptoms do not go away with lifestyle changes and drugs. Heartburn and other symptoms should improve after surgery, but you may still need to take drugs for your heartburn.

There are also new therapies for reflux that can be performed through an endoscope (a flexible tube passed through the mouth into the stomach).

Outlook (Prognosis)

Most people respond to lifestyle changes and medications. However, many patients need to continue taking drugs to control their symptoms.

Possible Complications

- Asthma
- Barrett's esophagus (a change in the lining of the esophagus that can increase the risk of cancer)
- Bronchospasm (irritation and spasm of the airways due to acid)
- Chronic cough or hoarseness
- Dental problems
- Esophageal ulcer

- Stricture (a narrowing of the esophagus due to scarring)

ACUTE PERITONITIS. LIMITED PERITONITIS. SPECIFIC CLINICAL FORMS OF PERITONITIS.

Peritonitis

Peritonitis – is the acute or chronic peritoneal inflammation with characteristic local and general changes in the organism and severe dysfunction of organs and vital systems of the organism. Peritonitis is an inflammation of the peritoneum, the thin tissue that lines the inner wall of the abdomen and covers most of the abdominal organs. Peritonitis may be localized or generalised, and may result from infection (often due to rupture of a hollow organ as may occur in abdominal trauma or appendicitis) or from a non-infectious process.

Anatomy

The peritoneum is the largest and most complex serous membrane in the body. It forms a closed sac (ie, coelom) by lining the interior surfaces of the abdominal wall (anterior and lateral), by forming the boundary to the retroperitoneum (posterior), by covering the extraperitoneal structures in the pelvis (inferior), and by covering the undersurface of the diaphragm (superior). This parietal layer of the peritoneum reflects onto the abdominal visceral organs to form the visceral peritoneum. It thereby creates a potential space between the 2 layers (ie, the peritoneal cavity).

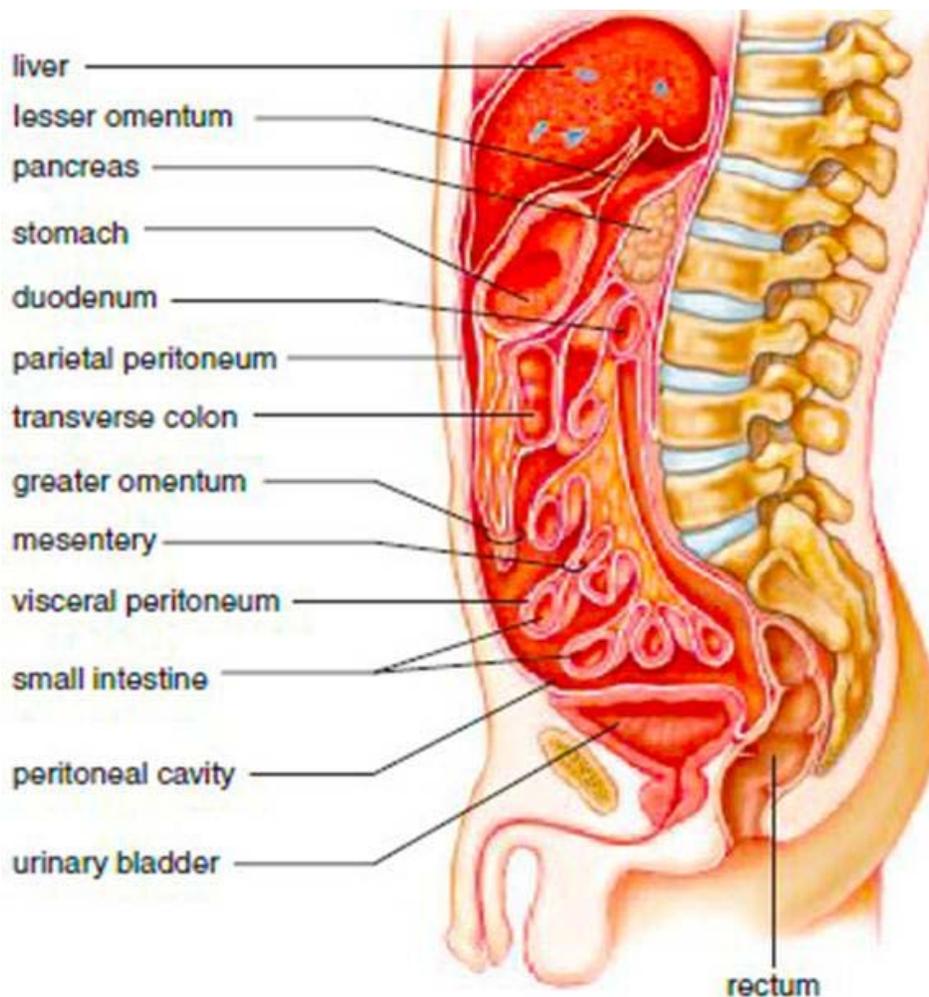

The peritoneum consists of a single layer of flattened mesothelial cells over loose areolar tissue. The loose connective tissue layer contains a rich network of vascular and lymphatic capillaries, nerve endings, and immune-competent cells, particularly lymphocytes and macrophages. The peritoneal surface cells are joined by junctional complexes, thus forming a dialyzing membrane that allows passage of fluid and certain small solutes. Pinocytotic activity of the mesothelial cells and phagocytosis by macrophages allow for clearance of macromolecules.

Normally, the amount of peritoneal fluid present is less than 50 mL, and only small volumes are transferred across the considerable surface area in a steady state each day. The peritoneal fluid represents a plasma ultrafiltrate, with electrolyte and solute concentrations similar to that of neighboring interstitial spaces and a protein content of less than 30 g/L, mainly albumin. In addition, peritoneal fluid contains small numbers of desquamated mesothelial cells and various numbers and morphologies of migrating immune cells (reference range is < 300 cells/ μ L, predominantly of mononuclear morphology).

The peritoneal cavity is divided incompletely into compartments by the mesenteric attachments and secondary retroperitonealization of certain visceral organs. A large peritoneal fold, the greater omentum, extends from the greater curvature of the stomach and the inferior aspect of the proximal duodenum

downward over a variable distance to fold upon itself (with fusion of the adjacent layers) and ascends back to the taenia omentalis of the transverse colon. This peritoneal fold demonstrates a slightly different microscopic anatomy, with fenestrated surface epithelium and a large number of adipocytes, lymphocytes, and macrophages, and it functions as a fat storage location and a mobile immune organ.

The compartmentalization of the peritoneal cavity, in conjunction with the greater omentum, influences the localization and spread of peritoneal inflammation and infections.

Etiology and pathogenesis

The main causes of peritonitis are the acute inflammation of abdominal viscera, discontinuity and disturbed permeability of their walls, open and closed traumas of the abdomen with the damage of viscera with following microbial contamination of peritoneal space.

Despite the cause of peritonitis, the disease is characterized by a typical bacterial inflammation. The infectious agents are represented by *Escherichia coli*, *Staphylococcus* and *Enterococcus*, *Proteus*, *Streptococcus* and also nonclostridial anaerobes. At least in 30 % of cases association of two or more agents occur.

Primary peritonites occur very rarely and result from pneumococcal, streptococcal and staphylococcal infection.

Besides microbial peritonites, caused by peritoneal contamination, distinguished also aseptic peritoneal inflammation, which result from entering of different chemical noninfectious agents into peritoneal cavity (blood, urine, bile, pancreatic juice, etc.). It's so called toxico-chemical peritonitis. But with the development of aseptic inflammation bacteria penetrate into peritoneal space with transformation of peritonitis into bacterial.

Chronic peritonitis is mainly caused by tuberculosis, which agents are usually located extraperitoneally (lungs, mediastinal lymph nodes) or in mesenteric lymph nodes and by hematogenous way enter the peritoneum.

Risk Factors:

The following factors may increase the risk for primary peritonitis:

- **Torn or twisted intestine**
- **Pancreatitis**
- **Inflammatory bowel disease, such as Crohn's disease or ulcerative colitis**
- **Injury caused by an operation**
- **Peritoneal dialysis**
- **Trauma**
- **Liver disease (cirrhosis)**
- **Fluid in the abdomen**
- **Weakened immune system**
- **Pelvic inflammatory disease**
- **Risk factors for secondary peritonitis include:**
- **Appendicitis (inflammation of the appendix)**
- **Stomach ulcers**

Infected peritonitis

Perforation of part of the gastrointestinal tract is the most common cause of peritonitis. Examples include perforation of the distal oesophagus (Boerhaave syndrome), of the stomach (peptic ulcer, gastric carcinoma), of the duodenum (peptic ulcer), of the

remaining intestine (e.g., appendicitis, diverticulitis, Meckel diverticulum, inflammatory bowel disease (IBD), intestinal infarction, intestinal strangulation, colorectal carcinoma, meconium peritonitis), or of the gallbladder (cholecystitis). Other possible reasons for perforation include abdominal trauma, ingestion of a sharp foreign body (such as a fish bone, toothpick or glass shard), perforation by an endoscope or catheter, and anastomotic leakage. The latter occurrence is particularly difficult to diagnose early, as abdominal pain and ileus paralyticus are considered normal in patients who have just undergone abdominal surgery. In most cases of perforation of a hollow viscus, mixed bacteria are isolated; the most common agents include Gram-negative bacilli (e.g., *Escherichia coli*) and anaerobic bacteria (e.g., *Bacteroides fragilis*). Fecal peritonitis results from the presence of faeces in the peritoneal cavity. It can result from abdominal trauma and occurs if the large bowel is perforated during surgery.

Table. Microbial Flora of Secondary Peritonitis

Type	Organism	Percentage
Aerobic	Gram negative	
	Escherichia coli	60%
	Enterobacter/Klebsiella	26%
	Proteus	22%
Gram positive	Pseudomonas	8%
	Streptococci	28%
	Enterococci	17%
	Staphylococci	7%
Anaerobic	Bacteroides	72%
	Eubacteria	24%
	Clostridia	17%
	Peptostreptococci	14%
	Peptococci	11%
Fungi	Candida	2%

Other rare, nonsurgical causes of intra-abdominal sepsis include the following:

Chlamydia peritonitis;

Tuberculosis peritonitis;

Acquired immunodeficiency syndrome (AIDS)-associated peritonitis.

Disruption of the peritoneum, even in the absence of perforation of a hollow viscus, may also cause infection simply by letting micro-organisms into the peritoneal cavity. Examples include trauma, surgical wound, continuous ambulatory peritoneal dialysis, and intra-peritoneal chemotherapy. Again, in most cases, mixed bacteria are isolated; the most common agents include cutaneous species such as *Staphylococcus aureus*, and coagulase-negative staphylococci, but many others are possible, including fungi such as *Candida*.

Spontaneous bacterial peritonitis (SBP) is a peculiar form of peritonitis occurring in the absence of an obvious source of contamination. It occurs in patients with ascites, in particular, in children. See the article on spontaneous bacterial peritonitis for more information.

Intra-peritoneal dialysis predisposes to peritoneal infection (sometimes named "primary peritonitis" in this context).

Systemic infections (such as tuberculosis) may rarely have a peritoneal localisation.

Non-infected peritonitis

Leakage of sterile body fluids into the peritoneum, such as blood (e.g., endometriosis, blunt abdominal trauma), gastric juice (e.g., peptic ulcer, gastric carcinoma), bile (e.g., liver biopsy), urine (pelvic trauma), menstruum (e.g., salpingitis), pancreatic juice (pancreatitis), or even the contents of a ruptured dermoid cyst. It is important to note that, while these body fluids are sterile at first, they frequently become infected once they leak out of their organ, leading to infectious peritonitis within 24 to 48 hours.

Sterile abdominal surgery, under normal circumstances, causes localised or minimal generalised peritonitis, which may leave behind a foreign body reaction and/or fibrotic adhesions. However, peritonitis may also be caused by the rare case of a sterile foreign body inadvertently left in the abdomen after surgery (e.g., gauze, sponge).

Much rarer non-infectious causes may include familial Mediterranean fever, TNF receptor associated periodic syndrome, porphyria, and systemic lupus erythematosus.

Classification

Peritonites are classified:

According to the character of microbial contamination:

A: primary

B: secondary.

According to clinical course:

A: acute

B: chronic.

According to the etiological agents:

A: peritonites, which caused by bacteria of digestive tract (E. colli, staphylococci, streptococci, proteus, anaerobes, etc.)

B: which caused by bacteria, which exist out of gastrointestinal tube (gonococci, pneumococci, streptococcus haemolyticus, etc.).

C: distinguished aseptic (nonbacterial peritonites), resulting from irritation by blood, bile, pancreatic juice or urine.

According to the character of exudate:

A: serous;

B: fibrinous;

C: fibrinopurulent;

D: purulent;

E: hemorrhagic;

F: "peritonitus sicca".

According to the extension of inflammatory process:

A: local;

B: diffuse;

C: generalized.

Dependent on duration of the disease and degree of pathological alterations in the clinical course of peritonitis distinguished three stages:

reactive (first 24 hours) maximal manifestation of local signs of the disease;

toxic (24-72 hours) – gradual reducing of local signs and increasing of general intoxication.

terminal (after 72 hours) – severe, often unreversable intoxication on the background of sharply expressed local manifestations of peritoneal inflammation.

Primary peritonitis.

Spontaneous bacterial peritonitis (SBP) is an acute bacterial infection of ascitic fluid. Contamination of the peritoneal cavity is thought to result from translocation of bacteria across the gut wall or mesenteric lymphatics and, less frequently, via hematogenous seeding in the presence of bacteremia.

SBP can occur as a complication of any disease state that produces the clinical syndrome of ascites, such as heart failure and Budd-Chiari syndrome. Children with nephrosis or systemic lupus erythematosus who have ascites have a high risk of developing SBP. The highest risk of SBP, however is in patients with cirrhosis who are in a decompensated state. In particular, decreased hepatic synthetic function with associated low total protein level, low complement levels, or prolonged prothrombin time (PT) is associated with maximum risk. Patients with low protein levels in ascitic fluid (< 1 g/dL) have a 10-fold higher risk of developing SBP than those with a protein level greater than 1 g/dL. Approximately 10-30% of patients with cirrhosis and ascites develop SBP. The incidence rises to more than 40% with ascitic fluid protein contents of less than 1 g/dL (which occurs 15% of patients), presumably because of decreased ascitic fluid opsonic activity.

More than 90% of cases of SBP are caused by a monomicrobial infection.

Secondary peritonitis

Common etiologic entities of secondary peritonitis (SP) include perforated appendicitis; perforated gastric or duodenal ulcer; perforated (sigmoid) colon caused by diverticulitis, volvulus, or cancer; and strangulation of the small bowel. Necrotizing pancreatitis can also be associated with peritonitis in the case of infection of the necrotic tissue.

The pathogens involved in SP differ in the proximal and distal GI tract. Gram-positive organisms predominate in the upper GI tract, with a shift toward gram-negative organisms in the upper GI tract in patients on long-term gastric acid suppressive therapy. Contamination from a distal small bowel or colon source initially may result in the release of several hundred bacterial species (and fungi); host defenses quickly eliminate most of these organisms. The resulting peritonitis is almost always polymicrobial, containing a mixture of aerobic and anaerobic bacteria with a predominance of gram-negative organisms.

As many as 15% of patients who have cirrhosis with ascites who were initially presumed to have SBP have SP. In many of these patients, clinical signs and symptoms alone are not sensitive or specific enough to reliably differentiate between the 2 entities. A thorough history, evaluation of the peritoneal fluid, and additional diagnostic tests are needed to do so; a high index of suspicion is required.

Source Regions	Causes
Esophagus	Boerhaave syndrome Malignancy

	Trauma (mostly penetrating) Iatrogenic*
Stomach	Peptic ulcer perforation Malignancy (eg, adenocarcinoma, lymphoma, gastrointestinal stromal tumor) Trauma (mostly penetrating) Iatrogenic*
Duodenum	Peptic ulcer perforation Trauma (blunt and penetrating) Iatrogenic*
Biliary tract	Cholecystitis Stone perforation from gallbladder (ie, gallstone ileus) or common duct Malignancy Choledochal cyst (rare) Trauma (mostly penetrating) Iatrogenic*
Pancreas	Pancreatitis (eg, alcohol, drugs, gallstones) Trauma (blunt and penetrating) Iatrogenic*
Small bowel	Ischemic bowel Incarcerated hernia (internal and external) Closed loop obstruction Crohn disease Malignancy (rare) Meckel diverticulum Trauma (mostly penetrating)
Large bowel and appendix	Ischemic bowel Diverticulitis Malignancy Ulcerative colitis and Crohn disease Appendicitis Colonic volvulus Trauma (mostly penetrating)

Iatrogenic

Uterus, salpinx, and ovaries Pelvic inflammatory disease (eg, salpingo-oophoritis, tubo-ovarian abscess, ovarian cyst)
Malignancy (rare)
Trauma (uncommon)

* Iatrogenic trauma to the upper GI tract, including the pancreas and biliary tract and colon, often results from endoscopic procedures; anastomotic dehiscence and inadvertent bowel injury (eg, mechanical, thermal) are common causes of leak in the postoperative period.

The most common cause of postoperative peritonitis is anastomotic leak, with symptoms generally appearing around postoperative days 5-7. After elective abdominal operations for noninfectious etiologies, the incidence of SP (caused by anastomotic disruption, breakdown of enterotomy closures, or inadvertent bowel injury) should be less than 2%. Operations for inflammatory disease (ie, appendicitis, diverticulitis, cholecystitis) without perforation carry a risk of less than 10% for the development of SP and peritoneal abscess. This risk may rise to greater than 50% in gangrenous bowel disease and visceral perforation.

After operations for penetrating abdominal trauma, SP and abscess formation are observed in a small number of patients. Duodenal and pancreatic involvement, as well as colon perforation, gross peritoneal contamination, perioperative shock, and massive transfusion, are factors that increase the risk of infection in these cases.

Peritonitis is also a frequent complication and significant limitation of peritoneal dialysis. Peritonitis leads to increased hospitalization and mortality rates.

Tertiary peritonitis.

Tertiary peritonitis (see Table 3, below) develops more frequently in immunocompromised patients and in persons with significant preexisting comorbid conditions. Although rarely observed in uncomplicated peritoneal infections, the incidence of tertiary peritonitis in patients requiring ICU admission for severe abdominal infections may be as high as 50-74%.

Tuberculous peritonitis (TP) is rare in the United States (< 2% of all causes of peritonitis), but it

continues to be a significant problem in developing countries and among patients with human immunodeficiency virus (HIV) infection. The presenting symptoms are often nonspecific and insidious in onset (eg, low-grade fever, anorexia, weight loss). Many patients with TP have underlying cirrhosis. More than 95% of patients with TP have evidence of ascites on imaging studies, and more than half of these patients have clinically apparent ascites.

In most cases, chest radiographic findings in patients with TP peritonitis are abnormal; active pulmonary disease is uncommon (< 30%). Results on Gram stain of ascitic fluid are rarely positive, and culture results may be falsely negative in up to 80% of patients. A peritoneal fluid protein level greater than 2.5 g/dL, a lactate dehydrogenase (LDH) level greater than 90 U/mL, or a predominantly mononuclear cell count of greater than 500 cells/ μ L should raise suspicion of TP but have limited specificity for the diagnosis. Laparoscopy and visualization of granulomas on peritoneal biopsy specimens, as well as cultures (requires 4-6 wk), may be needed for the definitive diagnosis; however, empiric therapy should begin immediately.

Chemical peritonitis. Chemical (sterile) peritonitis may be caused by irritants such as bile, blood, barium, or other substances or by transmural inflammation of visceral organs (eg, Crohn disease) without bacterial inoculation of the peritoneal cavity. Clinical signs and symptoms are indistinguishable from those of SP or peritoneal abscess, and the diagnostic and therapeutic approach should be the same.

Peritoneal abscess. Peritoneal abscess describes the formation of an infected fluid collection encapsulated by fibrinous exudate, omentum, and/or adjacent visceral organs. The overwhelming majority of abscesses occurs subsequent to SP. Abscess formation may be a complication of surgery. The incidence of abscess formation after abdominal surgery is less than 1-2%, even when the operation is performed for an acute inflammatory process. The risk of abscess increases to 10-30% in cases of preoperative perforation of the hollow viscus, significant fecal contamination of the peritoneal cavity, bowel ischemia, delayed diagnosis and therapy of the initial peritonitis, and the need for reoperation, as well as in the setting of immunosuppression. Abscess formation is the leading cause of persistent infection and development of tertiary peritonitis.

Symptomatology and clinical course

The clinical picture of acute peritonitis is determined by the character of primary causative lesion, duration of inflammatory process, its extension and also the stage of the disease. Predominant clinical sign is the abdominal pain, which gradually increases. Firstly it is localized in the region of the source of peritonitis and then extends all over the abdomen. Elderly patients may experience lacking pain and even pay no attention on it, but general malaise, loss of appetite, and weakness are evident. This course is also characteristic for postoperative peritonitis, which results from parting of sutures (of anastomosis or site of perforation) or leaking colon carcinoma. Simultaneously with the increase of pain also change the general appearance. The patient looks anxious, with drawn features, hollowed-eyed. Further this is accompanied by nausea and vomiting: on initial stages vomit is of gastric contents, later – duodenal and thereafter is of

intestinal contents. With progression of the disease vomiting becomes constant, effortless and overcomes into frequent regurgitation by brown fluid with foul-smelling. Patient's lips and tongue are dry, with brown fur. Respiration is of thoracic type and is shallow and rapid. In order to prevent pain the patient speaks very quite. Every change of position results in increase of pain, thus the patient lies with the knee drawn up to relax the abdominal wall.

Often the vomiting is accompanied by hiccup, which results from irritation of diaphragmatic peritoneum. This is considered to be an unfavorable prognostic sign. The patient tries to retain distended abdomen by his hands during hiccup and thus provokes increase of pain.

During examination observed restricted movements of abdominal wall, which is mainly expressed over the inflammatory focus. Abdominal percussion reveals the region of maximal painfulness, which response the site of lesion, high tympanic sound as a result of intestinal gaseous dilatation, but sometimes dullness, caused by cumulation of great amount of exudate. On palpation revealed muscular tension of abdominal wall. Especially expressed the muscular rigidity in case of perforation of hollow organs ("board-like abdomen"). Pelvic location of peritonitis usually causes less clinical manifestations. In such cases a diagnostic value has digital examination of the rectum and bimanual palpation of the pelvis and lower abdomen, which reveals overhanging and painfulness of anterior rectal wall or posterior vaginal vault owing to accumulation of the exudate.

The clinical manifestation of peritonitis is various and individual. It depends on the character of primary lesion, extension of inflammatory process, and defensive properties of the organism. The main manifestations of peritonitis are acute abdominal pain, abdominal tenderness, and abdominal guarding, which are exacerbated by moving the peritoneum, e.g., coughing (forced cough may be used as a test), flexing one's hips, or eliciting the Blumberg sign (a.k.a. rebound tenderness, meaning that pressing a hand on the abdomen elicits less pain than releasing the hand abruptly, which will aggravate the pain, as the peritoneum snaps back into place). The presence of these signs in a patient is sometimes referred to as peritonism. The localization of these manifestations depends on whether peritonitis is localized (e.g., appendicitis or diverticulitis before perforation), or generalized to the whole abdomen. In either case, pain typically starts as a generalized abdominal pain (with involvement of poorly localizing innervation of the visceral peritoneal layer), and may become localized later (with the involvement of the somatically innervated parietal peritoneal layer). Peritonitis is an example of an acute abdomen.

Collateral manifestations: diffuse abdominal rigidity ("washboard abdomen") is often present, especially in generalized peritonitis, Fever, Sinus tachycardia, Development of ileus paralyticus (i.e., intestinal paralysis), which also causes nausea, vomiting and bloating.

In reactive stage of the disease the most common are the pain, muscular rigidity and positive Shchotkin-Blumberg's symptom. The general state changed a little – the patient is active, sometimes excite. A moderate tachycardia and hypertension commonly observed.(Fig.1)

Fig.1. Shchotkin-Blumberg's symptom.

In toxic stage of the disease the pain and muscular defense tend to diminish, but on palpation the muscular tenderness and Shchotkin-Blumberg's symptom retain on the same level. More evident the signs of intestinal paresis (abdominal distension, absence of peristalsis). The general state is worsened. The patient is apathetic, the skin is blanched or cyanotic. Observed progressing of tachycardia, decreasing of blood pressure and rising of temperature. In blood analysis revealed leukocytosis and deviation of the differential

count to the left.

In terminal stage of the disease the feeling of pain disappears, but the patient suffer from the uncontrollable vomiting by congested fecal contents. The patient is adynamic, with drawn features and blanched or cyanotic skin. The pulse becomes increasingly rapid small and thready. The arterial pressure tends to diminish. No peristalsis is evident and no bowel sounds are heard on auscultation. Shchotkin-Blumberg's symptom is slightly expressed. The respiration is rapid, with congested rales, and oliguria develops. This clinical pattern resembles a septic shock. The prognosis in this stage is serious and the patient will die if the urgent treatment is not be applied.

Plain films of the chest and abdomen with the patient in both supine and the erect position are essential. The chest x-ray examination assists in identifying thoracic causes of the acute abdomen and sometimes reveals specific x-ray findings of intraabdominal catastrophes (e.g. free air under the diaphragm associated with perforation of the gastrointestinal tract).

Laparoscopy is a rapid, direct, and often definitive method of identifying the cause of peritonitis in difficult cases. Finally, for patients who have acute intraabdominal problem of unknown nature and whose symptoms, signs, and laboratory findings are suggestive of a threat of life, exploratory laparotomy remains the most prudent diagnostic procedure.

Complications:

Sequestration of fluid and electrolytes, as revealed by decreased central venous pressure, may cause electrolyte disturbances, as well as significant hypovolemia, possibly leading to shock and acute renal failure.

A peritoneal abscess may form (e.g., above or below the liver, or in the lesser omentum

Sepsis may develop, so blood cultures should be obtained.

Variants of clinical course and complications

Postoperative peritonitis is characterized by atypical and even asymptomatic course. This results from administering of analgesics, antibiotics and anesthetics. The general state of the patient after the operation is gradually worsens.

The most earliest and frequent sign of postoperative peritonitis is the increase of abdominal pain on the background of the previous satisfactory condition, tachycardia, high temperature, leukocytosis, deviation of the differential count to the left, elevation of erythrocyte sedimentation rate. The pain and muscular rigidity usually expressed slightly or absent at all. Later (on the 5-6th day) the general state continues to be worsened, which manifest by dry tongue, lack of peristalsis, expressed nausea, vomiting, tachycardia and shallow breathing. General weakness, adynamia, general intoxication and rebound tenderness symptoms progress. The outcomes of postoperative peritonitis are usually unfavorable, and they prevented by early repeated operation.

The specific complications of acute peritonitis include inflammatory infiltrates and abscesses of abdominal cavity (Fig.2) (subphrenic, subhepatic, interintestinal and pelvic), dynamic ileus, intestinal fistula, suppuration of postoperative wound, eventration, peritoneal adhesions, etc.

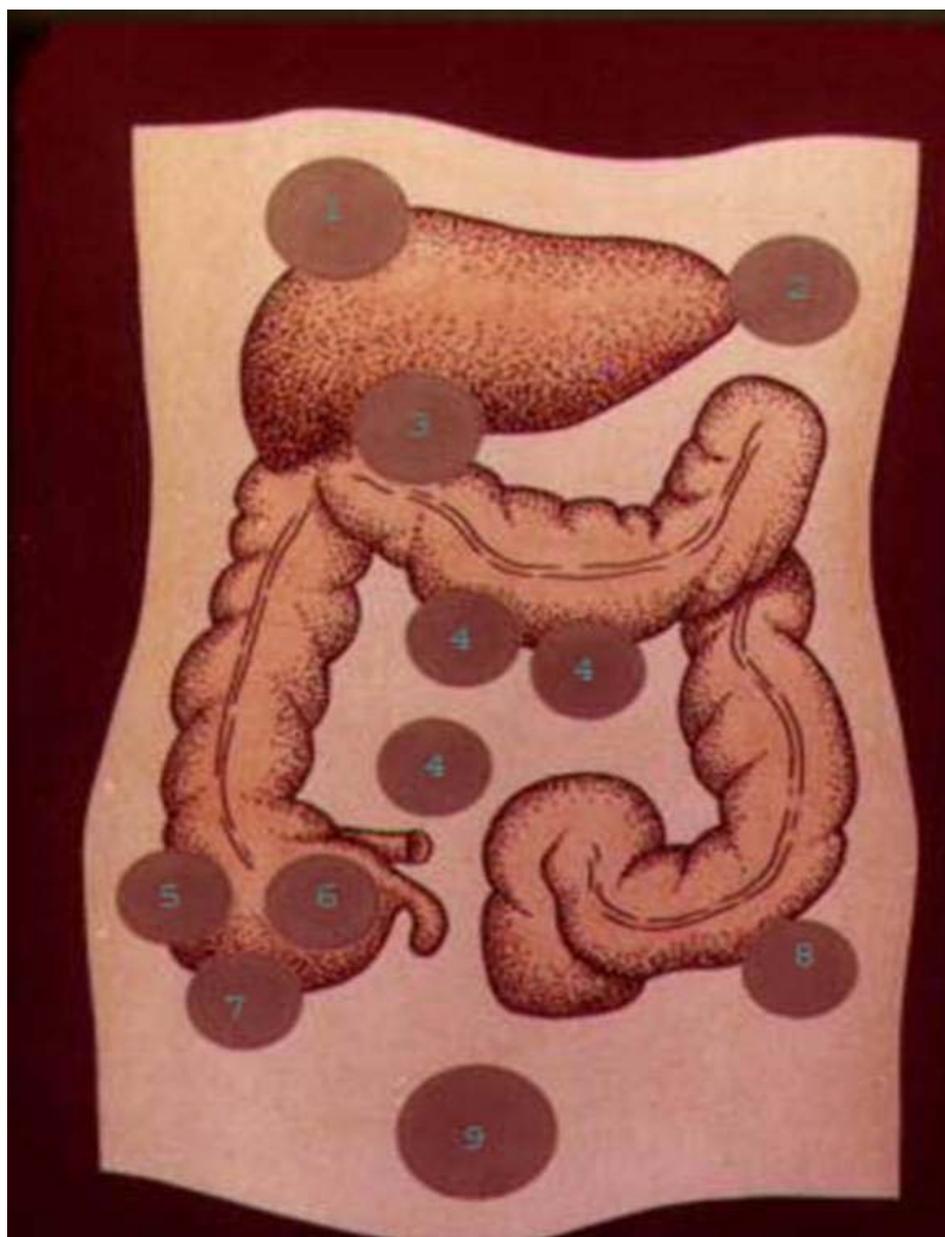

Fig.2. Localizations of abscesses of abdominal cavity

1, 2 – Right and left subdiaaphragmatic abscesses

3 - Subhepatic abscess

4 – Interintestinal abscesses

5, 6, 7 – Right iliac abscesses

8 – Left iliac abscess

9 – Abscess of the small pelvis (Douglas space abscess)

The patients with subphrenic abscess (Fig.3) as a rule complain of the pain in epigastrium and lower

chest, which irradiates into the shoulder and increases during cough and deep breathing. Sometimes revealed painfulness during digital pressing and swelling of soft tissues in the region of 7-10th Intercostals space. The patients are suffering from nausea, hiccup, and high temperature. Sometimes they must stay in forced position: supine or semisedentary. The tongue is dry, the abdomen is slightly bloated, and rebound tenderness symptoms are usually absent. In blood revealed leukocytosis, deviation of the differential count to the left. The abscess requires a surgical treatment. If the abscess is located near anterior abdominal wall, it is drained by means of oblique access under the costal arch. The abscesses, which located in posterior subphrenic space, are drained after the previous puncture through the access after resection of X rib. (Fig.4)

Fig.3. Subphrenic abscess

Fig.4. Drainage of subdiafragmatic abscess

Subhepatic abscess is characterized by the pain and presence of infiltrate below right costal arch, positive Shchotkin-Blumberg symptom. The abscess is drained through the incision along right costal arch.

The clinical pattern of interintestinal abscess is vague. It is formed mostly on the 12-14th day after appearance of peritonitis. The patients complain of the high temperature and dull pain in the site of its location. The abdomen is soft, but during palpation revealed dense, painful infiltrate. In case of localization near to abdominal wall one can observe muscular tension and positive Shchotkin-Blumberg symptom. The roentgenological or ultrasound investigation often reveals focal shadow with air-fluid level. The abscess is drained over the site of its localization, dividing the bowel loops.

Abscesses of small pelvis mostly occur as a result of appendicitis(Fig.5) or accumulation of the exudates in Douglas space in diffuse peritonitis.

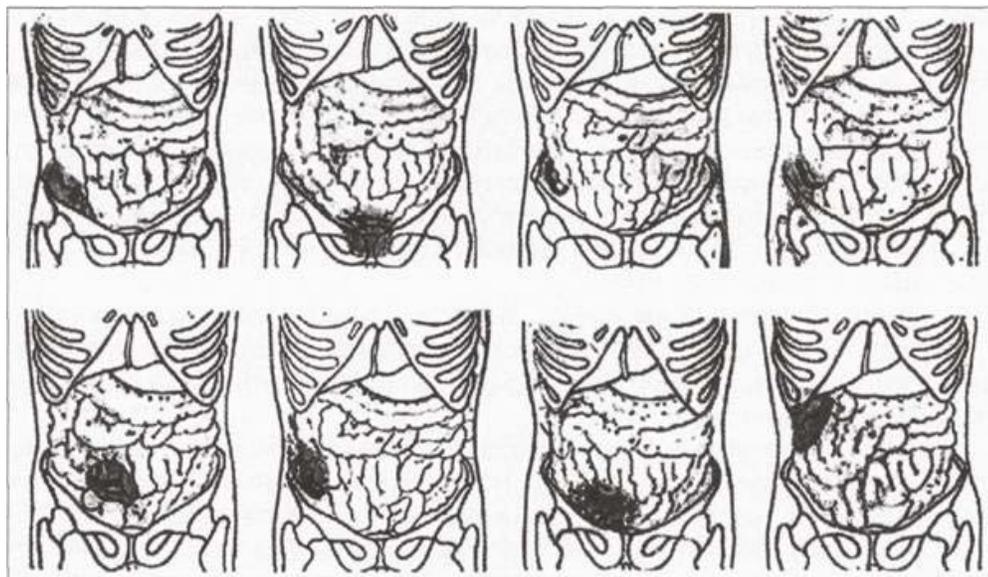

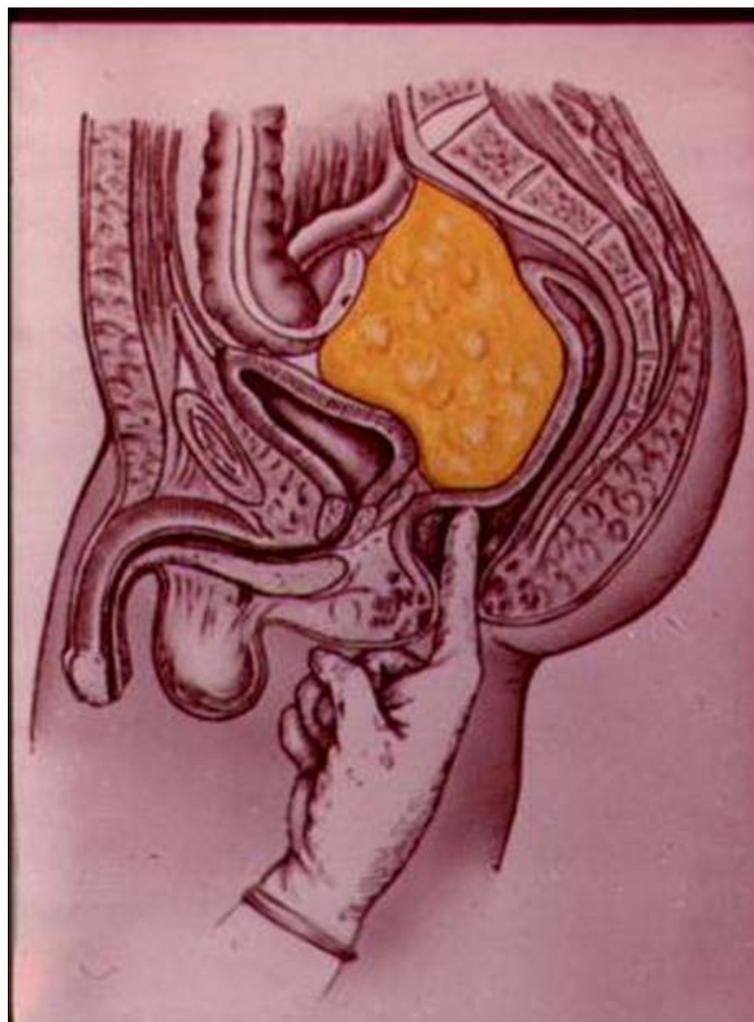

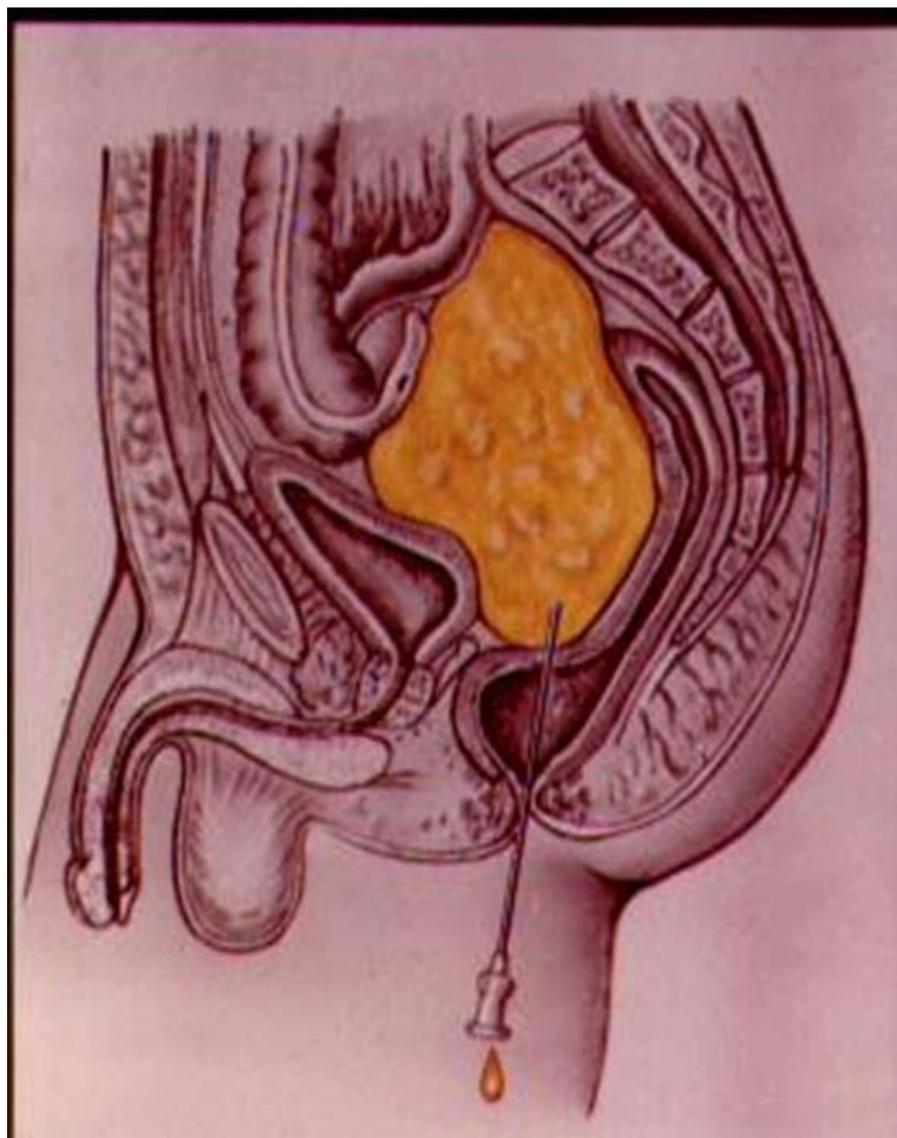

Fig.5. The localization of appendiceal abscess
depending the appendix location

Such patients complain of constant pain in the lower abdomen, high temperature, painful urinary excretion and tenesmus. The palpation of the abdomen usually reveals no pathology. But the digital rectal examination finds out a painful infiltrate that drawn into the rectum. (Fig.6) The mucosa over the infiltrate is edematous and immovable. The vaginal examination of the female patients reveals overhanging of posterior vaginal vault and painfulness of cervical shift. Often on the background of solid consistency of the infiltrate the softened regions are palpated, which respond to accumulation of pus. The purulent sites of small pelvis in males are drained through the anterior wall of the rectum and in females – through the posterior vaginal vault. For this purpose the infiltrate is punctured by thick needle and under its check the abscess is drained by means of scalpel incision. Then the incision is expanded by clamp, the pus is aspirated and the abscess cavity is drained by rubber strap, which is fixed to perineum.

Tests and diagnosis

To diagnose peritonitis, your doctor will talk with you about your medical history and perform a physical exam. When peritonitis is associated with peritoneal dialysis, your signs and symptoms, particularly cloudy dialysis fluid, may be enough for your doctor to diagnose the condition.

In cases of peritonitis in which the infection may be a result of other medical conditions (secondary peritonitis) or in which the infection arises from fluid buildup in your abdominal cavity (spontaneous peritonitis), your doctor may recommend the following tests to confirm a diagnosis:

Peritoneal fluid analysis. Using a thin needle, your doctor may take a sample of the fluid in your peritoneum (paracentesis). If you have peritonitis, examination of this fluid may show an increased white blood cell count, which typically indicates an infection or inflammation. A culture of the fluid may also reveal the presence of bacteria.

Diagnostic paracentesis should be performed in all patients who do not have an indwelling peritoneal

catheter and are suspected of having SBP. In peritoneal dialysis patients with a peritoneal catheter, fluid should be withdrawn using sterile technique. Ultrasonography may aid paracentesis if ascites is minimally detectable or questionable.

The results of aerobic and anaerobic bacterial cultures, used in conjunction with the cell count, prove the most useful in guiding therapy for those with SBP. With regard to ascitic fluid culture, direct inoculation of routine blood culture bottles at the bedside with 10 mL of ascitic fluid has been reported to significantly increase the sensitivity of microbiologic studies.

The single best predictor of SBP is an ascitic fluid neutrophil count of greater than 500 cells/ μ L, which carries a sensitivity of 86% and a specificity of 98%. By lowering the ascitic fluid neutrophil count threshold to 250 cells/ μ L, the sensitivity increases to 93% with only a minimal decrease in specificity to 94%.

The fluid should be evaluated for glucose, protein, lactate dehydrogenase (LDH), cell count, Gram stain, and aerobic and anaerobic cultures. If pancreatitis or a pancreatic leak is suspected, amylase analysis should be added to the panel. Bilirubin and creatinine levels can be analyzed as well, if a biliary or urinary leak is suspected as a possible etiology. The peritoneal/ascitic fluid characteristics or levels are then compared with their respective serum values.

The fluid in bacterial peritonitis generally demonstrates a low pH and low glucose levels with elevated protein and LDH levels. Traditionally, ascitic fluid pH of less than 7.34 was consistent with a diagnosis of SBP; however, ascitic pH is less commonly measured because it is unreliable and lacks specificity for the condition.

SBP is established when the polymorphonuclear neutrophil (PMN) count is 250 cells/ μ L or greater in conjunction with a positive bacterial culture result. In most of these cases, as mentioned previously, cultures are positive for a single organism. Obviously, these patients should receive antibiotic therapy. Although up to 30% of cultures remain negative, most of these patients are presumed to have bacterial peritonitis; they should be treated. A significantly decreased peritoneal fluid glucose level (< 50 mg/dL), a peritoneal fluid LDH level much greater than the serum LDH, a peritoneal fluid WBC count greater than 10,000 cells/ μ L, a pH lower than 7.0, high amylase levels, multiple organisms on Gram stain, or recovery of anaerobes from the culture raises the suspicion of SP in these patients. Some authors recommend repeating the paracentesis in 48-72 hours to monitor treatment success (decrease in neutrophil count to $< 50\%$ of the original value).

Culture-negative neutrocytic ascites (probable SBP) is established when the ascitic fluid culture results are negative but the PMN count is 250 cells/ μ L or greater. This may happen in as many as 50% of patients with SBP and may not actually represent a distinctly different disease entity. Rather, it may be the result of poor culturing techniques or late-stage resolving infection. Nonetheless, these patients should be treated just as aggressively as those with positive culture results.

Monomicrobial nonneutrocytic bacterascites exists when a positive culture result coexists with a PMN count 250 cells/ μ L or greater. Although this may often be the result of contamination of bacterial cultures, 38% of these patients develop SBP. Therefore, monomicrobial nonneutrocytic bacterascites may represent an early form of SBP. All study patients described who eventually developed SBP were symptomatic. For this

reason, any patient suspected clinically of having SBP in this setting must be treated.

Tuberculous peritonitis is identified by ascites with high protein content, a low glucose and low SAAG, elevated ascitic fluid WBC count, and lymphocyte predominance. In TP, the fluid Gram stain and acid-fast stain results are rarely positive, and routine culture results are falsely negative in as many as 80% of cases. A peritoneal fluid protein level greater than 2.5 g/dL, LDH level greater than 90 U/mL, and predominantly mononuclear cell count of more than 500 cells/ μ L should raise the suspicion of TP, but specificity for the diagnosis is limited. Laparoscopy with visualization of granulomas on peritoneal biopsy and specific culture (which requires 4-6 wk) may be needed for definitive diagnosis.

Peritonitis in patients receiving continuous ambulatory peritoneal dialysis (CAPD) is indicated by contamination of the dialysis catheter; cloudy effluent, total fluid WBC count of greater than 100 neutrophils/ μ L, or presence of organisms on Gram stain.

Routine intraoperative peritoneal fluid cultures in defined acute disease entities (ie, gastric or duodenal ulcer perforation, appendicitis, diverticulitis or perforation of the colon caused by obstruction or ischemia) are controversial. Several studies found no significant difference in patients with appendicitis, diverticulitis, and other common etiologies for bacterial peritonitis with regard to postoperative complication rates or overall outcomes. The antibiotic regimen was altered only 8-10% of the time based on operative culture data. In patients who had previous abdominal operations or instrumentation (eg, peritoneal dialysis catheter, percutaneous stents) and patients with prolonged antibiotic therapy, critical illness, and/or hospitalization, these cultures may reveal resistant or unusual organisms that should prompt alteration of the antibiotic strategy.

For a summary of ascitic fluid analysis, see table, below.

Table. Ascitic Fluid Analysis Summary

Routine	Optional	Unusual	Less Helpful
Cell count	Obtain culture in blood culture (BC) bottles.	Tuberculosis smear and culture	(TB) pH
Albumin	Glucose	Cytology	Lactate
Total protein	Lactate dehydrogenase (LDH)	Triglyceride	Cholesterol
	Amylase	Bilirubin	Fibronectin
	Gram stain		Alpha 1-antitrypsin

Glycosaminoglycans

Blood tests. A sample of your blood may be drawn and sent to a lab to check for a high white blood cell count. A blood culture also may be performed to determine if there are bacteria in your blood.

Most patients will have leukocytosis ($>11,000$ cells/ μ L), with a shift to the immature forms on the differential cell count. Patients who have severe sepsis, are immunocompromised, or have certain types of infections (eg, fungal, cytomegaloviral) may not have leukocytosis or leukopenia. In cases of suspected SBP, hypersplenism may reduce the polymorphonuclear leukocyte count.

Blood chemistry findings may reveal dehydration and acidosis. PT, PTT, and INR are indicated. Liver function tests may be indicated. Amylase and lipase levels should be obtained if pancreatitis is suspected. Blood culture results are positive for the offending agent in as many as 33% of patients with SBP and may help guide antibiotic therapy. Measurement of serum albumin allows calculation of the serum-to-ascites albumin gradient (SAAG). A SAAG of more than 1.1 is noted in SBP.

Imaging tests. Your doctor may want to use an X-ray to check for holes or other perforations in your gastrointestinal tract. Ultrasound may also be used. In some cases, your doctor may use a computerized tomography (CT) scan instead of an X-ray.

Radiography. Plain films of the abdomen (eg, supine, upright, and lateral decubitus positions) are often the first imaging studies obtained in patients presenting with peritonitis. Their value in reaching a specific diagnosis is limited.

Ultrasonography. Abdominal ultrasonography may be helpful in the evaluation of pathology in the right upper quadrant (eg, perihepatic abscess, cholecystitis, biloma, pancreatitis, pancreatic pseudocyst), right lower quadrant, and pelvis (eg, appendicitis, tubo-ovarian abscess, Douglas pouch abscess). However, the examination is sometimes limited because of patient discomfort, abdominal distention, and bowel gas interference. Ultrasonography may detect increased amounts of peritoneal fluid (ascites), but its ability to detect quantities of less than 100 mL is limited. The central (perimesenteric) peritoneal cavity is not visualized well with transabdominal ultrasonography. Examination from the flank or back may improve the diagnostic yield, and providing the ultrasonographer with specific information about the patient's condition and the suspected diagnosis before the examination is important. With an experienced ultrasonographer, a diagnostic accuracy of greater than 85% has been reported in several series. Ultrasonographically guided aspiration and placement of drains has evolved into a valuable tool in the diagnosis and treatment of abdominal fluid collections. Advantages of ultrasound include low cost, portability, and availability. Disadvantages are that the test is operator dependent, and there is reduced visualization in the presence of overlying bowel gas and abdominal dressings.

CT scanning. If the diagnosis of peritonitis is made clinically, a CT scan is not necessary and generally delays surgical intervention without offering clinical advantage. However, CT scanning is indicated in all

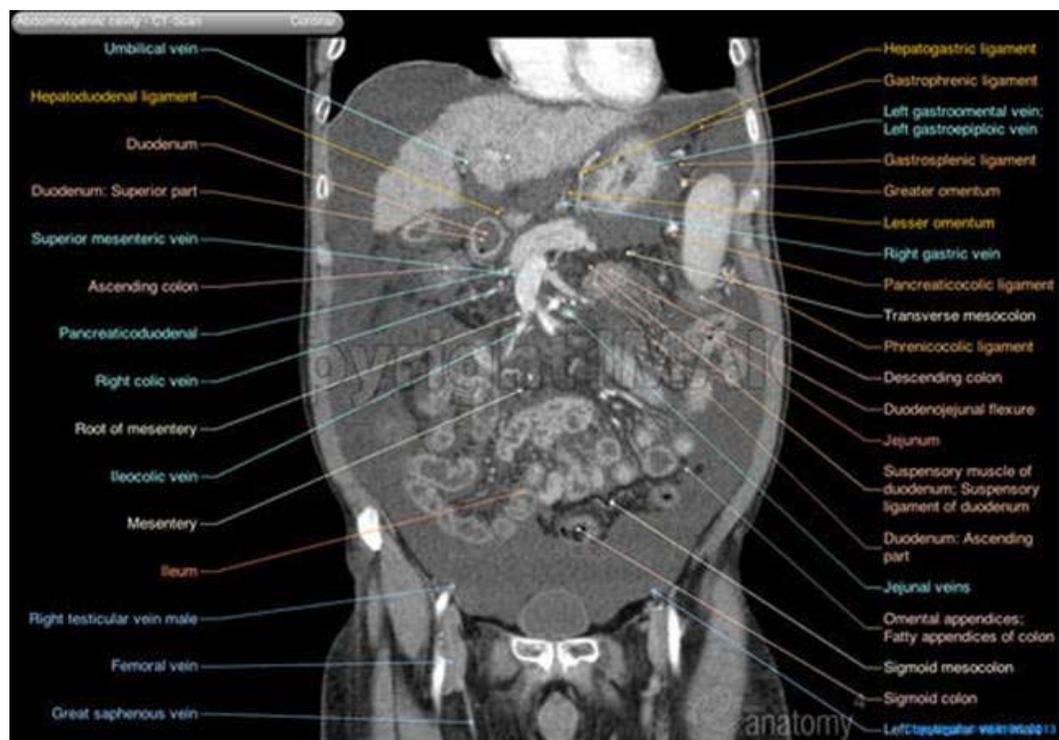

cases in which the diagnosis cannot be established on clinical grounds and findings on abdominal plain films. CT scans of the abdomen and pelvis remain the diagnostic study of choice for peritoneal abscess and related visceral pathology.

Whenever possible, the CT scan should be performed with enteral and intravenous contrast. CT scans can detect small quantities of fluid, areas of inflammation, and other GI tract pathology, with sensitivities that approach 100%. (See the image below.) CT scanning can be used to evaluate for ischemia, as well as to determine bowel obstruction. An abscess is suggested by the presence of fluid density that is not bound by the bowel or other known structures. Gas within an abdominal mass or the presence of an enhancing wall and adjacent inflammatory changes are also highly suggestive of an abscess. Ischemia can be demonstrated by a clot in a large vessel or by the absence of blood flow. Gas within the intestinal wall or in the portal vein may also suggest ischemia.

Free air is present in most cases of anterior gastric and duodenal perforation but is much less frequent with perforations of the small bowel and colon and is unusual with appendiceal perforation. Upright films are useful for identifying free air under the diaphragm (most often on the right) as an indication of a perforated viscus. Remember that the presence of free air is not mandatory with visceral perforation and that small amounts of free air are missed easily on plain films.

In abscess formation subsequent to secondary peritonitis (SP), approximately half of patients have a simple abscess without loculation, and the other half have complex abscesses secondary to fibrinous septation and organization of the abscess material. Abscess formation occurs most frequently in the subhepatic area, the pelvis, and the paracolic gutters, but it may also occur in the perisplenic area, the lesser sac, and between small bowel loops and their mesentery.

Peritoneal abscesses and other fluid collections may be aspirated for diagnosis and drained under CT guidance; this technique has become a mainstay of therapy.

MRI. MRI is an emerging imaging modality for the diagnosis of suspected intra-abdominal abscesses. Abdominal abscesses demonstrate decreased signal intensity on T1-weighted images and homogeneous or heterogeneous increased signal intensity on T2-weighted images; abscesses are observed best on gadolinium-enhanced, T1-weighted, fat-suppressed images as well-defined fluid collections with rim enhancement.

Limited availability and high cost, as well as the need for MRI-compatible patient support equipment and the length of the examination, currently limit its usefulness as a diagnostic tool in acute peritoneal infections, particularly for patients who are critically ill.

The above tests may also be necessary if you're receiving peritoneal dialysis and a diagnosis of peritonitis is uncertain after a physical exam and an examination of the dialysis fluid.\

Differential diagnostics

Thoracic processes with diaphragmatic irritation (eg, empyema), extraperitoneal processes (eg, pyelonephritis, cystitis, acute urinary retention), and abdominal wall processes (eg, infection, rectus hematoma) may mimic certain signs and symptoms of peritonitis. Always examine the patient for the presence of external hernias to rule out intestinal incarceration.

According to Adler and Gasbarra, the following should be considered in the differential diagnosis:

- Aneurysm, Abdominal
- Angioedema
- Appendicitis, Acute
- Mesenteric Ischemia
- Urinary Tract Infection in Females
- Whipple Disease
- Chemical irritants (eg, bile, blood, gastric juice, barium, enema or douche contents)
- Chronic peritoneal dialysis
- Chylous peritonitis
- Eosinophilic peritonitis
- Familial Mediterranean fever
- Fungal infections (eg, histoplasmosis, cryptococcosis, coccidioidomycosis)
- Granulomatous peritonitis (eg, parasitic infestations, sarcoidosis, tumors, Crohn disease, starch granules)
- Gynecologic disorders (Chlamydia peritonitis, salpingitis, endometriosis, teratoma, leiomyomatosis, dermoid cyst)
- HIV-associated peritonitis (from opportunistic organisms)
- Mesothelial hyperplasia and metaplasia
- Neoplasms (eg, primary mesothelioma, secondary carcinomatosis, Pseudomyxoma peritonei)
- Parasitic infections (eg, schistosomiasis, ascariasis, enterobiasis, amebiasis, strongyloidiasis)
- Perforated viscus
- Peritoneal encapsulation

Peritoneal loose bodies and peritoneal cysts

Peritoneal lymphangiectasis

Pyelonephritis

Sclerosing peritonitis

Splenosis

Vascular conditions (eg, mesenteric embolus, mesenteric nonocclusive ischemia, ischemic colitis, portal vein thrombosis, mesenteric vein thrombosis)

Vasculitis (eg, systemic lupus erythematosus, allergic vasculitis [Henoch-Schönlein purpura], Kohlmeier-Degos disease, polyarteritis nodosa)

The differential diagnostics in toxic and terminal stage of peritonitis when the typical signs of the disease are present commonly makes no difficulties. But in initial (reactive) stage the signs are similar to manifestation of causative disease (appendicitis, cholecystitis, pancreatitis, etc.). But there are variety of disorders, which according to their manifestation resemble peritonitis, renal colic for instance. A sharp pain, nausea, vomiting, intestinal paralysis, and false Shchotkin-Blumberg symptom (peritonism) frequently lead to misdiagnostics. A periodical pain attack with typical irradiation in thigh, perineum, dysuria, positive Pasternatsky's symptom, lack of inflammatory changes in blood analysis, presence of erythrocytes in urine help to make correct diagnosis. For its improvement applied x-ray film of the abdomen, urography and chromocystoscopy.

A diffuse abdominal pain, muscular tension of abdominal wall and peritonism often accompany hemorrhagic diatheses (Schonlein-Henoch's disease). This disorder mostly occurs in young people and manifests by multiple small hemorrhages on skin (forearm, chest, and thigh), mucous membranes of cheeks, tongue and peritoneum as well. The rectal examination reveals tarry stool or melena. In blood thrombocytopenia is observed.

Myocardial infarction especially in its location on posterior wall (abdominal form) usually accompanied by epigastric pain, nausea and vomiting. Also revealed abdominal wall tension with phenomena of peritonism. But ischemic heart disease in history and characteristic ECG changes can favor correct diagnostics.

Basal pleurisy and acute lower lobe pneumonia, causing the pain and muscular guard in epigastrium, also resemble peritonitis. Only thorough clinical examination leads to correct diagnostics.

Tactics and choice of treatment

Approach considerations. The current approach to peritonitis and peritoneal abscesses targets correction

of the underlying process, administration of systemic antibiotics, and supportive therapy to prevent or limit secondary complications due to organ system failure. treatment success is defined as adequate source control with resolution of sepsis and clearance of all residual intra-abdominal infection.

Early control of the septic source is mandatory and can be achieved by operative and nonoperative means.

NUTRITION AND DIETARY SUPPLEMENTS

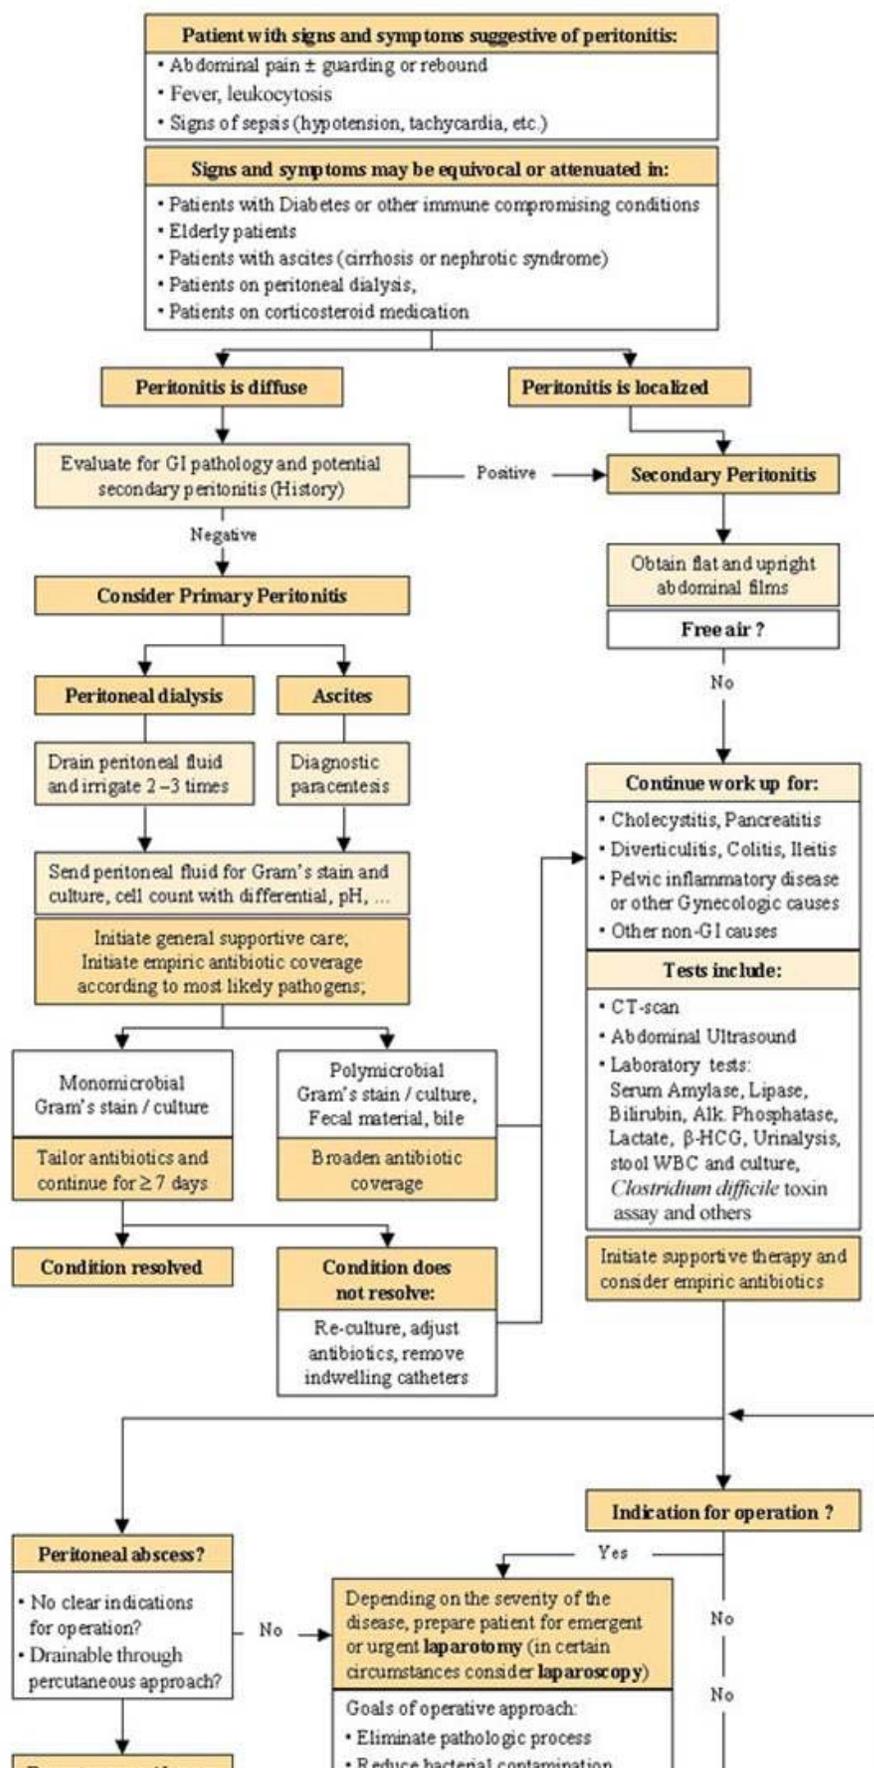

Peritonitis is a medical emergency and should be treated by a medical doctor. Do not try to treat peritonitis with herbs or supplements. However, a comprehensive treatment plan for recovering from peritonitis may include a range of complementary and alternative therapies. Ask your team of health care providers about the best ways to incorporate these therapies into your overall treatment plan. Always tell your health care provider about the herbs and supplements you are using or considering using.

These good nutrition habits may help you recover from any serious illness:

- Eat antioxidant foods, including fruits (such as blueberries, cherries, and tomatoes) and vegetables (such as squash and bell peppers).
- Eat foods high in B-vitamins and calcium, such as almonds, beans, whole grains (if no allergy), dark leafy greens (such as spinach and kale), and sea vegetables.
- Avoid refined foods, such as white breads, pastas, and especially sugar.
- Eat fewer red meats and more lean meats, cold-water fish, tofu, or beans for protein.
- Use healthy oils in foods, such as olive oil or vegetable oil.
- Avoid caffeine, alcohol, and tobacco.
- Drink 6 - 8 glasses of filtered water daily.
- Ask your doctor about taking a multivitamin daily, containing the antioxidant vitamins A, C, E, the B-complex vitamins, and trace minerals such as magnesium, calcium, zinc, and selenium.
- Probiotic supplement (containing *Lactobacillus acidophilus* among other species), 5 - 10 billion CFUs (colony forming units) a day, for gastrointestinal and immune health. Probiotics can be especially helpful when taking antibiotics, because probiotics can help restore the balance of "good" bacteria in the intestines.

Operative management addresses the need to control the infectious source and to purge bacteria and toxins.

Diagnostic and therapeutic approach to peritonitis and peritoneal abscess:

The type and extent of surgery depends on the underlying disease process and the severity of intra-abdominal infection. Definitive interventions to restore functional anatomy involve removing the source of the antimicrobial contamination and repairing the anatomic or functional disorder causing the infection. This is accomplished by surgical intervention. Occasionally, this can be achieved during a single operation; however, in certain situations, a second or a third procedure may be required. In some patients, definitive intervention is delayed until the condition of the patient improves and tissue healing is adequate to allow for a (sometimes) lengthy procedure.

To see complete information on the Surgical Approach to Peritonitis and Abdominal Sepsis, please go to the main article by clicking [here](#).

Nonoperative interventions include percutaneous abscess drainage, as well as percutaneous and endoscopic stent placements. If an abscess is accessible for percutaneous drainage and if the underlying visceral organ pathology does not clearly require operative intervention, percutaneous drainage is a safe and effective initial treatment approach. With percutaneous treatment, the definition of success includes the avoidance of further operative intervention and, in some cases, the delay of surgery until after resolution of the initial sepsis.

The general principles guiding the treatment of infections are 4-fold, as follows:

Control the infectious source

Eliminate bacteria and toxins

Maintain organ system function

Control the inflammatory process

The treatment of peritonitis is multidisciplinary, with complementary application of medical, operative, and nonoperative interventions. Medical support includes the following:

Systemic antibiotic therapy

Intensive care with hemodynamic, pulmonary, and renal support

Nutrition and metabolic support

Inflammatory response modulation therapy

Early control of the septic source is mandatory and can be achieved by operative and nonoperative means. Nonoperative interventional therapies include percutaneous drainage of abscesses and percutaneous and endoscopic stent placements.

Treatment of peritonitis and intra-abdominal sepsis always begins with volume resuscitation, correction of potential electrolyte and coagulation abnormalities, and empiric broad-spectrum parenteral antibiotic coverage.

The treatment of acute peritonitis should be always carried out with appreciation of clinical form and stage of the disease, causative factor, extension of inflammatory process, degree of metabolic disturbances

and dysfunction of vital organs of the patient.

The complex of treatment of peritonitis should include:

early operative approach in order to liquidate the source of peritonitis;

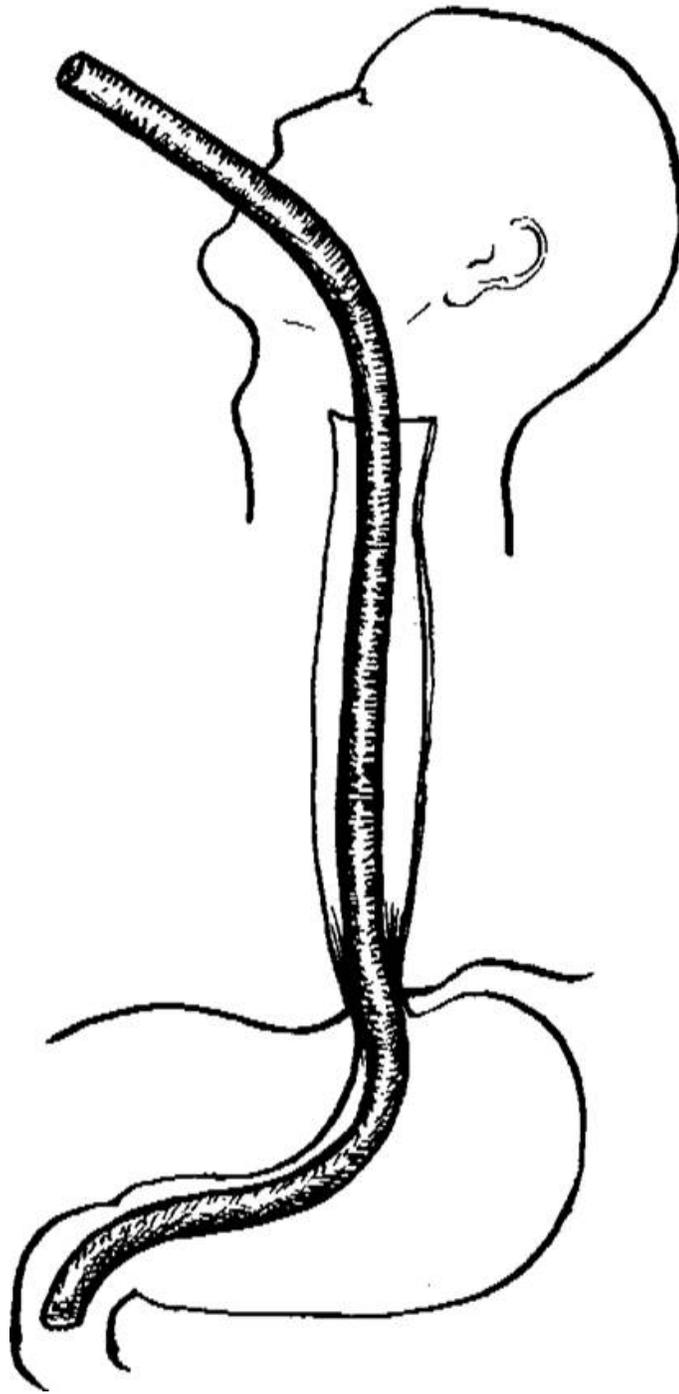

sanation of peritoneal cavity by means of lavage, adequate drainage and antibiotic therapy;

intubation and decompression of gastrointestinal tract and liquidation of paralytic ileus; (Fig.8)

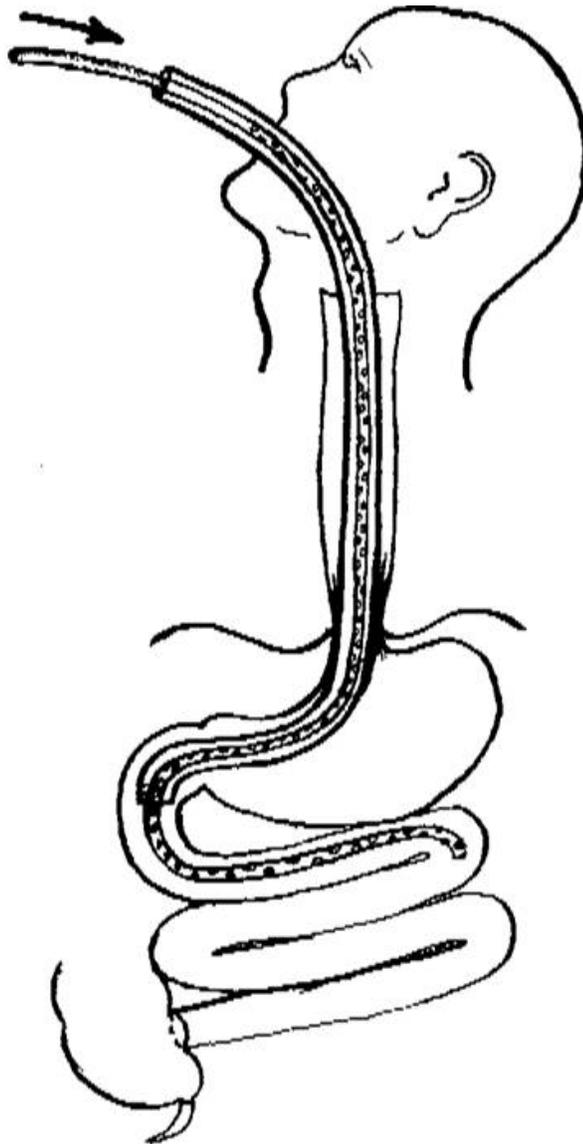

metabolic correction (acid-base balance, blood electrolytes, protein metabolism, energetic metabolism);

restore and support of visceral function (kidney, liver, heart, lung) and prevention of complications.

8. Final view of nasogastrintestinal intubation

Fig.8. Principles of nasogastrintestinal intubation

The preoperative preparation in patients with peritonitis should be individual and lasted at least 2-3 hours. In extremely advanced cases, which associated with toxic shock and low arterial pressure it can last to 4-6 hours and must include nasogastric decompression of the stomach with active aspiration, catheterization of two veins, one of which is central, catheterization of bladder for diuresis control, infusion therapy.

The infusion therapy includes 5 % solution of glucose, solution of albumins, plasma, rheopolyglucin, vitamins of B and C group, solution of sodium hydrocarbonatis. The volume of fluid infusion should be at least 1.5-2 l. If there are no improvement of patient's condition before the operation, the infusion therapy must go on during operative approach.

The most common access in diffuse peritonitis is a median laparotomy, which is the most suitable for abdominal revision. In case of localized peritonitis (acute appendicitis) oblique incision may be used. The main goal of surgery must be elimination of infectious focus (appendectomy, cholecystectomy) or closure of stomach opening (perforating ulcer) or disrapture of hollow viscera. The exudate must be maximum

removed and peritoneal cavity washed up by antiseptic solutions and thereafter the intestinal decompression and draining of peritoneal space is performed.

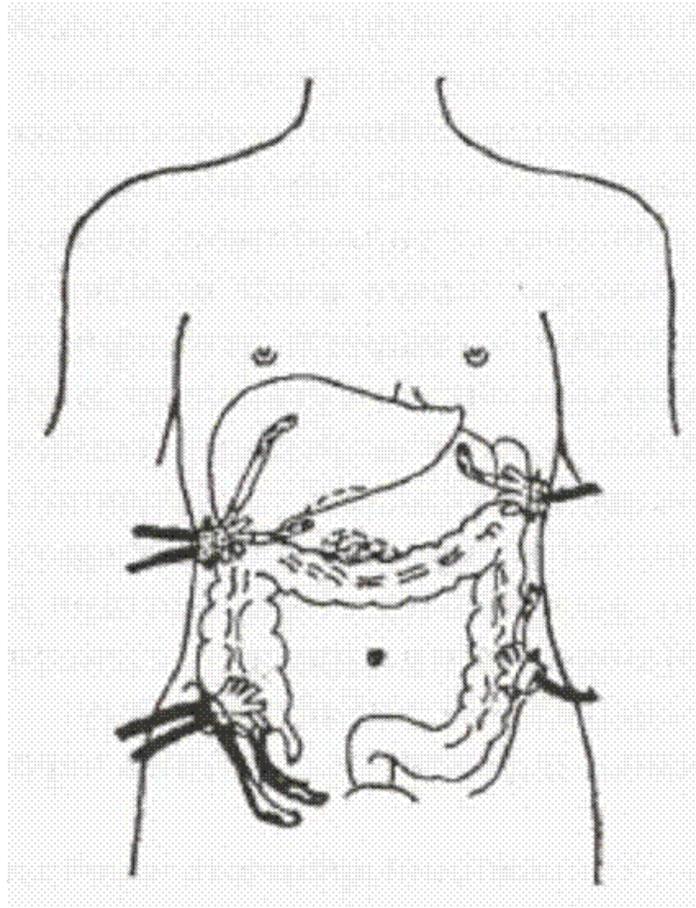

Fig.9. Scheme of the draining abdominal cavity
at extensive purulent peritonitis

In diffuse peritonitis the peritoneal cavity is drained in right and left hypochondrium and both left and right inguinal regions. It is better to use double or multiple polyethylene tubes, which are the most suitable for peritoneal dialysis. (Fig.9);(Fig.10);(Fig.11)

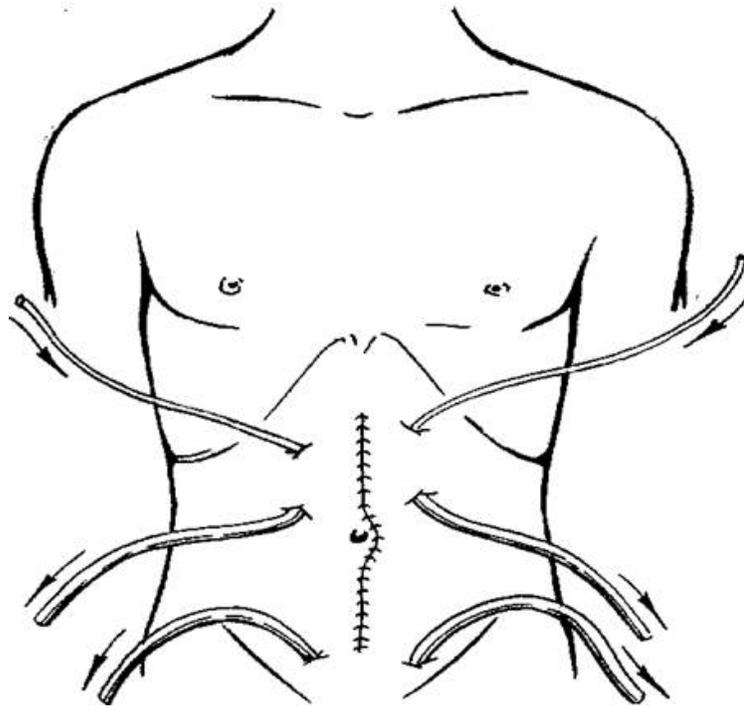

Fig.9. Localization of the drainages at peritoneal dialysis

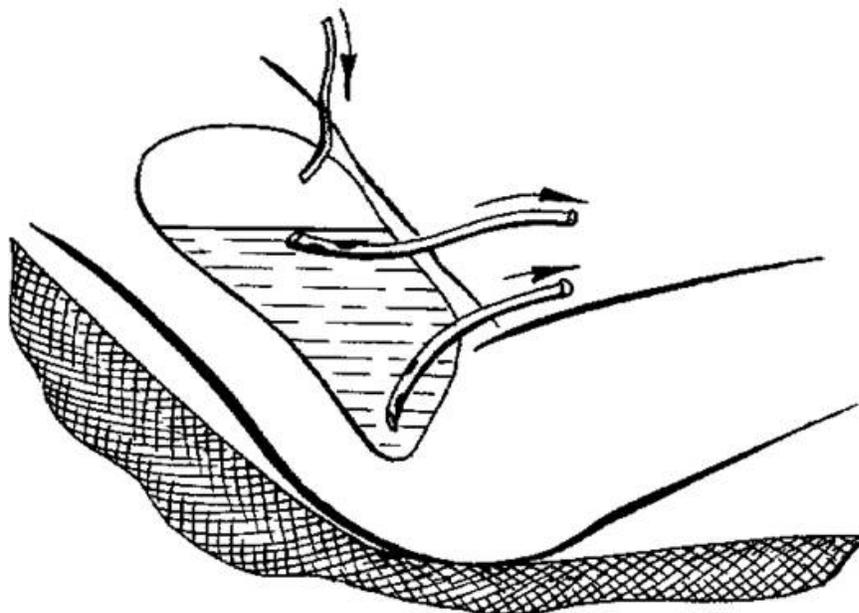

Fig.10. Scheme of localization of the drainages
at peritoneal dialysis(Lateral view)

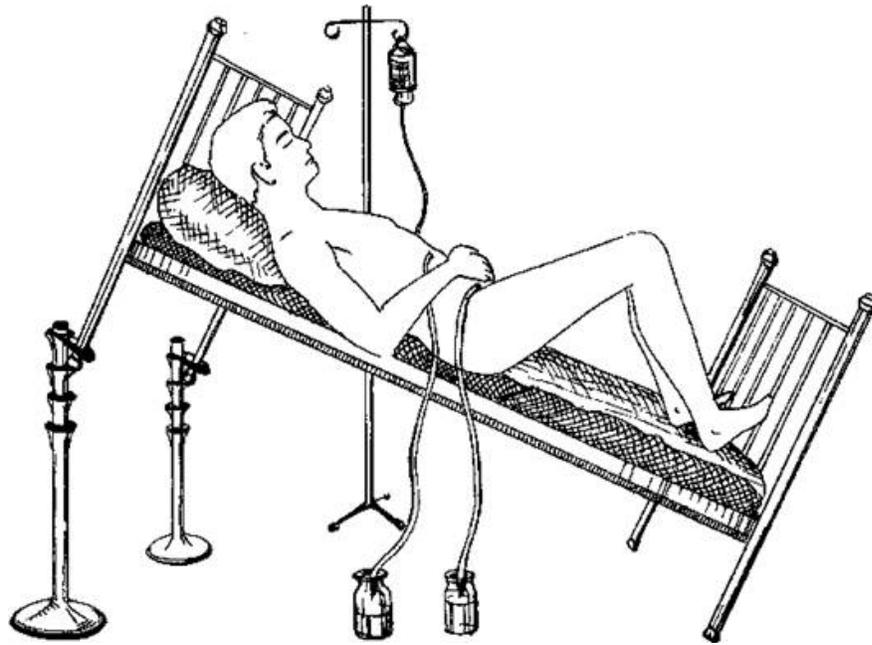

Fig.11. The position of the patient at peritoneal dialysis

Thus the infectious exudate and toxic substances are eliminated and antibiotics and antiseptic solutions are flown into the abdomen through these tubes. In 1.5-2 hours after the operation before the dialysis the patient takes a semisedentary position. Then the solutions flow in through the upper tubes and flow out through the lower. This procedure is performed as far as the solution from the lower tubes becomes clear, using for this purpose 10-25 l. of fluid.

In recent years instead of dialysis applied peritoneal lavage. Controllable peritoneostomy(Fig.12) in association with lavage, epidural anesthesia and intestinal intubation allow to rather promptly carry out sanitation of peritoneal cavity and liquidation of inflammatory process. These procedures are repeated in 1-2 days up to complete elimination of pus, fibrin and necrotic tissues. After the last sanitation the abdominal wall is closed.

Antibacterial therapy is performed by means of intraabdominal and parenteral (intramuscular, intravenous, endolymphatic) administering of antibiotics. It is desirable to use broad-spectrum antibiotics and after results of antibioticogram possible to apply direct correction. The antibiotics are advisable to use in combination with sulfanilamides, metrogyl, immunostimulators.

A struggle against paralytic ileus is a very important in the complex of treatment of peritonitis. It should begin during operation by means of intestinal decompression, mesenteric blockade, gastric lavage, and

detoxycation therapy. For restitution of peristalsis used proserin, 10 % solution of sodium chloride, hypertonic enema. One of the most important factors in the treatment of peritonitis is the complete restore of the volume of circulating blood, correction of acid-base balance, blood electrolytes, protein metabolism. The total amount of fluid is calculated with account of its loss during vomiting, urinary excretion, drainage discharges and also respiration. For energetic compensation infused concentrated solution of glucose, sorbitol and lipid emulsion. Also plasma, erythrocyte and blood transfusions are used. In order to prevent hypoxia oxygenotherapy or hyperbaric oxygenation are applied.

NEW TECHNOLOGIES IN SURGERY. MODERN METHODS OF DIAGNOSTIC AND TREATMENT

MINIMALLY INVASIVE SURGERY: INTRODUCTION

Minimally-invasive surgery describes an area of surgery that crosses all traditional disciplines, from general surgery to neurosurgery. It is not a discipline unto itself, but more a philosophy of surgery, a way of thinking. Minimally-invasive surgery is a means of performing major operations through small incisions, often using miniaturized, high-tech imaging systems, to minimize the trauma of surgical exposure. Some believe that minimal access surgery more accurately describes the small incisions generally necessary to gain access to surgical sites in high-tech surgery, but John Wickham's term minimally-invasive surgery (MIS) is widely used because it describes the paradox of postmodern high-tech surgery—small holes, big operations—and the "minimalness" of the access and invasiveness of the procedures, captured in three words.

Historical Background

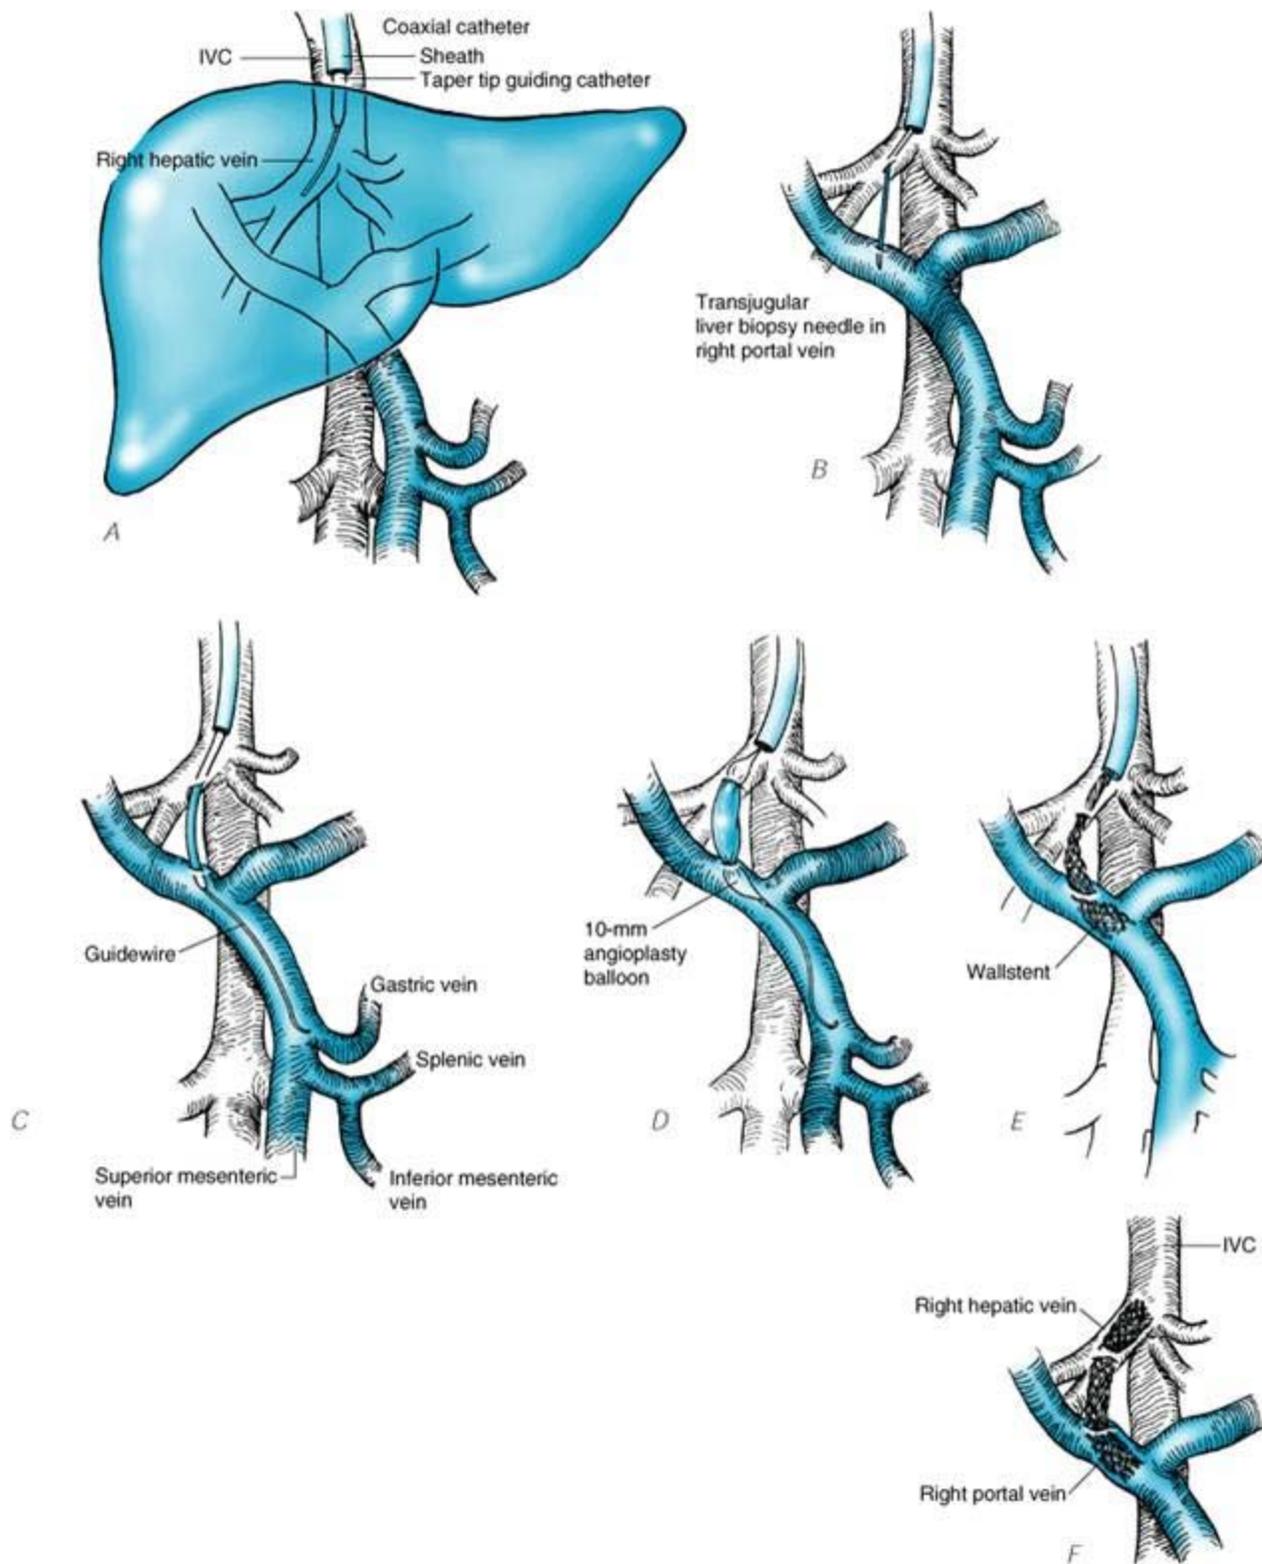

While the term *minimally-invasive surgery* is relatively recent, the history of its component parts is nearly 100 years old. What is considered the newest and most popular variety of MIS, laparoscopy, is in fact the oldest. Primitive laparoscopy, placing a cystoscope within an inflated abdomen, was first performed by Kelling in 1901. 1 Illumination of the abdomen required hot elements at the tip of the scope and was dangerous. In the late 1950s Hopkins described the rod lens, a method of transmitting light through a solid quartz rod with no heat and little light loss. 1 Around the same time, thin quartz fibers were discovered to be capable of trapping light internally and conducting it around corners, opening the field of fiberoptics and allowing the rapid development of flexible endoscopes. 2,3 In the 1970s the application of flexible endoscopy grew faster than that of rigid endoscopy except in a few fields such as gynecology and orthopedics. 4 By the mid-1970s rigid and flexible endoscopes made a rapid transition from diagnostic instruments to therapeutic ones. The explosion of video-assisted surgery in the past 10 years was a result of the development of compact, high-resolution charge-coupled devices which could be mounted on the internal end of flexible endoscopes or on the external end of a Hopkins telescope. Coupled with bright light sources, fiberoptic cables, and high-resolution video monitors, the videoendoscope has changed our understanding of surgical anatomy and reshaped surgical practice.

While optical imaging produced the majority of MIS procedures, other (traditionally radiologic) imaging technologies allowed the development of innovative procedures in the 1970s. Fluoroscopic imaging allowed the adoption of percutaneous vascular procedures, the most revolutionary of which was balloon angioplasty. Balloon-based procedures spread into all

fields of medicine, assisting in a minimally-invasive manner to open up clogged lumens. Stents were then developed that were used in many disciplines to keep the newly ballooned segment open. The culmination of fluoroscopic balloon and stent proficiency is exemplified by the transvenous intrahepatic portosystemic shunt (TIPS) (FIG. 1).

MIS procedures using ultrasound imaging have been limited to fairly crude exercises, such as fragmenting kidney stones and freezing liver tumors, because of the relatively low resolution of ultrasound devices. Newer, high-resolution ultrasound methods with high-frequency crystals may act as a guide while performing minimally-invasive resections of individual layers of the intestinal wall.

FIG. 1.

All rights reserved.

With the transvenous intrahepatic portosystemic shunt (TIPS), percutaneous access to the superior vena cava is followed by the retrograde cannulation of the hepatic veins. Next a needle is advanced through the hepatic parenchyma until the portal venous radicle is located. A guidewire is passed across this connection, and after dilation a metallic stent is expanded with

a balloon. While not often performed by surgeons, TIPS represents a particularly creative example of minimally-invasive surgery. (Reproduced with permission from Hunter JG, Sackier JM (eds): *Minimally-Invasive Surgery*. New York: McGraw-Hill, 1993, p 271.)

Axial imaging, such as computed tomography (CT), has allowed the development of an area of MIS that is not often recognized because it requires only a CT scanner and a long needle. CT-guided drainage of abdominal fluid collections and percutaneous biopsy of abnormal tissues are minimally-invasive means of performing procedures that previously required a celiotomy. Recently, CT-guided percutaneous radiofrequency ablation has emerged as a useful treatment for primary and metastatic liver tumors. This procedure has also been performed laparoscopically under ultrasound guidance. 5

A powerful, noninvasive method of imaging that will allow the development of the least invasive—and potentially noninvasive—surgery is magnetic resonance imaging (MRI).

MRI is an extremely valuable diagnostic tool, but it is only slowly coming to be of therapeutic value. One obstacle to the use of MRI for MIS is that image production and refreshment of the image as a procedure progresses are slow. Another is that all instrumentation must be nonmetallic when working with the powerful magnets of an MRI scanner. Moreover, MRI magnets are bulky and limit the surgeon's access to the patient. Open magnets have been developed that allow the surgeon to stand between two large MRI coils, obtaining access to the portion of the patient being scanned. The advantage of MRI, in addition to the superb images produced, is that there is no radiation exposure to patient or surgeon. Some neurosurgeons are accumulating experience using MRI to perform frameless stereotactic surgery.

The Minimally-Invasive Team

From the beginning, the tremendous success of minimally-invasive surgery has been founded on the understanding that a team approach is necessary. The numerous laparoscopic procedures range from basic to advanced complexity, and require that the surgical team have an intimate understanding of the operative conduct (Table 13-1). Minimally-invasive procedures require complicated and fragile equipment that demands constant maintenance. In addition, multiple intraoperative adjustments to the equipment, camera, insufflator, monitors, and patient/surgeon position are made during these procedures. As such, a coordinated team approach is mandated in order to ensure patient safety and excellent outcomes.

A typical MIS team may consist of a laparoscopic surgeon and an operating room nurse with an interest in laparoscopic surgery. Adding dedicated laparoscopic assistants and circulating staff with an intimate knowledge of the equipment will add to and enhance the team nucleus. Studies have demonstrated that having a designated laparoscopic team reduces the conversion rate and overall operative time, which is translated into a cost savings for patient and hospital.

Physiology

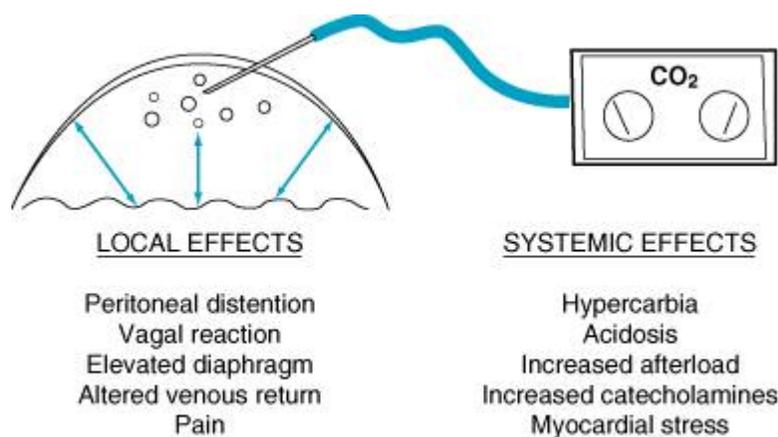

Even with the least invasive of the MIS procedures, physiologic changes occur. Many minimally-invasive procedures require minimal or no sedation, and there are few alterations to the cardiovascular, endocrinologic, or immunologic systems. The least invasive of such procedures include stereotactic biopsy of breast lesions and flexible gastrointestinal endoscopy. Minimally-invasive procedures that require general anesthesia have a greater physiologic impact because of the anesthetic agent, the incision (even if small), and the induced pneumoperitoneum.

Laparoscopy

The unique feature of endoscopic surgery in the peritoneal cavity is the need to lift the abdominal wall from the abdominal organs. Two methods have been devised for achieving this. 7 The first, used by most surgeons, is the induction of a pneumoperitoneum. Throughout the early twentieth century intraperitoneal visualization was achieved by inflating the abdominal cavity with air, using a sphygmomanometer bulb. 8 The problem with using air insufflation is that nitrogen is poorly soluble in blood and is slowly absorbed across the peritoneal surfaces. Air pneumoperitoneum was believed to be more painful than nitrous oxide pneumoperitoneum but less painful than carbon dioxide pneumoperitoneum. Subsequently, carbon dioxide and nitrous oxide were used for inflating the abdomen. N₂O had the advantage of being physiologically inert and rapidly absorbed. It also provided better analgesia for laparoscopy performed under local anesthesia when compared with CO₂ or air. 9 Despite initial concerns that N₂O would not suppress combustion, controlled clinical trials have established its safety within the peritoneal cavity. 10 In addition, nitrous oxide has recently been shown to reduce the intraoperative end-tidal CO₂ and minute ventilation required to maintain homeostasis when compared to CO₂ pneumoperitoneum. 10 The effect of N₂O on tumor biology and the development of port site metastasis are unknown. As such, caution should be exercised when performing laparoscopic cancer surgery with this agent. Finally, the safety of N₂O pneumoperitoneum in pregnancy has yet to be elucidated.

The physiologic effects of CO₂ pneumoperitoneum can be divided into two areas: (1) gas-specific effects and (2) pressure-specific effects (FIG. 2). CO₂ is rapidly absorbed across the peritoneal membrane into the circulation. In the circulation, CO₂ creates a respiratory acidosis by the generation of carbonic acid. 11 Body buffers, the largest reserve of which lies in bone, absorb CO₂ (up to 120 L) and minimize the development of hypercarbia or respiratory acidosis during brief endoscopic procedures. 11 Once the body buffers are saturated, respiratory acidosis develops rapidly, and the respiratory system assumes the burden of keeping up with the absorption of CO₂ and its release from these buffers.

Carbon dioxide gas insufflated into the peritoneal cavity has both local and systemic effects that cause a complex set of hemodynamic and metabolic alterations. [Reproduced with permission from Hunter JG (ed): *Baillière's Clinical Gastroenterology Laparoscopic Surgery*. London/Philadelphia: Baillière Tindall, 1993, p 758.]

In patients with normal respiratory function this is not difficult; the anesthesiologist increases the ventilatory rate or vital capacity on the ventilator. If the respiratory rate required exceeds 20 breaths per minute, there may be less efficient gas exchange and increasing hypercarbia. 12 Conversely, if vital capacity is increased substantially, there is a greater opportunity for barotrauma and greater respiratory motion–induced disruption of the upper abdominal operative field. In some situations it is advisable to evacuate the pneumoperitoneum or reduce the intra-abdominal pressure to allow time for the anesthesiologist to adjust for hypercarbia. 13 While mild respiratory acidosis probably is an insignificant problem, more severe respiratory acidosis leading to cardiac arrhythmias has been reported. 14 Hypercarbia also causes tachycardia and increased systemic vascular resistance, which elevates blood pressure and increases myocardial oxygen demand. 11,14

The pressure effects of the pneumoperitoneum on cardiovascular physiology also have been studied. In the hypovolemic individual, excessive pressure on the inferior vena cava and a reverse Trendelenburg position with loss of lower extremity muscle tone may cause decreased venous return and cardiac output. 11,15 This is not seen in the normovolemic patient. The most common arrhythmia created by laparoscopy is bradycardia. A rapid stretch of the peritoneal membrane often causes a vagovagal response with bradycardia and occasionally hypotension. 16 The appropriate management of this event is desufflation of the abdomen, administration of vagolytic agents (e.g., atropine), and adequate volume replacement. 17

With the increased intra-abdominal pressure compressing the inferior vena cava, there is diminished venous return from the lower extremities. This has been well documented in the patient placed in the reverse Trendelenburg position for upper abdominal operations. Venous engorgement and decreased venous return promote venous thrombosis. 18,19 Many series of

advanced laparoscopic procedures in which deep venous thrombosis (DVT) prophylaxis was not used demonstrate the frequency of pulmonary embolus. This usually is an avoidable complication with the use of sequential compression stockings, subcutaneous heparin, or low-molecular-weight heparin. 20 In short-duration laparoscopic procedures, such as appendectomy, hernia repair, or cholecystectomy, the risk of DVT may not be sufficient to warrant extensive DVT prophylaxis.

The increased pressure of the pneumoperitoneum is transmitted directly across the paralyzed diaphragm to the thoracic cavity, creating increased central venous pressure and increased filling pressures of the right and left sides of the heart. If the intra-abdominal pressures are kept under 20 mm Hg, the cardiac output usually is well maintained. 19,20,21 The direct effect of the pneumoperitoneum on increasing intrathoracic pressure increases peak inspiratory pressure, pressure across the chest wall, and also the likelihood of barotrauma. Despite these concerns, disruption of blebs and consequent pneumothoraces are rare after uncomplicated laparoscopic surgery. 21

Increased intra-abdominal pressure decreases renal blood flow, glomerular filtration rate, and urine output. These effects may be mediated by direct pressure on the kidney and the renal vein. 22,23 The secondary effect of decreased renal blood flow is to increase plasma renin release, thereby increasing sodium retention. Increased circulating antidiuretic hormone (ADH) levels also are found during the pneumoperitoneum, increasing free water reabsorption in the distal tubules. 24 Although the effects of the pneumoperitoneum on renal blood flow are immediately reversible, the hormonally mediated changes, such as elevated ADH levels, decrease urine output for up to 1 hour after the procedure has ended. Intraoperative oliguria is common during laparoscopy, but the urine output is not a reflection of intravascular volume status; intravenous fluid administration during an uncomplicated laparoscopic procedure should not be linked to urine output. Because fluid losses through the open abdomen are eliminated with laparoscopy, the need for supplemental fluid during a laparoscopic surgical procedure is rare.

The hemodynamic and metabolic consequences of pneumoperitoneum are well tolerated by healthy individuals for a prolonged period and by most individuals for at least a short period. Difficulties can occur when a patient with compromised cardiovascular function is subjected to a long laparoscopic procedure. It is during these procedures that alternative approaches should be considered or insufflation pressure reduced. Alternative gases that have been suggested for laparoscopy include the inert gases helium, neon, and argon. These gases are appealing because they cause no metabolic effects, but are poorly soluble in blood (unlike CO₂ and N₂O) and are prone to create gas emboli if the gas has direct access to the venous system. 19 Gas emboli are rare but serious complications of laparoscopic surgery. 20,25 They should be suspected if hypotension develops during insufflation. Diagnosis may be made by listening (with an esophageal stethoscope) for the characteristic "mill wheel" murmur. The treatment of gas embolism is to place the patient in a left lateral decubitus position with the head down to trap the gas in the apex of the right ventricle. 20 A rapidly placed central venous catheter then can

be used to aspirate the gas out of the right ventricle.

In some situations minimally-invasive abdominal surgery should be performed without insufflation. This has led to the development of an abdominal lift device that can be placed through a 10- to 12-mm trocar at the umbilicus. 26 These devices have the advantage of creating little physiologic derangement, but they are bulky and intrusive. The exposure and working room offered by lift devices also are inferior to those accomplished by pneumoperitoneum. Lifting the anterior abdominal wall causes a "pinching in" of the lateral flank walls, displacing the bowel medially and anteriorly into the operative field. A pneumoperitoneum, with its well-distributed intra-abdominal pressure, provides better exposure. Abdominal lift devices also cause more postoperative pain, but they do allow the performance of MIS with standard (nonlaparoscopic) surgical instruments.

Early it was predicted that the surgical stress response would be significantly lessened with laparoscopic surgery, but this is not always the case. Serum cortisol levels after laparoscopic operations are often higher than after the equivalent operation performed through an open incision. 27 In terms of endocrine balance, the greatest difference between open and laparoscopic surgery is the more rapid equilibration of most stress-mediated hormone levels after laparoscopic surgery. Immune suppression also is less after laparoscopy than after open surgery. There is a trend toward more rapid normalization of cytokine levels after a laparoscopic procedure than after the equivalent procedure performed by celiotomy. 28

Transhiatal mobilization of the thoracic esophagus is commonly performed as a component of many laparoscopic upper abdominal procedures. Entering the posterior mediastinum transhiatally exposes the thoracic organs to positive insufflation pressure and may result in decreased venous return and a resultant decrease in cardiac output. If there is compromise of the mediastinal pleura with resultant CO₂ pneumothorax, the defect should be enlarged so as to prevent a tension pneumothorax.

Thoracoscopy

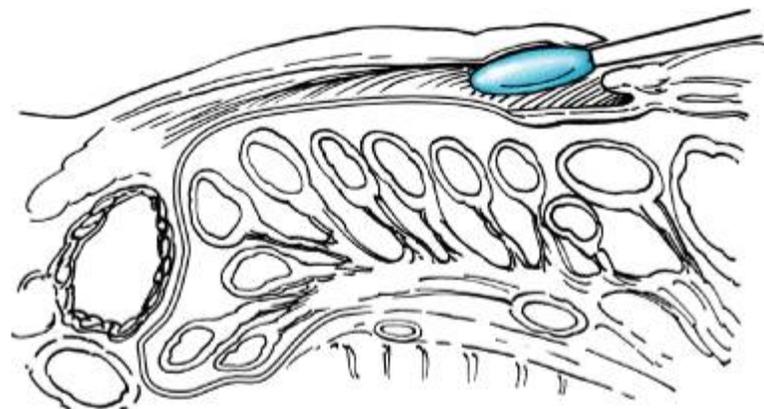

The physiology of thoracic MIS (thoracoscopy) is different from that of laparoscopy. Because of the bony confines of the thorax it is unnecessary to use positive pressure when working in the thorax. 29 The disadvantages of positive pressure in the chest include decreased venous return, mediastinal shift, and the need to keep a firm seal at all trocar sites. Without positive pressure, it is necessary to place a double-lumen endotracheal tube so that the ipsilateral lung can be deflated when the operation starts. By collapsing the ipsilateral lung, working space within the thorax is obtained. Because insufflation is unnecessary in thoracoscopic surgery, it can be beneficial to utilize standard instruments via extended port sites in conjunction with thoracoscopic instruments. This approach is particularly useful when performing advanced procedures such as thoracoscopic anatomic pulmonary resection.

Extracavitary Minimally-Invasive Surgery

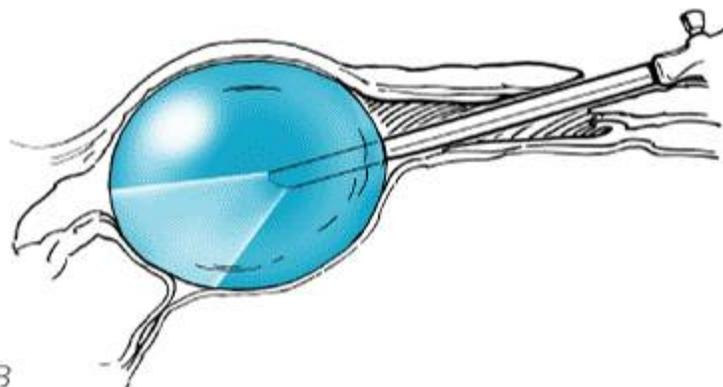

Many new MIS procedures are creating working spaces in extrathoracic and extraperitoneal locations. Laparoscopic inguinal hernia repair usually is performed in the anterior

extraperitoneal Retzius space. 30,31 Laparoscopic nephrectomy often is performed with retroperitoneal laparoscopy. Recently, an endoscopic retroperitoneal approach to pancreatic necrosectomy has been introduced. 32 Lower extremity vascular procedures and plastic surgical endoscopic procedures require the development of working space in unconventional planes, often at the level of the fascia, sometimes below the fascia, and occasionally in nonanatomic regions. 33 Some of these techniques use insufflation of gas, but many use balloon inflation to develop the space, followed by low-pressure gas insufflation or lift devices to maintain the space (FIG. 3). These techniques produce fewer and less severe adverse physiologic consequences than does the pneumoperitoneum, but the insufflation of gas into extraperitoneal locations can spread widely, causing subcutaneous emphysema and metabolic acidosis.

Balloons are used to create extra-anatomic working spaces. In this example a balloon is introduced into the space between the posterior rectus sheath and the rectus abdominis muscle. The balloon is inflated in the preperitoneal space to create working room for extraperitoneal endoscopic hernia repair.

Anesthesia

The most important factors in appropriate anesthesia management are related to CO₂

pneumoperitoneum. 17 The laparoscopic surgeon can influence cardiovascular performance by releasing intra-abdominal retraction and dropping the pneumoperitoneum. Insensible fluid losses are negligible, and therefore intravenous fluid administration should not exceed a maintenance rate. MIS procedures usually are outpatient procedures, and short-acting anesthetic agents are preferable. Because the factors that require hospitalization after laparoscopic procedures include the management of nausea, pain, and urinary retention, the anesthesiologist should minimize the use of agents that provoke these conditions and maximize the use of medications that prevent such problems. Critical to the anesthesia management of these patients is the use of nonnarcotic analgesics (e.g., ketorolac) and the liberal use of antiemetic agents.

General Principles of Access and Equipment

The most natural ports of access for MIS are the anatomic portals of entry and exit. The nares, mouth, urethra, and anus are used to access the respiratory, gastrointestinal, and urinary systems. The advantage of using these points of access is that no incision is required. The disadvantages lie in the long distances between the orifice and the region of interest.

Access to the vascular system may be accomplished under local anesthesia by cutting down and exposing the desired vessel, usually in the groin. Increasingly, vascular access is obtained with percutaneous techniques using a small incision, a needle, and a guidewire, over which are passed a variety of different sized access devices. This approach, known as the Seldinger technique, is most frequently used by general surgeons for placement of Hickman catheters, but also is used to gain access to the arterial and venous system for performance of minimally-invasive procedures. Guidewire-assisted, Seldinger-type techniques also are helpful for gaining access to the gut for procedures such as percutaneous endoscopic gastrostomy, for gaining access to the biliary system through the liver, and for gaining access to the upper urinary tract.

In thoracoscopic surgery, the access technique is similar to that used for placement of a chest tube. In these procedures general anesthesia and split-lung ventilation are essential. A small incision is made over the top of a rib and, under direct vision, carried down through the pleura. The lung is collapsed, and a trocar is inserted across the chest wall to allow access with a telescope. Once the lung is completely collapsed, subsequent access may be obtained with direct puncture, viewing all entry sites through the videoendoscope. Because insufflation of the chest is unnecessary, simple ports that keep the small incisions open are all that is required to allow repeated access to the thorax.

Laparoscopic Access

The requirements for laparoscopy are more involved, because the creation of a pneumoperitoneum requires that instruments of access (trocars) contain valves to maintain abdominal inflation.

Two methods are used for establishing abdominal access during laparoscopic procedures. 34,35 The first, direct puncture laparoscopy, begins with the elevation of the relaxed abdominal

wall with two towel clips or a well-placed hand. A small incision is made in the umbilicus, and a specialized spring-loaded (Veress) needle is placed in the abdominal cavity (FIG. 4A and B). With the Veress needle, two distinct pops are felt as the surgeon passes the needle through the abdominal wall fascia and the peritoneum. The umbilicus usually is selected as the preferred point of access because in this location the abdominal wall is quite thin, even in obese patients. The abdomen is inflated with a pressure-limited insufflator. CO₂ gas is usually used, with maximal pressures in the range of 14 to 15 mm Hg. During the process of insufflation it is essential that the surgeon observe the pressure and flow readings on the monitor to confirm an intraperitoneal location of the Veress needle tip (FIG. 5). Laparoscopic surgery can be performed under local anesthesia, but general anesthesia is preferable. Under local anesthesia, N₂O is used as the insufflating agent, and insufflation is stopped after 2 L of gas is insufflated or when a pressure of 10 mm Hg is reached.

FIG. 4.

A

A. Insufflation of the abdomen is accomplished with a Veress needle held at its serrated collar with a thumb and forefinger. B. Because linea alba is fused to the umbilicus, the abdominal wall is grasped with fingers or penetrating towel clip in order to elevate the abdominal wall away from the underlying structures.

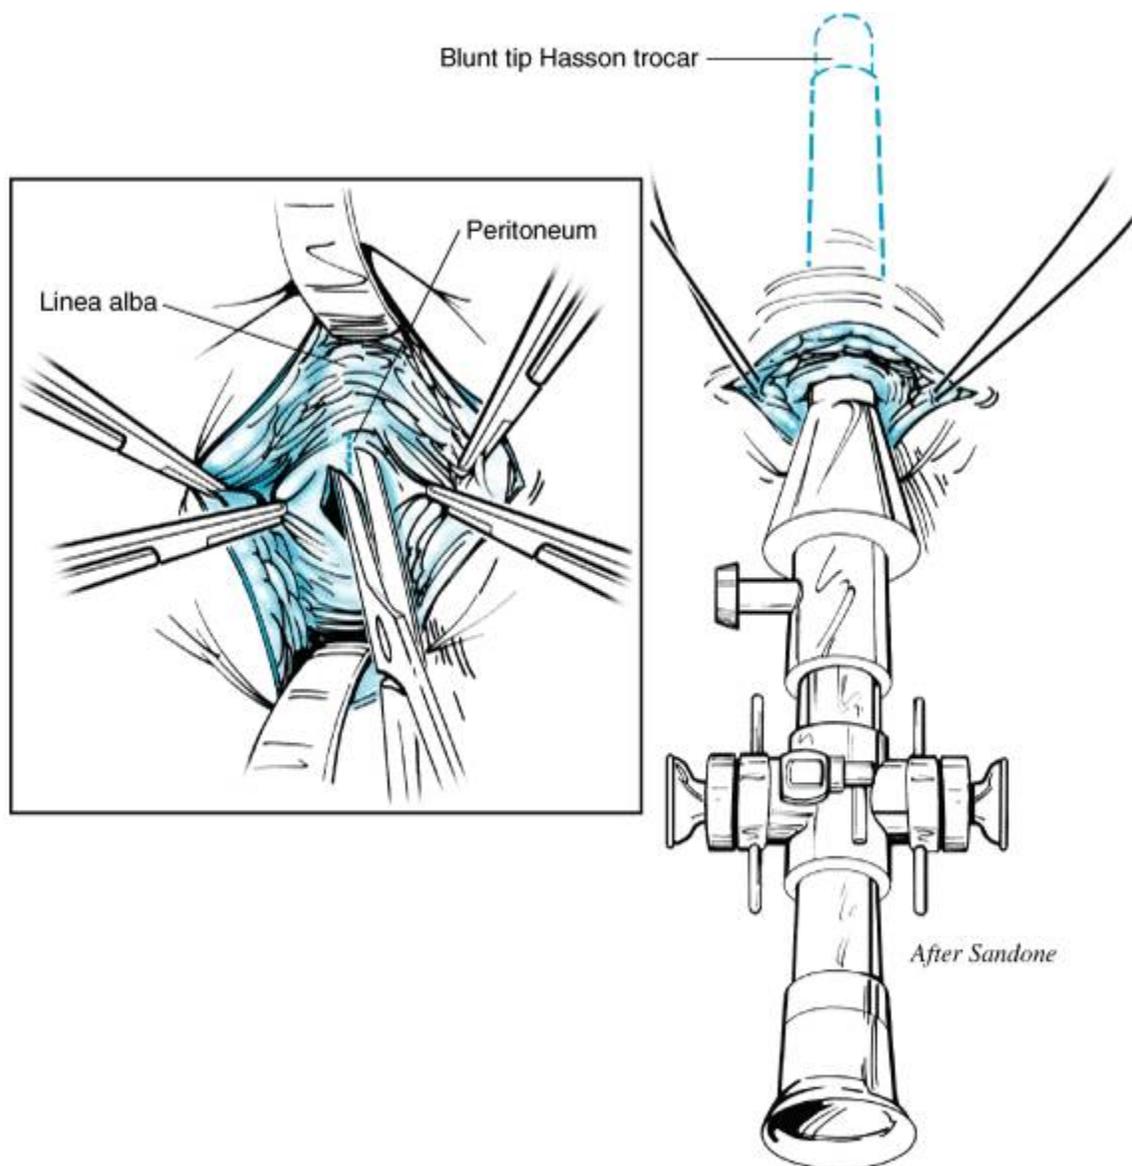

It is essential to be able to interpret the insufflator pressure readings and flow rates. These readings indicate proper intraperitoneal placement of the Veress needle.

After peritoneal insufflation, direct access to the abdomen is obtained with a 5- or 10-mm trocar. The critical issues for safe direct-puncture laparoscopy include the use of a vented stylet for the trocar, or a trocar with a safety shield or dilating tip. The trocar must be pointed away from the sacral promontory and the great vessels. 36 Patient position should be surveyed prior to trocar placement to ensure a proper trajectory. For performance of laparoscopic cholecystectomy, the trocar is angled toward the right upper quadrant.

Occasionally the direct peritoneal access (Hasson) technique is advisable. 37 With this technique, the surgeon makes a small incision just below the umbilicus and under direct vision locates the abdominal fascia. Two Kocher clamps are placed on the fascia, and with a curved Mayo scissors a small incision is made through the fascia and underlying peritoneum. A finger is placed into the abdomen to make sure that there is no adherent bowel. A sturdy suture is placed on each side of the fascia and secured to the wings of a specialized trocar, which is then passed directly into the abdominal cavity (FIG. 6). Rapid insufflation can make up for some of the time lost with the initial dissection. This technique is preferable for the abdomen of patients who have undergone previous operations in which small bowel may be adherent to the undersurface of the abdominal wound. The close adherence of bowel to the peritoneum in the previously operated abdomen does not eliminate the possibility of intestinal injury, but should

make great vessel injury extremely unlikely. Because of the difficulties in visualizing the abdominal region immediately adjacent to the primary trocar, it is recommended that the telescope be passed through a secondary trocar in order to inspect the site of initial abdominal access. 35 Secondary punctures are made with 5- and 10-mm trocars. For safe access to the abdominal cavity, it is critical to visualize all sites of trocar entry. 35,36 At the completion of the operation, all trocars are removed under direct vision and the insertion sites are inspected for bleeding. If bleeding occurs, direct pressure with an instrument from another trocar site or balloon tamponade with a Foley catheter placed through the trocar site generally stops the bleeding within 3 to 5 minutes. When this is not successful, a full-thickness abdominal wall suture has been used successfully to tamponade trocar site bleeding.

FIG. 6.

The open laparoscopy technique involves identification and incision of the peritoneum, followed by the placement of a specialized trocar with a conical sleeve to maintain a gas seal. Specialized wings

on the trocar are attached to sutures placed through the fascia to prevent loss of the gas seal.

It is generally agreed that 5-mm trocars need no site suturing. Ten-millimeter trocars placed off the midline and above the transverse mesocolon do not require repair. Conversely, if the fascia has been dilated to allow the passage of the gallbladder, all midline 10-mm trocar sites should be repaired at the fascial level with interrupted sutures. Specialized suture delivery systems similar to crochet needles have been developed for mass closure of the abdominal wall in obese patients, in whom it is difficult to visualize the fascia through a small skin incision. Failure to close lower abdominal trocar sites that are 10 mm in diameter or larger can lead to an incarcerated hernia.

Access for Subcutaneous and Extraperitoneal Surgery

There are two methods for gaining access to nonanatomic spaces. For retroperitoneal locations, balloon dissection is effective. This access technique is appropriate for the extraperitoneal repair of inguinal hernias and for retroperitoneal surgery for adrenalectomy, nephrectomy, lumbar discectomy, pancreatic necrosectomy, or para-aortic lymph node dissection. 38,39 The initial access to the extraperitoneal space is performed in a way similar to direct puncture laparoscopy, except that the last layer (the peritoneum) is not traversed. Once the transversalis fascia has been punctured, a specialized trocar with a balloon on the end is introduced. The balloon is inflated in the extraperitoneal space to create a working chamber. The balloon then is deflated and a Hasson trocar is placed. An insufflation pressure of 10 mm Hg usually is adequate to keep the extraperitoneal space open for dissection and will limit subcutaneous emphysema. Higher gas pressures force CO₂ into the soft tissues and may contribute to hypercarbia. Extraperitoneal endosurgery provides less working space than laparoscopy, but eliminates the possibility of intestinal injury, intestinal adhesion, herniation at the trocar sites, and ileus. These issues are important for laparoscopic hernia repair because extraperitoneal approaches prevent the small bowel from sticking to the prosthetic mesh. 31

Subcutaneous surgery, the newest method of access in minimally-invasive surgery, uses the creation of working room in nonanatomic spaces. This technique has been most widely used in cardiac, vascular, and plastic surgery. 33 In cardiac surgery, subcutaneous access has been used for saphenous vein harvesting, and in vascular surgery for ligation of subfascial perforating veins (Linton procedure). With minimally-invasive techniques the entire saphenous vein above the knee may be harvested through a single incision 40,41 (FIG. 7). Once the saphenous vein is located, a long retractor that holds a 5-mm laparoscope allows the coaxial dissection of the vein and coagulation or clipping of each side branch. A small incision above the knee also can be used to ligate perforating veins in the lower leg.

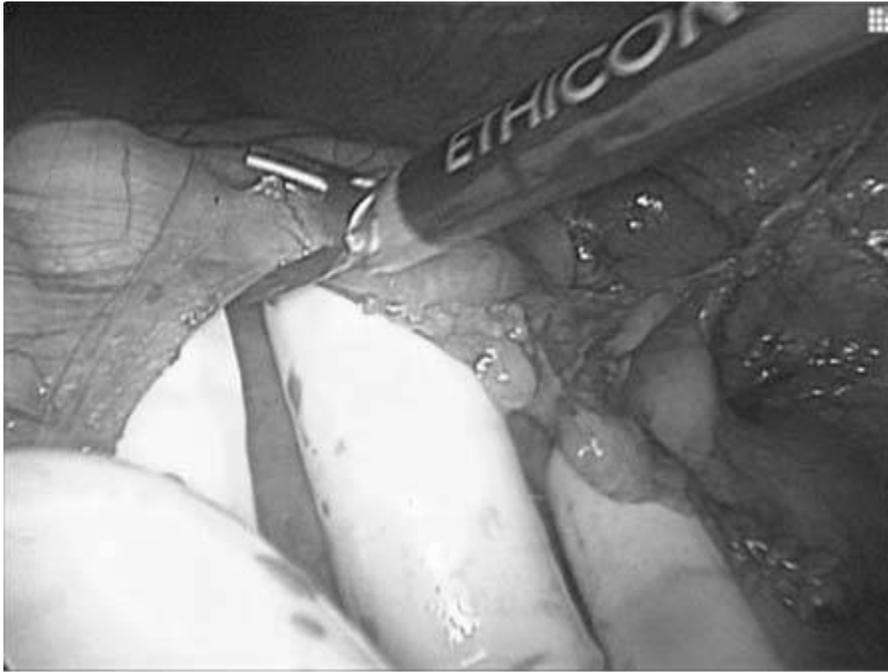

Subcutaneous access is also used for plastic surgical procedures. 41 Minimally-invasive approaches are especially well suited to cosmetic surgery, in which attempts are made to hide the incision. It is easier to hide several 5-mm incisions than one long incision. The technique of blunt dissection along fascial planes combined with lighted retractors and endoscope-holding retractors is most successful for extensive subcutaneous surgery. Some prefer gas insufflation of these soft tissue planes. The primary disadvantage of soft tissue insufflation is that

subcutaneous emphysema can be created.

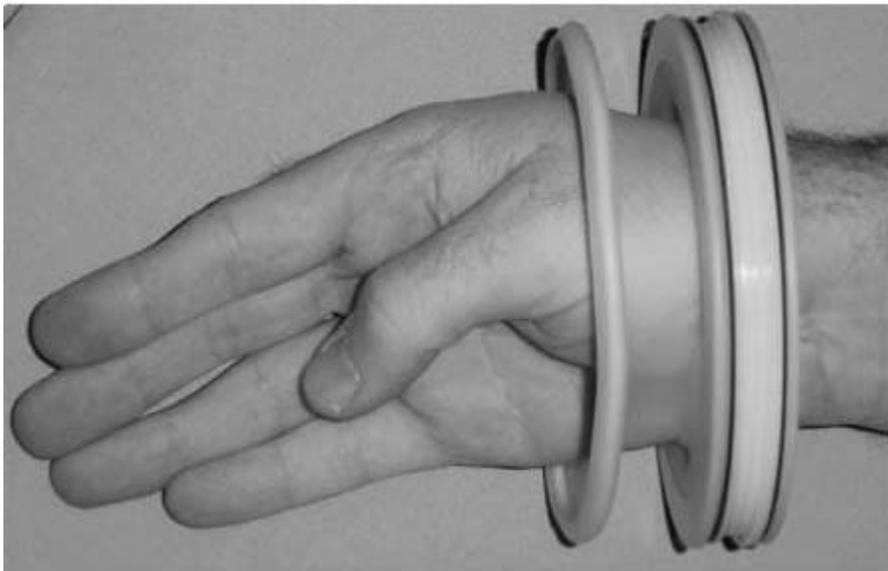

Hand-Assisted Laparoscopic Access

Hand-assisted laparoscopic surgery (HALS) is thought to combine the tactile advantages of open surgery with the minimal access of laparoscopy and thoracoscopy. This approach is commonly used to assist with difficult cases before conversion to celiotomy is necessary. Additionally, HALS is employed to help surgeons negotiate the steep learning curve associated with advanced laparoscopic procedures. 42 This technology employs a "port" for the hand which preserves the pneumoperitoneum and enables endoscopic visualization in combination with the use of minimally-invasive instruments (FIG. 8). Formal investigation of this modality has been limited primarily to case reports and small series, and has focused primarily on solid organ and colon surgery.

FIG. 8.

This is an example of hand-assisted laparoscopic surgery during left colectomy. The surgeon uses a hand to provide retraction and counter tension during mobilization of the colon from its retroperitoneal attachments, as well as during division of the mesocolon. This technique is particularly useful in the region of the transverse colon.

Port Placement

Trocars for the surgeon's left and right hand should be placed at least 10 cm apart. For most operations it is possible to orient the telescope between these two trocars and slightly retract

from them. The ideal trocar orientation creates an equilateral triangle between the surgeon's right hand, left hand, and the telescope, with 10 to 15 cm on each leg. If one imagines the target of the operation (e.g., the gallbladder or gastroesophageal junction) oriented at the apex of a second equilateral triangle built on the first, these four points of reference create a diamond (FIG. 9). The surgeon stands behind the telescope, which provides optimal ergonomic orientation but frequently requires that a camera operator (or robotic arm) reach between the surgeon's hands to guide the telescope.

FIG. 9.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

The diamond configuration created by placing the telescope between the left and the right hand, recessed from the target by about 15 cm. The distance between the left and the right hand is also ideally 10 to 15 cm. In this "baseball diamond" configuration, the surgical target occupies the second base position.

The position of the operating table should permit the surgeon to work with both elbows in at the sides, with arms bent 90° at the elbow. 43 It usually is necessary to alter the operating table position with left or right tilt with the patient in the Trendelenburg or reverse Trendelenburg position, depending on the operative field. 44,45

Imaging Systems

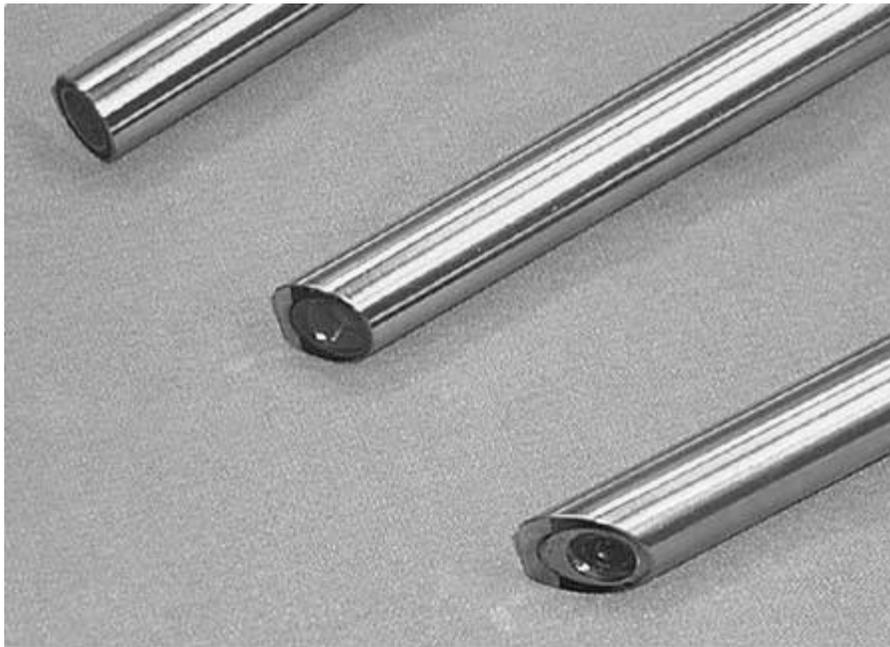

Two methods of videoendoscopic imaging are widely used. Both methods use a camera with a charge-coupled device (CCD), which is an array of photosensitive sensor elements (pixels) that convert the incoming light intensity to an electric charge. The electric charge is subsequently converted into a black-and-white image. 46 The first of these is flexible videoendoscopy, where the CCD camera is placed on the internal end of a long, flexible endoscope. In the second method, thin quartz fibers are packed together in a bundle, and the CCD camera is mounted on the external end of the endoscope. Most standard gastrointestinal endoscopes have the CCD chip at the distal end, but small, delicate choledochoscopes and

nephroscopes are equipped with fiberoptic bundles. 47 Distally-mounted CCD chips were developed for laparoscopy, but are unpopular.

Video cameras come in two basic designs. The one-chip camera has a black-and-white video chip that has an internal processor capable of converting gray scales to approximate colors. Perfect color representation is not possible with a one-chip camera, but perfect color representation is rarely necessary for endosurgery. The most accurate color representation is obtained using a three-chip video camera. A three-chip camera has red, green, and blue (RGB) input, and is identical to the color cameras used for television production. 46 RGB imaging provides the highest fidelity, but is probably not necessary for everyday use. An additional feature of newer video cameras is digital enhancement. Digital enhancement detects edges, areas where there are drastic color or light changes between two adjacent pixels. 48 By enhancing this difference, the image appears sharper and surgical resolution is improved. Digital enhancement is available on one- and three-chip cameras. Priorities in a video system for MIS are illumination first, resolution second, and color third. Without the first two attributes, video surgery is unsafe. Imaging for laparoscopy, thoracoscopy, and subcutaneous surgery uses a rigid metal telescope, usually 30 cm in length. This telescope contains a series of quartz optical rods with differing optical characteristics that provide a specific character to each telescope. 49 These metal telescopes vary in size from 2 to 10 mm in diameter. Since light transmission is dependent on the cross-sectional area of the quartz rod, when the diameter of a rod/lens system is doubled, the illumination is quadrupled. Little illumination is needed in highly-reflective, small spaces such as the knee, and a very small telescope will suffice. When working in the abdominal cavity, especially if blood is present, the full illumination of a 10-mm telescope usually is necessary.

Rigid telescopes may have a flat or angled end. The flat end provides a straight view (0°), and the angled end provides an oblique view (30 or 45°). 46 Angled scopes allow greater flexibility in viewing a wider operative field through a single trocar site (FIG. 10); rotating an angled telescope changes the field of view. The use of an angled telescope has distinct advantages for most videoendoscopic procedures, particularly in visualizing the common bile duct during laparoscopic cholecystectomy or visualizing the posterior esophagus or the tip of the spleen during laparoscopic fundoplication.

FIG. 10.

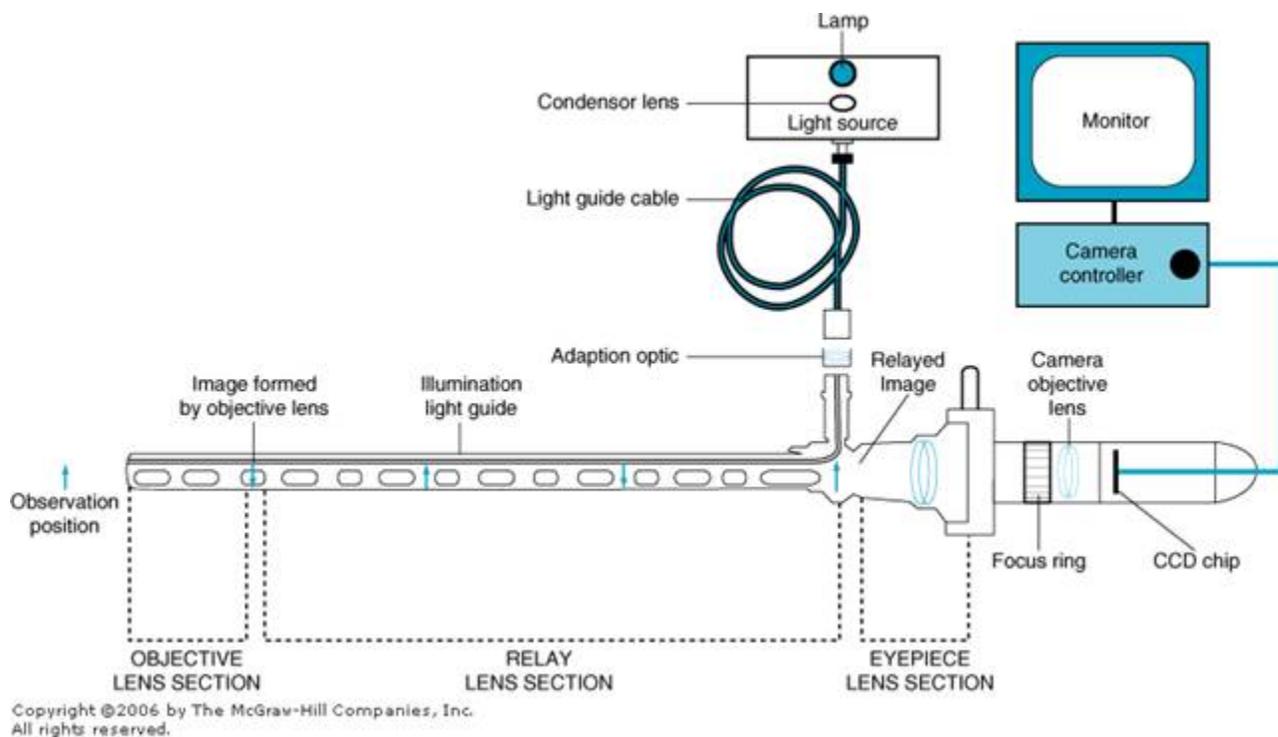

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

The laparoscope tips come in a variety of angled configurations. All laparoscopes have a 70° field of view. A 30° angled scope enables the surgeon to view this field at a 30° angle to the long axis of the scope.

Light is delivered to the endoscope through a fiberoptic light cable. These light cables are highly inefficient, losing more than 90% of the light delivered from the light source. Extremely bright light sources (300 watts) are necessary to provide adequate illumination for video endosurgery.

The quality of the videoendoscopic image is only as good as the weakest component in the imaging chain (FIG. 11). Therefore it is important to use a video monitor that has a resolution equal to or greater than the camera being used. ⁴⁹ *Resolution* is the ability of the optical system to distinguish between line pairs. The larger the number of line pairs per millimeter, the sharper and more detailed the image. Most high-resolution monitors have up to 700 horizontal lines. High definition television (HDTV) can deliver up to eight times more resolution than the standard NTSC/PAL monitors; when combined with digital enhancement, a very sharp and well-defined image can be achieved. ^{46,49} A heads-up display (HUD) is a high-resolution liquid crystal monitor that is built into eyewear worn by the surgeon. ⁵⁰ This technology allows the surgeon to view the endoscopic image and operative field simultaneously. The proposed advantages of HUD include a high-resolution monocular image, which affords the surgeon mobility and reduces vertigo and eyestrain. However, this technology has not yet been widely adopted.

FIG. 11.

The Hopkins rod lens telescope includes a series of optical rods that effectively transmit light to the eyepiece. The video camera is placed on the eyepiece to provide the working image. The image is only as clear as the weakest link in the image chain. (*Reproduced with permission from Prescher et al. 46*)

There has been recent interest in three-dimensional endoscopy. Three-dimensional laparoscopy provides the additional depth of field that is lost with two-dimensional endosurgery and allows greater facility for novice laparoscopists performing complex tasks of dexterity, including suturing and knot tying. 51 The advantages of three-dimensional systems are less obvious to experienced laparoscopists. Additionally, because three-dimensional systems require the flickering of two similar images, which are resolved with special glasses, the images' edges become fuzzy and resolution is lost. The optical accommodation necessary to rectify these slightly differing images negates any advantage offered by the additional depth of field.

Energy Sources for Endoscopic and Endoluminal Surgery

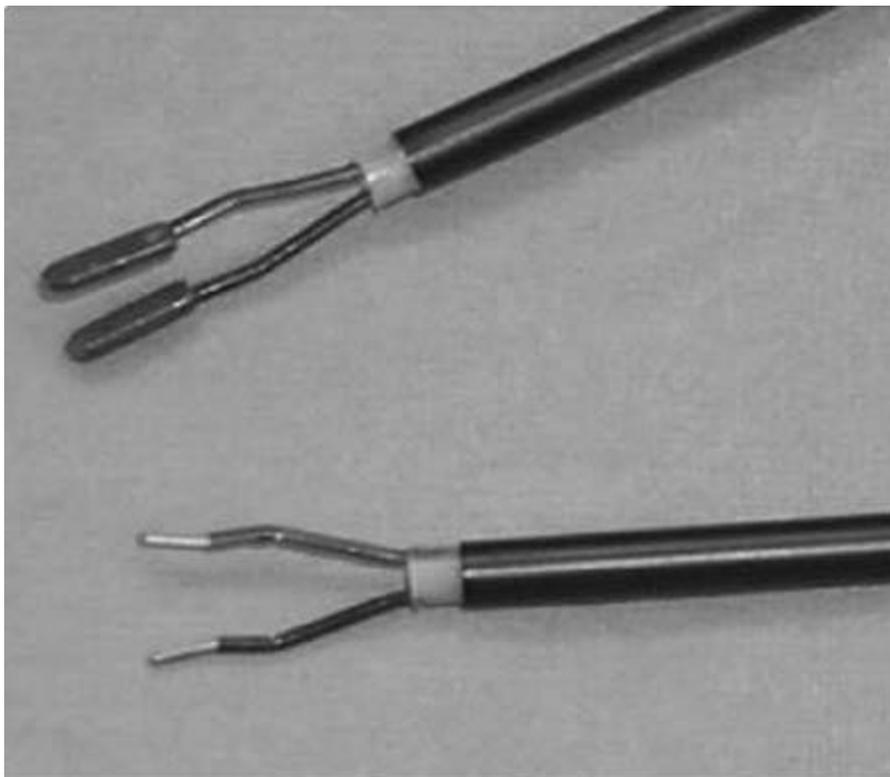

MIS uses conventional energy sources, but the requirement of bloodless surgery to maintain optimal visualization has spawned new ways of applying energy. The most common energy source is radiofrequency (RF) electrosurgery using an alternating current with a frequency of 500,000 cycles/s (Hz). Tissue heating progresses through the well-known phases of coagulation (60°C), vaporization and desiccation (100°C), and carbonization (>200°C). 52

The two most common methods of delivering RF electrosurgery are with monopolar and bipolar electrodes. With monopolar electrosurgery a remote ground plate on the patient's leg or

back receives the flow of electrons that originate at a point source, the surgical electrode. A fine-tipped electrode causes a high current density at the site of application and rapid tissue heating. Monopolar electrosurgery is inexpensive and easy to modulate to achieve different tissue effects. 53 A short-duration, high-voltage discharge of current (coagulation current) provides extremely rapid tissue heating. Lower-voltage, higher-wattage current (cutting current) is better for tissue desiccation and vaporization. When the surgeon desires tissue division with the least amount of thermal injury and least coagulation necrosis, a cutting current is used.

With bipolar electrosurgery the electrons flow between two adjacent electrodes. The tissue between the two electrodes is heated and desiccated. There is little opportunity for tissue cutting when bipolar current is used, but the ability to coapt the electrodes across a vessel provides the best method of small-vessel coagulation without thermal injury to adjacent tissues 54 (FIG. 12).

FIG. 12.

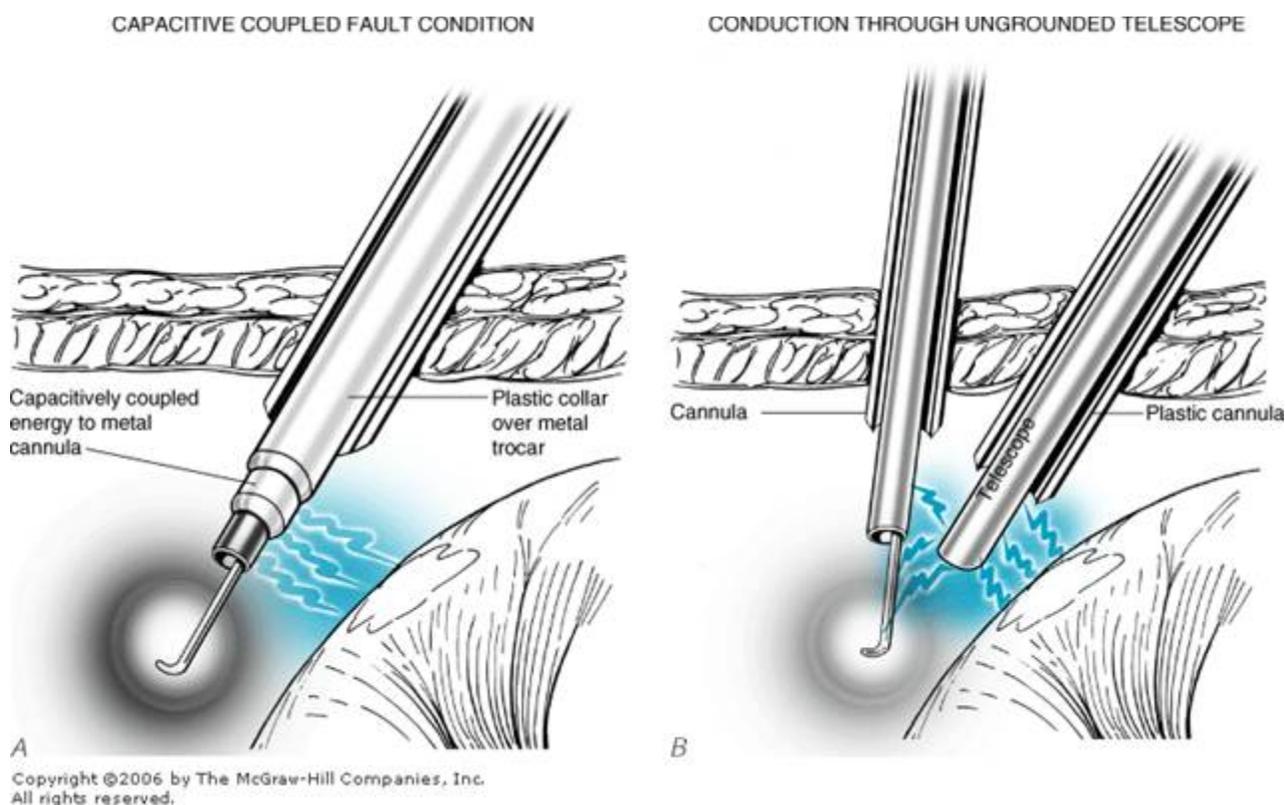

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

An example of bipolar coagulation devices. The flow of electrons passes from one electrode to the other and the intervening tissue is heated and desiccated.

In order to avoid thermal injury to adjacent structures, the laparoscopic field of view must include all uninsulated portions of the electrosurgical electrode. In addition, the integrity of the insulation must be maintained and assured. Capacitive coupling occurs when a plastic trocar insulates the abdominal wall from the current; in turn the current is bled off of a metal sleeve or

laparoscope into the viscera 52 (Fig. 13–13A). This may result in thermal necrosis and a delayed fecal fistula. Another potential mechanism for unrecognized visceral injury may occur with the direct coupling of current to the laparoscope and adjacent bowel 52 (FIG. 13B).

FIG. 13.

A. Capacitive coupling occurs as a result of high current density bleeding from a port sleeve or laparoscope into adjacent bowel. B. Direct coupling occurs when current is transmitted directly from the electrode to a metal instrument or laparoscope, and then into adjacent tissue.

(Reproduced with permission from Odell. 52)

Another method of delivering radiofrequency electrosurgery is argon beam coagulation. This is a type of monopolar electrosurgery in which a uniform field of electrons is distributed across a tissue surface by the use of a jet of argon gas. The argon gas jet distributes electrons more evenly across the surface than does spray electrofulguration. This technology has its greatest application for coagulation of diffusely bleeding surfaces such as the cut edge of liver or spleen. It is of less use in laparoscopic procedures because the increased intra-abdominal pressures created by the argon gas jet can increase the chances of a gas embolus. It is paramount to vent the ports and closely monitor insufflation pressure when using this source of energy within the context of laparoscopy.

With endoscopic endoluminal surgery, radiofrequency alternating current in the form of a monopolar circuit represents the mainstay for procedures such as snare polypectomy, sphincterotomy, lower esophageal sphincter ablation, and "hot" biopsy. 55,56 A grounding ("return") electrode is necessary for this form of energy. Bipolar electrocoagulation is used primarily for thermal hemostasis. The electrosurgical generator is activated by a foot pedal so the endoscopist may keep both hands free during the endoscopic procedure.

Gas, liquid, and solid-state lasers have been available for medical application since the mid-1960s. 57 The CO₂ laser (wavelength 10.6 μm) is most appropriately used for cutting and superficial ablation of tissues. It is most helpful in locations unreachable with a scalpel such as excision of vocal cord granulomas. The CO₂ laser beam must be delivered with a series of mirrors and is therefore somewhat cumbersome to use. The next most popular laser is the neodymium yttrium-aluminum-garnet (Nd:YAG) laser. Nd:YAG laser light is 1.064 μm (1064 nm) in wavelength. It is in the near-infrared portion of the spectrum, and, like CO₂ laser light, is invisible to the naked eye. A unique feature of the Nd:YAG laser is that 1064-nm light is poorly absorbed by most tissue pigments and therefore travels deep into tissue. 58 Deep tissue penetration provides deep tissue heating (FIG. 14). For this reason the Nd:YAG laser is capable of the greatest amount of tissue destruction with a single application. 57 Such capabilities make it the ideal laser for destruction of large fungating tumors of the rectosigmoid, tracheobronchial tree, or esophagus. A disadvantage is that the deep tissue heating may cause perforation of a hollow viscus.

When it is desirable to coagulate flat lesions in the cecum, a different laser should be chosen. The frequency-doubled Nd:YAG laser, also known as the KTP laser (potassium thionyl phosphate crystal is used to double the Nd:YAG frequency), provides 532-nm light. This is in the green portion of the spectrum, and at this wavelength, selective absorption by red pigments in tissue (such as hemangiomas and arteriovenous malformations) is optimal. The depth of tissue heating is intermediate, between those of the CO₂ and the Nd:YAG lasers. Coagulation (without vaporization) of superficial vascular lesions can be obtained without intestinal perforation. 58

In flexible gastrointestinal endoscopy, the CO₂ and Nd:YAG lasers have largely been replaced by heater probes and endoluminal stents. The heater probe is a metal ball that is heated to a temperature (60 to 100°C) that allows coagulation of bleeding lesions without perforation.

Photodynamic therapy (PDT) is a palliative treatment for obstructing cancers of the gastrointestinal tract. 59 Patients are given an intravenous dose of porfimer sodium, which is a photosensitizing agent that is taken up by malignant cells. Two days after administration, the drug is endoscopically activated using a laser. The activated porfimer sodium generates oxygen free radicals, which kills the tumor cells. The tumor is later endoscopically débrided. The use of this modality for definitive treatment of early cancers is in experimental phases and has yet

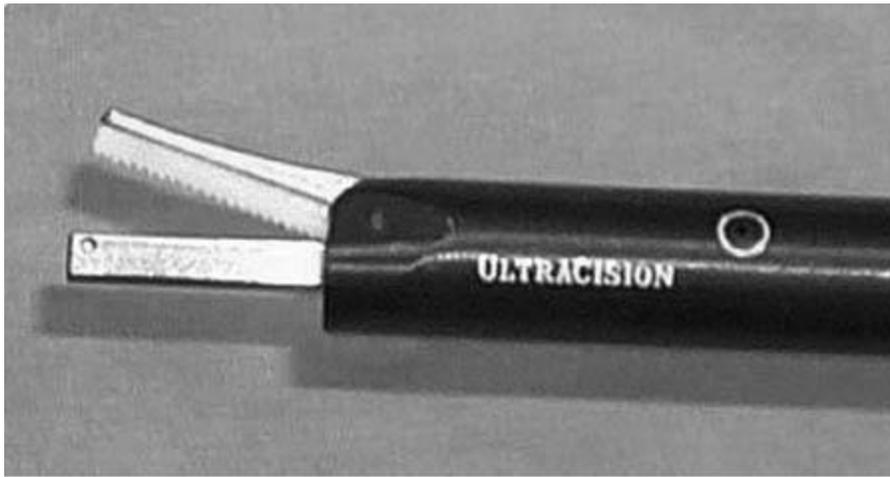

to become established.

A unique application of laser technology provides extremely rapid discharge ($<10^{-6}$ s) of large amounts of energy ($>10^3$ volts). These high-energy lasers, of which the pulsed dye laser has seen the most clinical use, allow the conversion of light energy to mechanical disruptive energy in the form of a shock wave. Such energy can be delivered through a quartz fiber, and with rapid repetitive discharges, can provide sufficient shock-wave energy to fragment kidney stones and gallstones. Shock waves also may be created with miniature electric spark-plug discharge systems known as electrohydraulic lithotriptors. These devices also are inserted through thin probes for endoscopic application. Lasers have the advantage of pigment selectivity, but electrohydraulic lithotriptors are more popular because they are substantially less expensive and are more compact.

Methods of producing shock waves or heat with ultrasonic energy are also of interest. Extracorporeal shockwave lithotripsy creates focused shock waves that intensify as the focal point of the discharge is approached. When the focal point is within the body, large amounts of energy are capable of fragmenting stones. Slightly different configurations of this energy can be used to provide focused internal heating of tissues. Potential applications of this technology include the ability to noninvasively produce sufficient internal heating to destroy tissue without an incision.

A third means of using ultrasonic energy is to create rapidly-oscillating instruments that are capable of heating tissue with friction; this technology represents a major step forward in energy technology. An example of its application is the laparoscopic coagulation shears (LCS) device (Harmonic Scalpel), which is capable of coagulating and dividing blood vessels by first occluding them and then providing sufficient heat to weld the blood vessel walls together and to divide the vessel (FIG. 15). This nonelectric method of coagulating and dividing tissue with a minimal amount of collateral damage has facilitated the performance of numerous endosurgical procedures. It is especially useful in the control of bleeding from medium-sized vessels that are too big to manage with monopolar electrocautery and require bipolar desiccation followed by cutting.

FIG. 15.

The Harmonic Scalpel has revolutionized hemostasis and dissection in minimally-invasive surgery and has significantly facilitated the performance of advanced laparoscopic and thoracoscopic procedures. Ultrasonic energy is used to create a rapidly oscillating "working arm" which serves to heat intervening tissue with friction, which fuses the cell membranes together.

Instrumentation

Hand instruments for MIS usually are duplications of conventional surgical instruments made longer, thinner, and smaller at the tip. It is important to remember that when grasping tissue with laparoscopic instruments, a greater force is applied over a smaller surface area, which increases the risk for perforation or injury. 63

Certain conventional instruments such as scissors are easy to reproduce with a diameter of 3 to 5 mm and a length of 20 to 45 cm, but other instruments, such as forceps and clamps, cannot provide remote access. Different configurations of graspers were developed to replace the various configurations of surgical forceps and clamps. Standard hand instruments are 5 mm in diameter and 30 cm in length, but smaller and shorter hand instruments are now available for pediatric surgery, for microlaparoscopic surgery, and for arthroscopic procedures. 63 A unique laparoscopic hand instrument is the monopolar electrical hook. This device is usually configured with a suction and irrigation apparatus to eliminate smoke and blood from the operative field. The monopolar hook allows tenting of tissue over a bare metal wire with subsequent coagulation and division of the tissue.

Robotic Assistance

The term "robot" defines a device that has been programmed to perform specific tasks in place of those usually performed by people. The equipment that has been introduced under the heading of robotic assistance would perhaps be more aptly termed computer-assisted surgery, as it is controlled entirely by the surgeon for the purpose of improving team performance. An example of computer-assisted surgery includes laparoscopic camera holders, which enable the surgeon to maneuver the laparoscope either with head movements or voice activation (FIG. 16). Randomized studies with such camera holders have demonstrated a reduction in operative time, steadier image, and a reduction in the number of required laparoscope cleanings. 64 This

device has the advantage of eliminating the need for a human camera holder, which serves to free valuable operating room personnel for other duties.

FIG. 16.

The surgeon controlled computer-assisted camera holder obviates the need for an additional assistant. This device may reduce operative times and provide a steadier image.

Another form of computer assistance involves the use of voice-activated system controls for the camera, light source, insufflators, and telephone. Studies have demonstrated a reduction in the time required to perform these tasks when compared to human intervention. 65

Room Setup and the Minimally-Invasive Suite

Nearly all MIS, whether using fluoroscopic, ultrasound, or optical imaging, incorporates a video monitor as a guide. Occasionally two images are necessary to adequately guide the operation, as in procedures such as endoscopic retrograde cholangiopancreatography (ERCP), laparoscopic common bile duct exploration, and laparoscopic ultrasonography. When two images are necessary, the images should be displayed on two adjacent video monitors or projected on a single screen with a picture-in-picture effect. The video monitor(s) should be set across the operating table from the surgeon. The patient should be interposed between the surgeon and the video monitor; ideally, the operative field also lies between the surgeon and the monitor. In pelviscopic surgery it is best to place the video monitor at the patient's feet, and in laparoscopic cholecystectomy, the monitor is placed at the 10 o'clock position (relative to

the patient) while the surgeon stands on the patient's left at the 4 o'clock position. The insufflating and patient-monitoring equipment ideally also is placed across the table from the surgeon, so that the insufflating pressure and the patient's vital signs and end-tidal CO₂ tension can be monitored.

The development of the minimally-invasive surgical suite has been a tremendous contribution to the field of laparoscopy in that it has facilitated the performance of advanced procedures and techniques (FIG. 17). By having the core equipment (monitors, insufflators, and imaging equipment) located within mobile, ceiling-mounted consoles, the surgery team is able to accommodate and make small adjustments rapidly and continuously throughout the procedure. The specifically designed minimally-invasive surgical suite serves to decrease equipment and cable disorganization, ease the movements of operative personnel around the room, improve ergonomics, and facilitate the use of advanced imaging equipment such laparoscopic ultrasound. 66 While having a minimally-invasive surgical suite available is very useful, it is not essential to successfully carry out advanced laparoscopic procedures.

FIG. 17.

An example of a typical minimally-invasive surgery suite. All core equipment is located on easily movable consoles. These operating rooms tend to be larger in size because of the need for multiple types of equipment.

Patient Positioning

Patients usually are placed in the supine position for laparoscopic surgery. When the operative field is the gastroesophageal junction or the left lobe of the liver, it is easiest to

operate from between the legs. The legs may be elevated in Allen stirrups or abducted on leg boards to achieve this position. When pelvic procedures are performed, it usually is necessary to place the legs in Allen stirrups to gain access to the perineum. A lateral decubitus position with the table flexed provides the best access to the retroperitoneum when performing nephrectomy or adrenalectomy. For laparoscopic splenectomy, a 45°-tilt of the patient provides excellent access to the lesser sac and the lateral peritoneal attachments to the spleen. For thoracoscopic surgery, the patient is placed in the lateral position with table flexion in order to open the intercostal spaces and the distance between the iliac crest and costal margin (FIG. 18).

When the patient's knees are to be bent for extended periods or the patient is going to be placed in a reverse Trendelenburg position for more than a few minutes, deep venous thrombosis prophylaxis should be used. Sequential compression of the lower extremities during prolonged (more than 90 min) laparoscopic procedures increases venous return and provides inhibition of thromboplastin activation.

Special Considerations

Pediatric Considerations

The advantages of MIS in children may be more significant than in the adult population. 67 MIS in the adolescent is little different from that in the adult, and standard instrumentation and trocar positions can usually be used. However, laparoscopy in the infant and young child requires specialized instrumentation. The instruments are shorter (15 to 20 cm), and many are 3 mm in diameter rather than 5 mm. 68 Because the abdomen of the child is much smaller than that of the adult, a 5-mm telescope provides sufficient illumination for most operations. The development of 5-mm clippers and bipolar devices has obviated the need for 10-mm trocars in pediatric laparoscopy. 68 Because the abdominal wall is much thinner in infants, a pneumoperitoneum pressure of 8 mm Hg can provide adequate exposure. Deep venous thrombosis is rare in children, and prophylaxis against thrombosis is probably unnecessary.

Pregnancy

Concerns about the safety of laparoscopic cholecystectomy or appendectomy in the pregnant patient have been eliminated. The pH of the fetus follows the pH of the mother linearly, and therefore fetal acidosis may be prevented by avoiding a respiratory acidosis in the mother. 69 A second concern was that of increased intra-abdominal pressure, but it has been proved that midpregnancy uterine contractions provide a much greater pressure in utero than a pneumoperitoneum. Experience in well over 100 cases of laparoscopic cholecystectomy in pregnancy have been reported with uniformly good results. 70 The operation should be performed during the second trimester if possible. Protection of the fetus against intraoperative x-rays is imperative. Some believe it advisable to track fetal pulse rates with a transvaginal ultrasound probe. Access to the abdomen in the pregnant patient should take into consideration the height of the uterine fundus, which reaches the umbilicus at 20 weeks. In order not to damage the uterus or its blood supply, most surgeons feel that the open (Hasson) approach

should be used in favor of direct puncture laparoscopy. The patient should be positioned slightly on the left side in order to avoid compression of the vena cava by the uterus. Because pregnancy poses a risk for thromboembolism, sequential compression devices are essential for all procedures.

Cancer

MIS techniques have been used for many decades to provide palliation for the patient with an obstructive cancer. Laser treatment, intracavitary radiation, stenting, and dilation are outpatient techniques that can be used to reestablish the continuity of an obstructed esophagus, bile duct, ureter, or airway. MIS techniques also have been used in the staging of cancer.

Mediastinoscopy is still used occasionally before thoracotomy to assess the status of the mediastinal lymph nodes. Laparoscopy also is used to assess the liver in patients being evaluated for pancreatic, gastric, or hepatic resection. New technology and greater surgical skills allow for accurate minimally-invasive staging of cancer. ⁷¹ Occasionally it is appropriate to perform palliative measures (e.g., laparoscopic gastrojejunostomy to bypass a pancreatic cancer) at the time of diagnostic laparoscopy if diagnostic findings preclude attempts at curative resection. ⁷²

The most controversial role of MIS techniques is that of providing potentially curative surgery to the patient with cancer. It is possible to perform laparoscopy-assisted colectomy, gastrectomy, pancreatectomy, and hepatectomy in patients with intra-abdominal malignant disease, as well as thoracoscopic esophagectomy and pneumonectomy in patients with intrathoracic malignant disease. There are not yet enough data to indicate whether minimally-invasive surgical techniques provide survival rates or disease-free intervals comparable to those of conventional surgical techniques. It has been proven that in laparoscopy-assisted colectomy and gastrectomy a number of lymph nodes equal to that of an open procedure can be removed without any compromise of resection margins. A second concern centers on excessive tumor manipulation and the possibility that cancer cells would be shed during the dissection. Alarming reports of trocar site implantation with viable cancer cells have appeared in the literature.

Considerations in the Elderly and Infirm

Laparoscopic cholecystectomy has made possible the removal of a symptomatic gallbladder in many patients previously thought to be too elderly or too ill to undergo a laparotomy. Older patients are more likely to require conversion to celiotomy because of disease chronicity. ⁷³

Operations on these patients require close monitoring of anesthesia. The intraoperative management of these patients may be more difficult with laparoscopic access than with open access. The advantage of MIS lies in what happens after the operation. Much of the morbidity of surgery in the elderly is a result of impaired mobility. ⁷³ In addition, pulmonary complications, urinary tract sepsis, deep venous thrombosis, pulmonary embolism, congestive heart failure, and myocardial infarction often are the result of improper fluid management and

decreased mobility. By allowing rapid and early mobilization, laparoscopic surgery has made possible the safe performance of procedures in the elderly and infirm.

Cirrhosis and Portal Hypertension

Patients with hepatic insufficiency pose a significant challenge for any type of surgical intervention. 74 The ultimate surgical outcome in this population relates directly to the degree of underlying hepatic dysfunction. 75 Often, this group of patients has minimal reserve, and the stress of an operation will trigger complete hepatic failure or hepatorenal syndrome. These patients are at risk for major hemorrhage at all levels, including trocar insertion, operative dissection in a field of dilated veins, and secondary to an underlying coagulopathy. 75 Additionally, ascitic leak from a port site may occur, leading to bacterial peritonitis. Therefore a watertight port site closure should be carried out in all patients.

It is essential that the surgeon be aware of the Child class of severity of cirrhosis of the patient prior to intervening so that appropriate preoperative optimization can be completed. For example, if a patient has an eroding umbilical hernia and ascites, a preoperative paracentesis or transjugular intrahepatic portosystemic shunt (TIPS) procedure in conjunction with aggressive diuresis may be considered. Because these patients commonly are intravascularly depleted, insufflation pressures should be reduced in order to prevent a decrease in cardiac output and minimal amounts of low-salt intravenous fluids should be given.

Economics of Minimally-Invasive Surgery

Minimally-invasive surgical procedures reduce the costs of surgery most when length of hospital stay can be shortened. For example, shorter hospital stays can be demonstrated in laparoscopic cholecystectomy, fundoplication, splenectomy, and adrenalectomy. Procedures such as inguinal herniorrhaphy that are already performed as outpatient procedures are less likely to provide cost advantage. Procedures that still require a 4- to 7-day hospitalization, such as laparoscopy-assisted colectomy, are even less likely to deliver a lower bottom line than their open-surgery counterparts. Nonetheless, with responsible use of disposable instrumentation and a commitment to the most effective use of the inpatient setting, most laparoscopic procedures can be made less expensive than their conventional equivalents.

Robotic Surgery

With the development of advanced laparoscopic procedures, the limitations of minimally-invasive surgical techniques and instrumentation have become accentuated. For example, the mobility and positioning of a laparoscopic instrument is limited by the placement of the port site on the abdominal wall. This may prevent the surgeon from obtaining the desired instrument angle and position to perform a complex maneuver. In addition, the fine motor movements required to perform complex minimally-invasive surgical procedures may be difficult to perform with standard laparoscopic instruments and imaging. Computer-enhanced ("robotic") surgery was developed with the intent of circumventing the limitations of laparoscopy and

thoracoscopy, and to make minimally-invasive surgical techniques accessible to those without a laparoscopic background. 76 In addition, remote site surgery (telesurgery), in which the surgeon is a great distance from the patient (e.g., combat or space), has potential future applications. This was recently exemplified when a team of surgeons located in New York performed a cholecystectomy on a patient located in France. 77

These devices offer a three-dimensional view with hand- and wrist-controlled instruments that possess multiple degrees of freedom, thereby facilitating surgery with a one-to-one movement ratio that mimics open surgery (FIG. 19). Additionally, computer-enhanced surgery also offers tremor control. The surgeon is physically separated from the operating table and the working arms of the device are placed over the patient (FIG. 20). An assistant remains at the bedside and changes the instruments as needed.

Room set-up and position of surgeon and assistant for robotic surgery.

Because this equipment is very costly, a primary limitation to its uniform acceptance has been attempting to achieve increased value in the form of improved clinical outcomes. There have been two randomized controlled trials that compared robotic and conventional laparoscopic approaches to Nissen fundoplication. 78,79 While there was a reduction in operative time, there was no difference in ultimate outcome. Similar results have been achieved for laparoscopic cholecystectomy. 80 Finally, it may be too early in its development (due to bulky equipment, difficulty in accessing patients, and limited instrumentation) for widespread adoption of this technology.

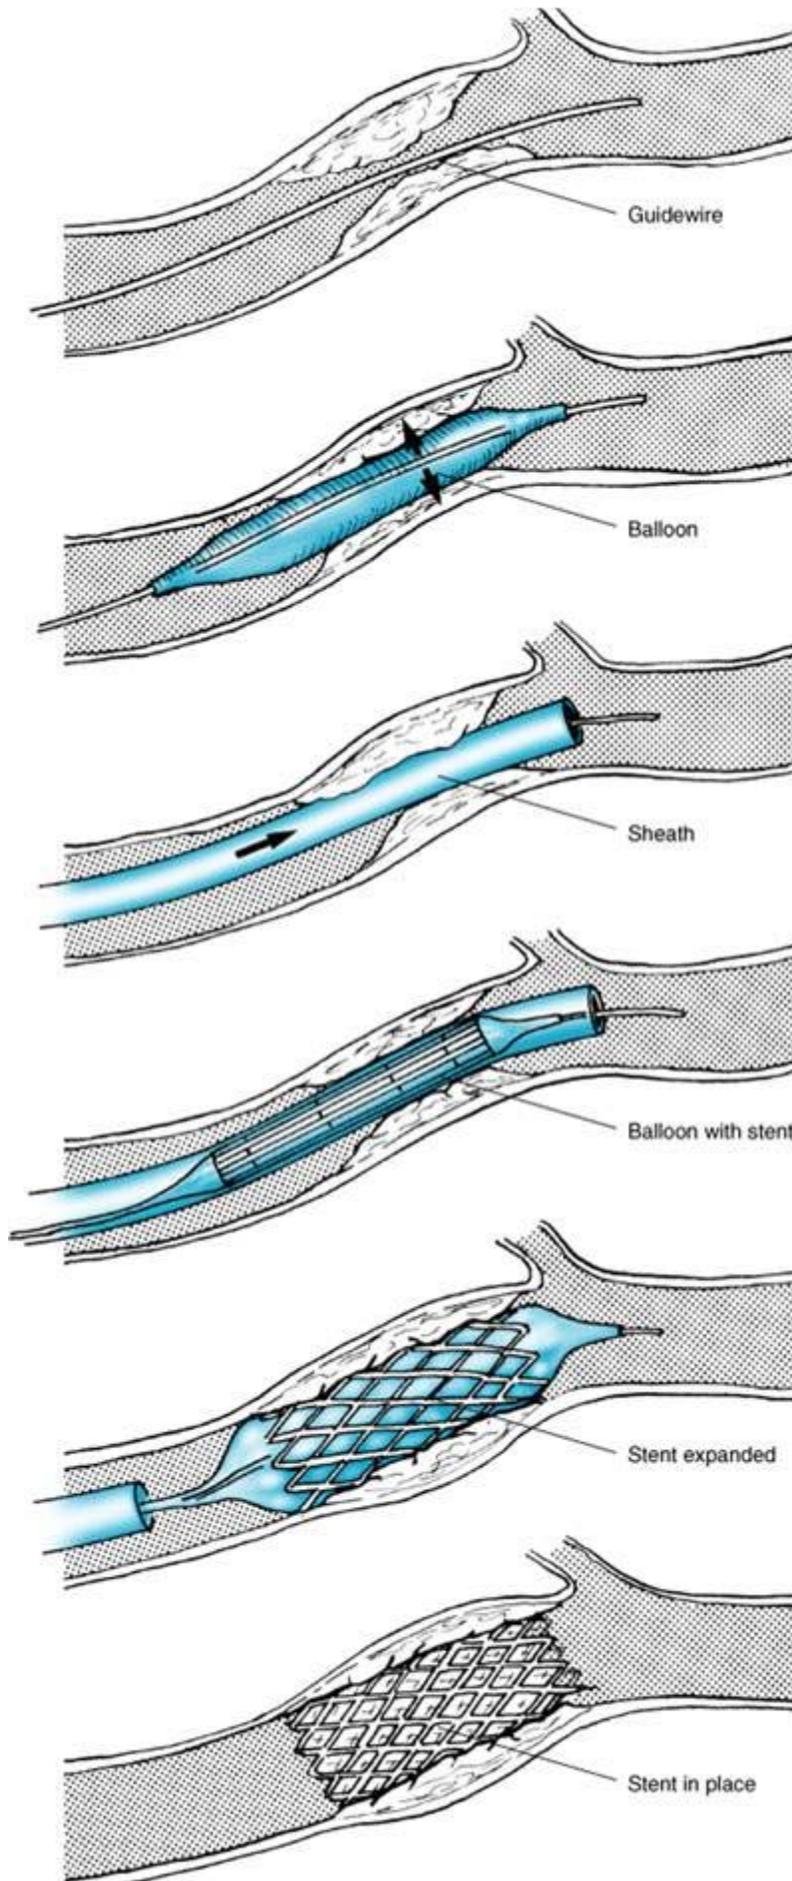

Endoluminal Surgery

The fields of vascular surgery, interventional radiology, neuroradiology, gastroenterology, general surgery, pulmonology, and urology all encounter clinical scenarios that require the urgent restoration of luminal patency of a "biologic cylinder." 81 Based on this need, fundamental techniques have been pioneered that are applicable to all specialties and virtually every organ system. As a result, all minimally-invasive surgical procedures, from coronary artery angioplasty to palliation of pancreatic malignancy, involve the use of an endoluminal balloon, dilator, prostheses, biopsy forceps, chemical agent, or thermal technique 81 (Table 13-2). Endoluminal balloon dilators may be inserted through an endoscope, or they may be

fluoroscopically guided. Balloon dilators all have low compliance—that is, the balloons do not stretch as the pressure within the balloon is increased. The high pressures achievable in the balloon create radial expansion of the narrowed vessel or orifice, usually disrupting the atherosclerotic plaque, the fibrotic stricture, or the muscular band (e.g., esophageal achalasia).
82

Once the dilation has been attained, it is frequently beneficial to hold the lumen open with a stent. 83 Stenting is particularly valuable in treating malignant lesions and in endovascular procedures (FIG. 21). Stenting usually is not applicable for long-term management of benign gastrointestinal strictures except in patients with limited life expectancy 83–85 (FIG. 22A and B).

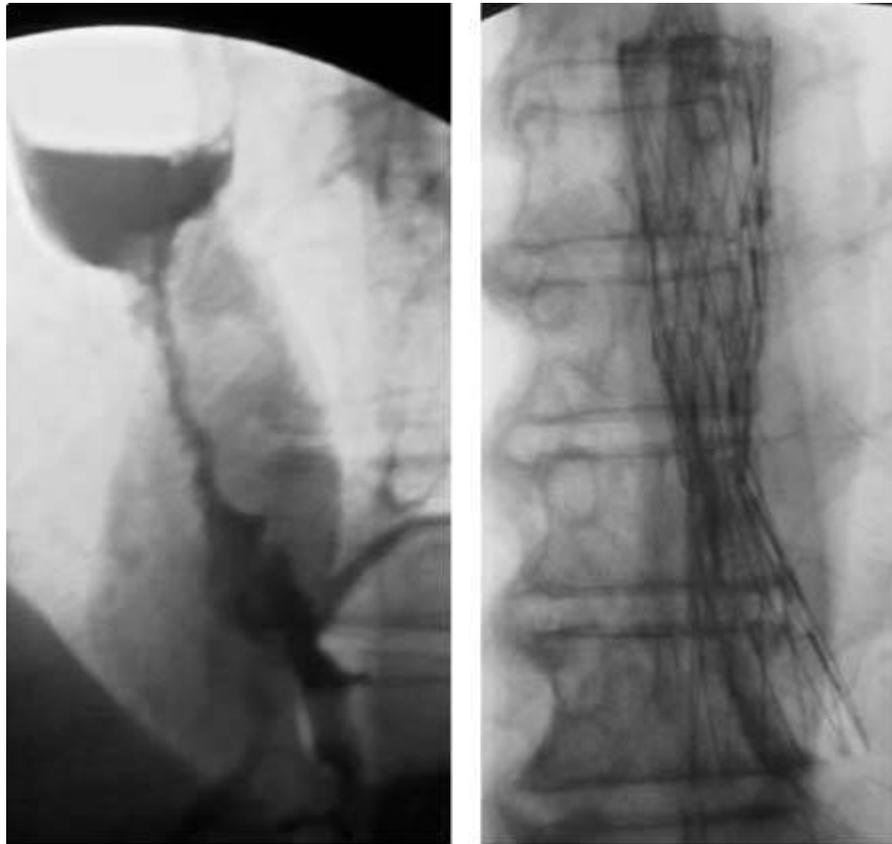

FIG. 21.

This is an esophagram in a patient with severe dysphagia secondary to advanced esophageal cancer (A) before and (B) after placement of a covered self-expanding metal stent.

A variety of stents are available that are divided into two basic categories, plastic stents and expandable metal stents 84 (FIG. 23). Plastic stents came first and are used widely as endoprotheses for temporary bypass of obstructions in the biliary or urinary systems. Metal stents generally are delivered over a balloon and expanded with the balloon to the desired size. These metal stents usually are made of titanium or nitinol. Although great progress has been

made with expandable metal stents, two problems remain: propensity for tissue ingrowth through the interstices of the stent and stent migration. Ingrowth may be an advantage in preventing stent migration, but such tissue ingrowth may occlude the lumen and cause obstruction anew. This is a particular problem when stents are used for palliation of gastrointestinal malignant growth, and may be a problem for the long-term use of stents in vascular disease. Filling the interstices with Silastic or other materials may prevent tumor ingrowth, but also makes stent migration more likely. In an effort to minimize stent migration, stents have been incorporated with hooks and barbs.

FIG. 23.

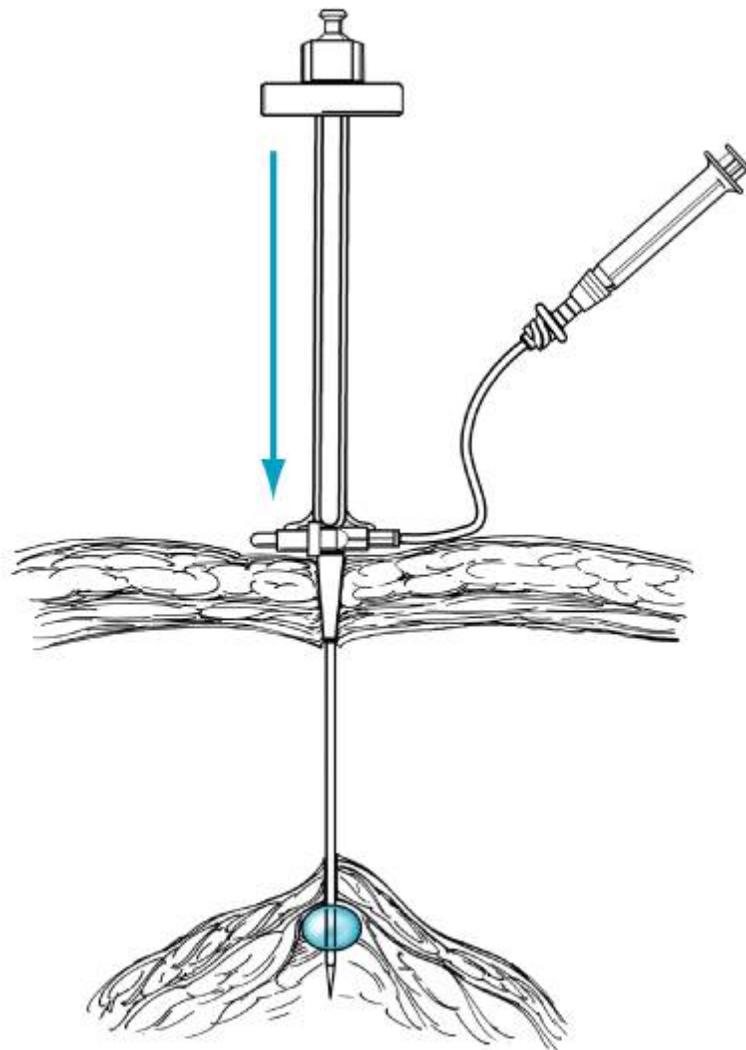

Covered self-expanding metal stents. These devices can be placed fluoroscopically or endoscopically.

Most recently, anticoagulant-eluting coronary artery stents have been placed in specialized centers. 86 This exciting technological advance may dramatically increase the long-term patency rates of stents placed in patients with coronary artery disease and peripheral atherosclerosis.

Intraluminal Surgery

The successful application of minimally-invasive surgical techniques to the lumen of the gastrointestinal tract has hinged upon the development of a port that maintains access to the gastrointestinal lumen while preventing intraperitoneal leakage of intestinal contents and facilitating adequate insufflation 87 (FIG. 24). Procedures that are gaining acceptance include resection of benign and early malignant gastric tumors, transanal resection of polyps (transanal endoscopic microsurgery), pancreatic cyst gastrostomy, and biliary sphincterotomy.

FIG. 24.

Copyright ©2006 by The McGraw-Hill Companies, Inc.

An illustration of a radially expanding trocar used for intraluminal surgery. The stomach is insufflated using a nasogastric tube, and the anterior gastric wall is pierced with the trocar under laparoscopic guidance. A balloon is inflated and used to draw the stomach up to the anterior abdominal wall. [Reproduced with permission from Eubanks WS, Swanstrom LL, Soper NJ (eds): *Mastery of Endoscopic and Laparoscopic Surgery*. Philadelphia: Lippincott

Williams & Wilkins, 1999, p 215.]

The location of the lesion within the gastrointestinal tract is of utmost importance when considering an intraluminal approach. For example, a leiomyoma that is located on the anterior gastric wall may not be amenable to intraluminal resection because the working ports must also penetrate the anterior surface of the stomach. Preoperative endoscopy and endoscopic ultrasound should be routinely employed in order to determine resectability. 87

Education and Skill Acquisition

Surgeons in Training and Skill Acquisition

Surgeons in training acquire their skills in minimally-invasive techniques through a series of operative experiences of graded complexity. This training occurs on patients. With the recent constraints placed on resident work hours, providing adequate minimally-invasive training to future surgeons within a relatively brief time frame has become of paramount importance.

Laparoscopic surgery demands a unique set of skills that require the surgeon to function at the limit of his or her psychomotor abilities. The introduction of virtual reality training devices presents a unique opportunity to improve and enhance experiential learning in endoscopy and laparoscopy for all surgeons. This technology has the advantage of enabling objective measurement of psychomotor skills, which can be used to determine progress in skill acquisition, and ultimately technical competency. 88,89 This technology will most likely be used to create benchmarks for the performance of future minimally-invasive techniques. In addition, virtual reality training enables the surgeon to build an experience base prior to venturing into the operating room. 90 Be that as it may, no studies have demonstrated that simulator training improves overall patient outcome.

Some hospitals and training programs have established virtual reality and laparoscopic training centers that are accessible at all hours for surgeons' use.

Telementoring

In response to the Institute of Medicine's call for the development of unique technologic solutions to deliver health care to rural and underserved areas, surgeons are beginning to explore the feasibility of telementoring. Teleconsultation or telementoring is two-way audio and visual communication between two geographically separated providers. This communication can take place in the office setting, or directly in the operating room when complex scenarios are encountered. Although local communication channels may limit its performance in rural areas, the technology is available and currently being employed (FIG. 25).

FIG. 25.

Teleconsultation and telementoring are carried out between two providers who are geographically separated. The console has a video camera, microphone, and flat screen display which can be positioned at the operating room table or in the clinic.

Innovation and Introduction of New Procedures

The revolution in minimally-invasive general surgery, which occurred in 1990, created ethical challenges for the profession. The problem was this: If competence is gained from experience, how was the surgeon to climb the competence curve (otherwise known as the learning curve) without injuring patients? If it was indeed impossible to achieve competence without making mistakes along the way, how should one effectively communicate this to patients such that they understand the weight of their decisions? Even more fundamentally important is determining the path that should be followed before one recruits the first patient for a new procedure.

Although procedure development is fundamentally different than drug development (i.e., there is great individual variation in the performance of procedures, but no difference between one tablet and the next), adherence to a process similar to that used to develop a new drug is a reasonable path for a surgical innovator. At the outset the surgeon must identify the problem that is not solved with current surgical procedures. For example, while the removal of a gallbladder through a Kocher incision is certainly effective, it creates a great deal of disability,

pain, and scarification. As a result of those issues, many patients with very symptomatic biliary colic delayed operation until life-threatening complications occurred. Clearly there was a need for developing a less invasive approach (FIG. 26).

Once the opportunity has been established, the next step involves a search through other disciplines for technologies and techniques that might be applied. Again, this is analogous to the drug industry, where secondary drug indications have often turned out to be more therapeutically important than the primary indication for drug development. The third step is in vivo studies in the most appropriate animal model. Certainly these types of studies are controversial because of the resistance to animal experimentation, and yet without such studies many humans would be injured or killed during the developmental phase of medical drugs, devices, and techniques. These steps are often called the preclinical phase of procedure development.

The decision as to when such procedures are ready to come out of the lab is a difficult one. Put simply, the procedure should be reproducible, provide the desired effect, and not have serious side effects. Once these three criteria are reached, the time for human application has arrived. Before the surgeon discusses the new procedure with his patient, it is important to achieve full institutional support. Clearly, involvement of the medical board, the chief of the medical staff, and the institutional review board are essential before commencing on a new procedure. These bodies are responsible for the use of safe, high quality medical practices within their institution, and they will demand that great caution and all possible safeguards are in place before proceeding.

The dialogue with the patient who is to be first must be thorough, brutally honest, and well documented. The psychology that allows a patient to decide to be first is quite interesting, and may under certain circumstances require psychiatric evaluation. Certainly if a dying cancer patient has a chance with a new drug, this makes sense. Similarly, if the standard surgical procedure has a high attendant morbidity and the new procedure offers a substantially better outcome, the decision to be first is understandable. On the other hand, when the benefits of the new approach are small and the risks are largely unknown, a more complete psychological profile may be necessary before proceeding.

For new surgical procedures, it is generally wise to assemble the best possible operative team, including a surgeon experienced with the old technique, and assistants who have participated in the earlier animal work. This initial team of experienced physicians and nurses should remain together until full competence with the procedure is attained. This may take 10 procedures, or it may take 50 procedures. The team will know that it has achieved competence when the majority of procedures take the same length of time, and the team is relaxed and sure of the flow of the operation. This will complete phase I of the procedure development.

In phase II, the efficacy of the procedure is tested in a nonrandomized fashion. Ideally, the outcome of new techniques must be as good or better than the procedure that is being replaced.

This phase should occur at several medical centers to prove that good outcomes are achievable outside of the pioneering institution. These same requirements may be applied to the introduction of new technology into the operating room. The value equation requires that the additional measurable procedure quality exceeds the additional measurable cost to the patient or health care system. In phase III, a randomized trial pits the new procedure against the old.

Once the competence curve has been climbed, it is appropriate for the team to engage in the education of others. During the ascension of the competence curve, other learners in the institution (i.e., surgical residents) may not have the opportunity to participate in the first case series. While this may be difficult for them to swallow, the best interest of the patient must be put before the education of the resident.

The second stage of learning occurs when the new procedure has proven its value and a handful of experts exist, but the majority of surgeons have not been trained to perform the new procedure. In this setting, it is relatively unethical for surgeons to forge ahead with a new procedure in humans as if they had spent the same amount of time in intensive study that the first team did. The fact that one or several surgical teams were able to perform an operation does not ensure that all others with the same medical degrees can perform the operation with equal skill. It behooves the learners to contact the experts and request their assistance to ensure an optimal outcome at the new center. While it is important that the learners contact the experts, it is equally important that the experts be willing to share their experience with their fellow professionals. As well, the experts should provide feedback to the learners as to whether they feel the learners are equipped to forge ahead on their own. If not, further observation and assistance from the experts are required. While this approach may sound obvious, it is fraught with difficulties. In many situations ego, competitiveness, and monetary concerns have short-circuited this process and led to poor patient outcomes. To a large extent, MIS has recovered from the black eye that it received early in development, when inadequately trained surgeons caused an excessive number of significant complications.

If innovative procedures and technologies are to be developed and applied without the mistakes of the past, surgeons must be honest when they answer these questions: Is this procedure safe? Would I consider undergoing this procedure if I developed a surgical indication? Is the procedure as good or better than the procedure it is replacing? Do I have the skills to apply this procedure safely and with equivalent results to the more experienced surgeon? If the answer to any of these questions is "no," or "I don't know," there is a professional obligation to seek another procedure or outside assistance before subjecting a patient to the new procedure.

LAPAROSCOPIC MANAGEMENT OF BILIARY STONE DISEASE

The management of biliary stones diseases has dramatically changed with the advent of the

Laparoscopic Cholecystectomy. It has now become a true outpatient laparoscopic procedure with negligible morbidity.

In the past few years, our surgical team has designed and revised numerous management protocols for various clinical settings effectively achieving impressive improvements in our surgical performance for the treatment of biliary stone diseases. This chapter will describe these management protocols and our latest technical updates.

The original Laparoscopic Cholecystectomy technique has undergone a vast maturation process over the past decade. Various technical steps has been modified and adapted to improve surgical performance and clinical outcome. As a result, nowadays, most surgeons in the Western World can safely perform a Laparoscopic Cholecystectomy with a minimal conversion rate.

ROUTINE INTRA-OPERATIVE CHOLANGIOGRAPHY

Routine operative cholangiography is recommended by most laparoscopic authors in the United States. However, recent reports demonstrate it does not significantly decrease the rate of common bile duct injury in cases where the anatomy is well-identified. Our recommendation is that routine intraoperative cholangiography should be performed by inexperienced laparoscopic surgeons and in cases where the anatomy is not well-defined.

IDENTIFYING PATIENTS WITH CHOLEDOCHOLITHIASIS

In order to achieve the level of Maximum Surgical Performance with this procedure, patients at high risk of presenting with Common Bile Duct Stones need to be identified pre-operatively. The simplest methods to initially identify these patients are:

- 1) History and Physical Examination,
- 2) Liver Function Studies,
- 3) Sonographic Findings.

Patients with a recent history of gallstone pancreatitis, jaundice, or presenting with such symptoms are at a high risk of having common bile duct pathology; the same is valid for patients with altered liver function studies. The most accurate studies are the Serum Transaminases (SGOT, SGPT). Elevations of these enzymes over 20% of their normal values are significant. But patients with severe, acute cholecystitis can occasionally generate such elevations. Also, extreme elevations of these two enzymes could represent hepatocytes necrosis as seen in hepatitis. The bilirubin level may also be elevated in certain patients with acute cholecystitis, but elevations above 2.5 or 3.0 mg/dl could identify a patient with choledocholithiasis. Finally, we find the enzymes LDH and GGTP to have no real specific value in this clinical setting.

It is interesting that in spite of our intensive efforts to identify Common Bile Duct pathology preoperatively, missed Common Bile Duct Stones are found in 1.92% of all patients.

Of these patients 76% will require additional surgical intervention (ERCP).

ROUTINE INTRA-OPERATIVE CHOLANGIOGRAPHY

This technology is being used with increasing frequency in our surgical service to identify patients with choledocholithiasis. A GE Magnetic Resonance machine was used for all studies. To date the specificity and accuracy of these studies in our services is 98.2% for common bile duct stones over 1 mm in size.

ROUTINE INTRA-OPERATIVE CHOLANGIO-SONOGRAPHY

Intra-operative cholangio-sonography is being used in many medical centers to rule out common bile duct stone. Although this modality was used on numerous occasions, we found it too time consuming to be used on a routine basis.

ANTERIOR OR SUBTOTAL LAPAROSCOPIC CHOLECYSTECTOMY

In our never-ending quest of increasing surgical performance, we meticulously analyzed when and why conversion occurred during the performance of a laparoscopic cholecystectomy. Most of them occurred in patients with acute, severe and gangrenous cholecystitis. Thus, we introduced the anterior-subtotal laparoscopic cholecystectomy to be used **ONLY** in these clinical settings when a standard laparoscopic Cholecystectomy could not be completed safely. (Refer to Technique and Surgical Performance later in chapter).

THE DECREASING IMPACT OF THE LAPAROSCOPIC CBD EXPLORATION

Significant problems have impaired the growth of Laparoscopic Common Bile Duct exploration. This technique is simply not easy to perform and good results are only achieved by experienced operators. In addition, this procedure is hardware intensive and the choledochoscopes are not as reliable as they are touted to be. For these reasons it quickly become obvious to us, the indications for this procedure were becoming more and more limited.

Our surgical team promotes the use of Endoscopic Retrograde Cholangiography and Papillotomy. When not feasible, a laparoscopic transcystic or via anterior choledochotomy CBDE is performed. It should be mentioned that some critics claim there are no studies available on the long term effects of endoscopic papillotomies and that it represents a significant additional cost. Although, this statement is correct, there are also no reports of long term adverse effects of such procedures.

CLASSIFYING THE BILIARY STONE PATIENT

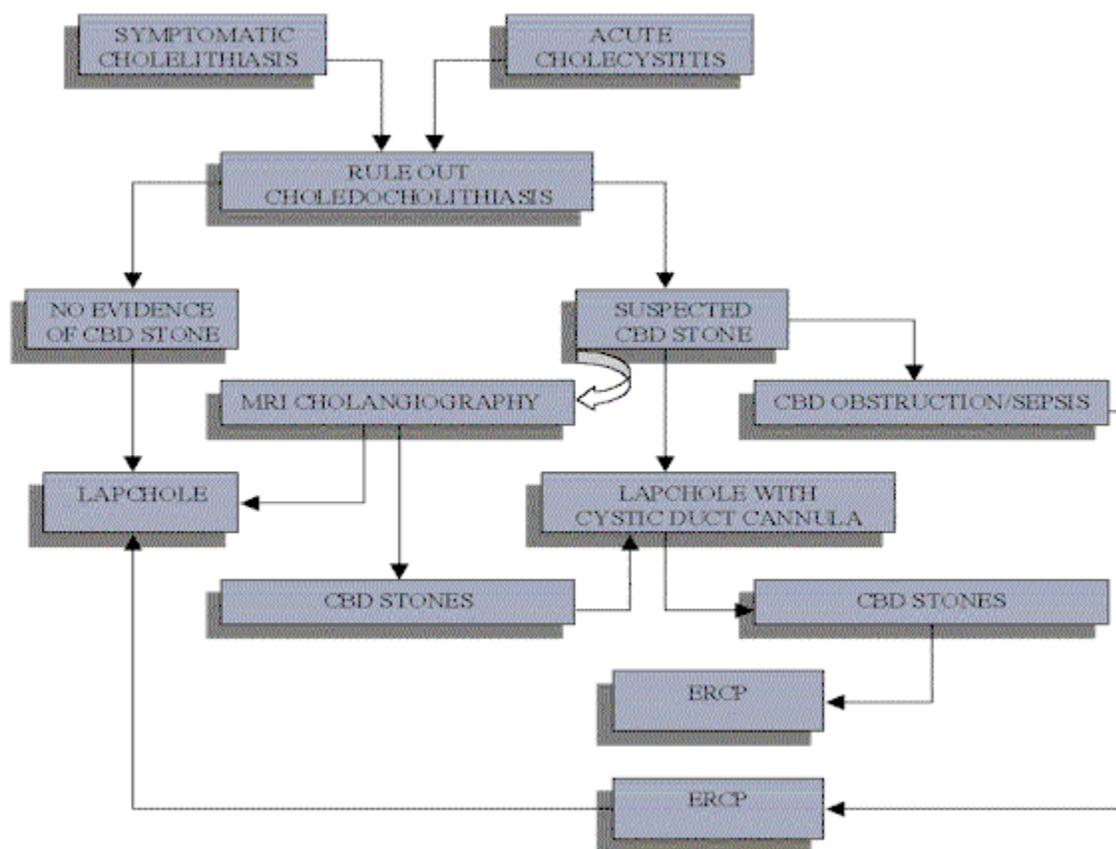

Asymptomatic Cholelithiasis	Incidental Finding on Sonogram
Acute Cholecystitis	Cholelithiasis on Sonogram, clinical Cholecystitis diagnosis or Positive Pipida Scan
Symptomatic Cholelithiasis	Positive Sonogram, normal Liver Function Tests
Cholelithiasis with Suspected Choledocholithiasis	Abnormal Liver Function Tests (Serum Transaminases elevation or Bilirubin >3.0, gallstone pancreatitis)
Cholelithiasis with Choledocholithiasis	CBD Stone on Sonogram, MR Cholangiography or Jaundice
Cholelithiasis with Resolving Gallstone Pancreatitis	Pancreatitis on Sonogram, CT or MER Cholangiography or clinically, Documented High Serum Amylase and Lipase - WITH - Decreasing Serum Pancreatic Enzymes after initial attack

IDENTIFYING PATIENTS WITH CHOLEDOCHOLITHIASIS

MANAGEMENT PROTOCOLS FOR UNCOMPLICATED BILIARY STONE DISEASES	PROPOSED MANAGEMENT
Asymptomatic Cholelithiasis	No Surgical Intervention
Asymptomatic Cholelithiasis in Diabetic Patients	No Surgical Intervention
Symptomatic Cholelithiasis or Acute Cholecystitis	LapChole
Symptomatic Cholelithiasis with Suspected Choledocholithiasis	LapChole with Insertion of Cystic Duct Cannula with Cholangiography, if Choledocholithiasis, postop ERCP
Symptomatic Cholelithiasis with Choledocholithiasis	LapChole with Insertion of Cystic Duct Cannula with Cholangiography, if Choledocholithiasis, postop ERCP
Cholelithiasis with Resolving Pancreatitis	LapChole with Insertion of Cystic Duct Cannula with Cholangiography, if Choledocholithiasis, postop ERCP

Cholelithiasis with Unresolved Pancreatitis	After acute phase subsides, MRI Cholangiography or ERC, if Choledocholithiasis ERCP followed by LapChole
Asymptomatic Gallbladder Polyps	No Surgical Intervention
Symptomatic Gallbladder Polyps	LapChole
Severe, Gangrenous Cholecystitis with Subhepatic Phlegmon	LapChole, if not safely feasible, Anterior-subtotal LapChole
Post Cholecystectomy (Lap or open) Suspected Choledocholithiasis	MR Cholangiogram or ERC
Post Cholecystectomy (Lap or open) Choledocholithiasis	ERCP, if failure Laparoscopic Common Bile Duct Exploration.

OPERATING ROOM SET-UP

TROCARS PLACEMENT

Trocar	Type	Location
1	5 mm Trocar	<u>RUQ Lateral</u> - 4 cm below costal margin
2	5 mm Trocar	<u>RUQ Medial</u> - 4 cm below costal margin
3	5 mm Trocar	<u>Sub-umbilical</u>
4	Universal Trocar 5/10 or 5/11	<u>Epigastrium</u>

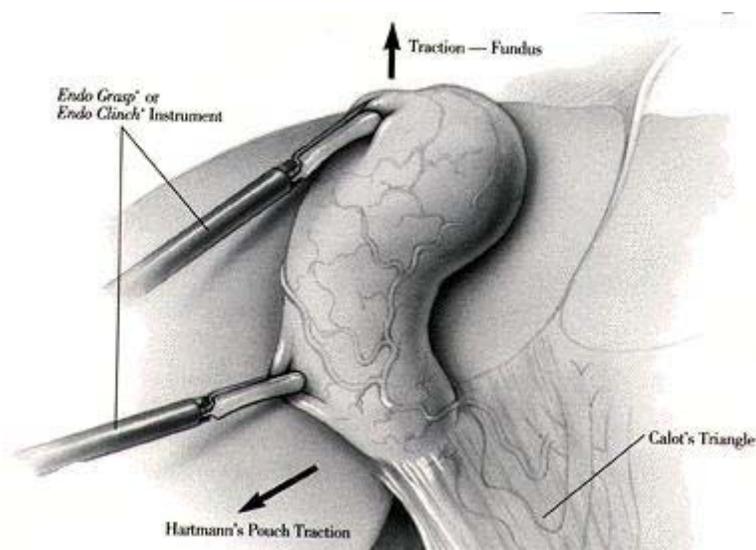

STANDARD LAPAROSCOPIC CHOLECYSTECTOMY

The pneumoperitoneum is obtained in the usual fashion. The trocars are inserted as indicated.

STEP 1: EXPOSING THE CYSTIC DUCT AND ARTERY

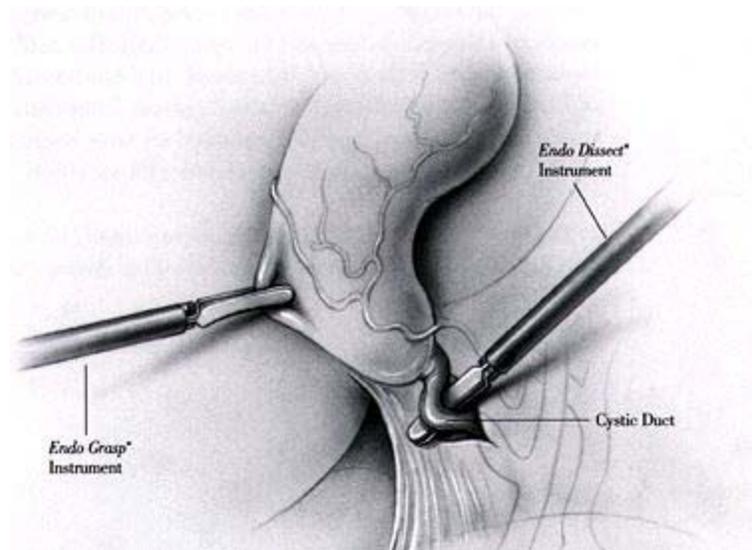

The stationary grasper [1: lateral position] is utilized to grasp the tip of the gallbladder and push it over the anterior edge of the liver by progressive traction. Hartmann's pouch is pulled upward. This exposes the cystic duct and artery as well as the common bile duct. It is important to constantly maintain this traction. In most cases, the scrub nurse or assistant hold this retractor. In difficult, longer cases, the handle of the grasper is clamped onto the skin of the abdomen or onto the protective field. The patient is now positioned head down.

CAUTION: It is not always possible to push the tip of the gallbladder (Re: cirrhotic patients) over the anterior hepatic edge. In these cases, gently push its tip against the liver, being very meticulous not to penetrate the parenchyma of the liver.

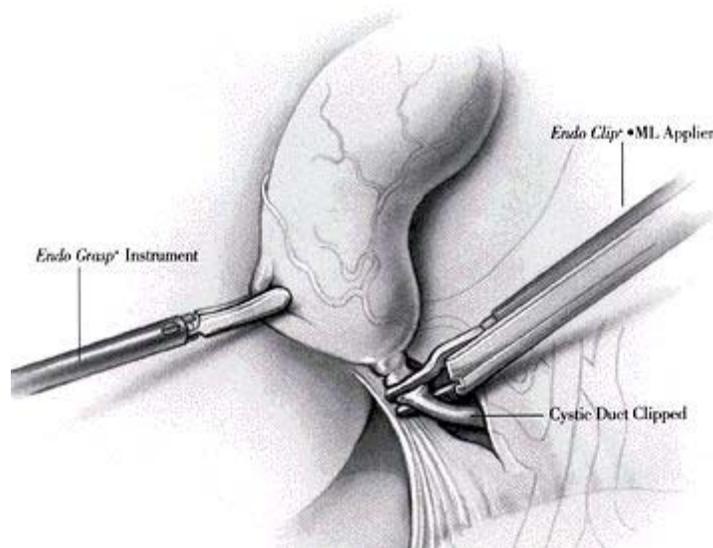

STEP 2: DISSECTING THE CYSTIC DUCT AND ARTERY

Once the field is exposed, Hartmann's pouch is grasped with the lateral working grasper and pulled laterally, further exposing Calot's triangle. The operator will then pass a dissecting grasper through the subxyphoid trocar and begin to identify the cystic duct. In acute cholecystitis, edematous layers of tissue will have to be stripped downward to expose the cystic duct.

The subxyphoid Dolphin Nose Grasper instrument is passed behind the cystic duct or actually between the cystic duct and the cystic artery. In most cases, the duct is anterior to the artery.

CAUTION : Hartmann's pouch should always be identified and visualized. The dissection of Calot's triangle can be done safely starting from the pouch and moving toward the cystic duct. This is particularly important in acute cases, when anatomical landmarks are difficult to find. It is essential to visualize Calot's triangle, which includes the cystic artery, cystic duct and the common bile duct. If visualization of this area becomes difficult, always check the tension on the stationary grasper and the intra-abdominal pressure.

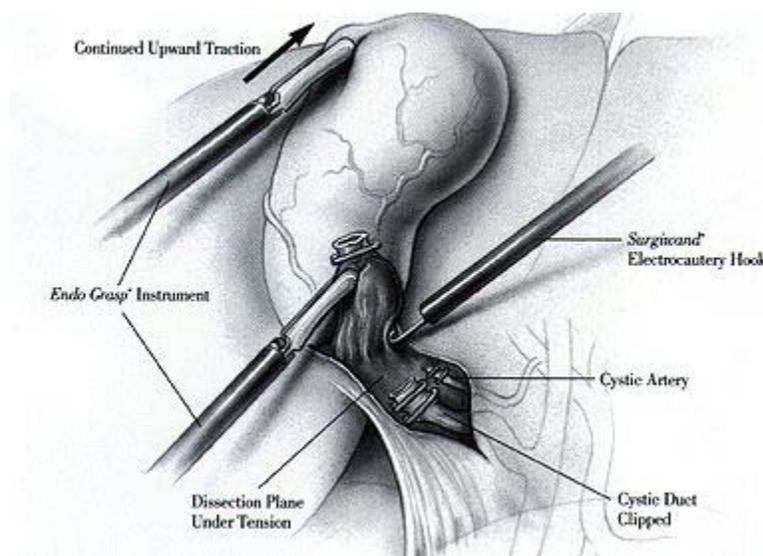

STEP 3: ROUTINE INTRA-OPERATIVE CHOLANGIOGRAM

To view the technique of Routine Intra-operative Cholangiography.

STEP 4: TRANSECTING THE CYSTIC DUCT AND ARTERY

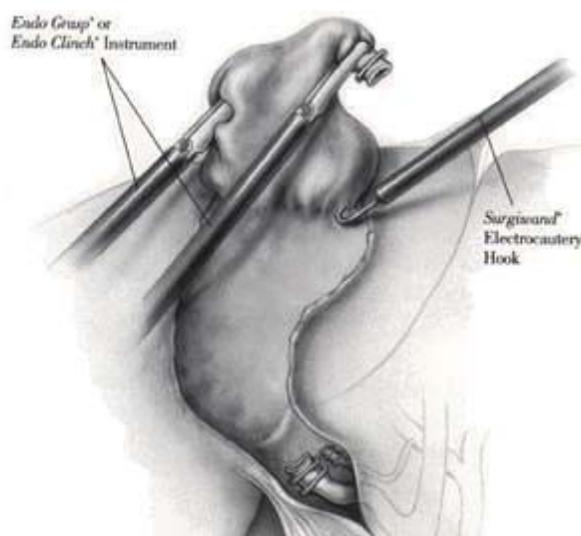

At this juncture, the cystic window is created (i.e., free space behind the cystic duct and the cystic artery). The clip applier is inserted via the subxyphoid trocar. The cystic duct and artery are clipped (three clips) as close as possible to the gallbladder. The ENDO CLIP* Applier is then withdrawn and the EndoShears™ instrument is inserted to cut them.

CAUTION: Be very careful to clearly identify the junction of the gallbladder and cystic duct and plan your transection from this anatomical landmark. In doubt, always check with an IOC.

STEP 5: DISSECTING THE BODY OF THE GALLBLADDER

Hartmann's pouch is now retracted upward. Using the EndoShears* instrument, the most lower lateral aspect of Hartmann's pouch should be dissected meticulously.

The ENDO SHEARS*instrument is withdrawn and replaced by the electrocautery hook. The gallbladder is retracted upward and tension is placed on the surgical plane between the gallbladder and its liver bed. The dissection is extended to the top of the gallbladder. Occasionally the grasper holding the cystic duct stump can be used to flip the body of the gallbladder around the stationary grasper which is still holding the fundus of the gallbladder.

In most instances, this dissection will generate smoke which can impair the surgeon's visualization. This smoke can be aspirated by opening the insufflation of the lateral trocar.

STEP 6: EXTRACTING THE GALLBLADDER

A 10 mm, large grasper is introduced via the sub-xyphoid trocar. The two lateral graspers holding the gallbladder present the gallbladder to the newly introduced large grasper. The gallbladder is pulled from the the intra-abdominal cavity through the same trocar site. This trocar site can enlarged bluntly with a peon clamp of a few millimeters. An Endocatch™ Instrument can be used to remove the specimen.

The intra-abdominal cavity is then thoroughly irrigated with normal saline. All stones that have dropped into the intra-abdominal cavity are retrieved with a morcillator or stone retrieving forceps.

The abdomen is deflated; the trocars removed, and the trocar insertion sites are closed in the usual fashion.

ROUTINE INTRA-OPERATIVE CHOLANGIOGRAM

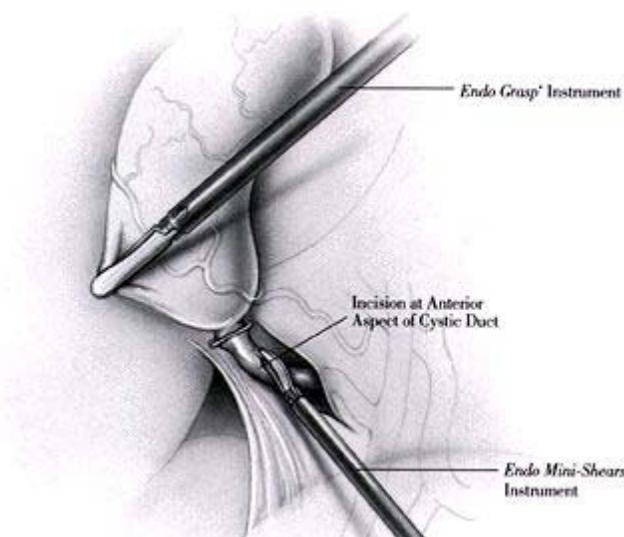

Additional Instruments:

1. Storz Cholangiograsper 5 mm
2. 1 Ureteral Catheter 4 or 5 F with Adapter
3. Dye Used: Renographin 60

STEP 1: EXPOSING THE CYSTIC DUCT AND ARTERY

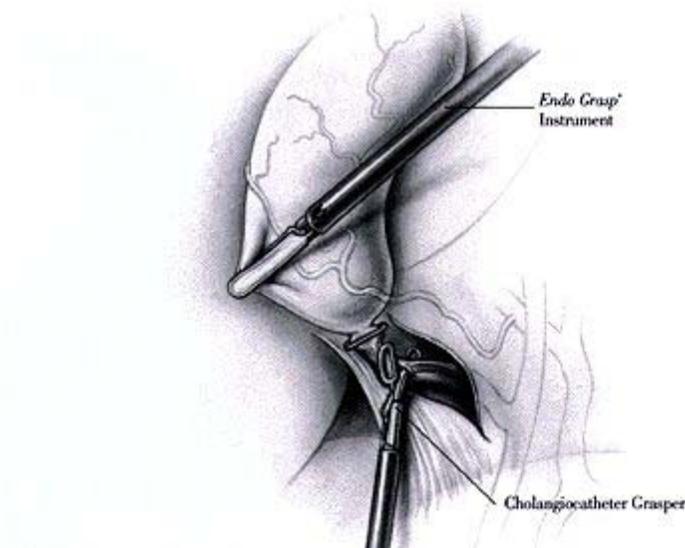

The cystic duct is dissected meticulously as close as possible to the gallbladder. The ENDO CLIP* Applier is inserted via the sub-xyphoid trocar and the cystic duct is clipped at its junction with the gallbladder. While maintaining the same exposure, the ENDO CLIP* applier is withdrawn, an ENDO SHEARS* instrument is inserted via the subxyphoid trocar.

An anterior incision is made on the cystic duct.

The ENDO SHEARS* instrument is then withdrawn and a cholangi catheter grasper with a French #4 catheter is inserted. All the side ports of the catheter have been eliminated by cutting the last 3 cm of the tip. The catheter is inserted into the duct.

In most cases, the intraluminal valves on the cystic duct will make this insertion difficult. However, with the cholangi catheter only the very tip of the catheter needs to be inserted to ensure the flow of bile enters the common bile duct. The grasper is closed around the duct; the jaws should enclose the entire width of the duct for better performance. The catheter is irrigated, and no leak should be seen around the entry site.

If the injection of dye is difficult and slow, and in most cases it is, use a 10cc syringe to inject the dye.

The cholangiogram is obtained. The following should be visible on the radiogram:

1. The cystic duct
2. The common bile duct with its hepatic bifurcation
3. Renografin in the duodenum
4. Absence of CBD stones

After completing the operative cholangiogram, the cholangiometer and grasper are removed.

LAPAROSCOPIC COMMON BILE DUCT EXPLORATION: TRANS-CYSTIC DUCT

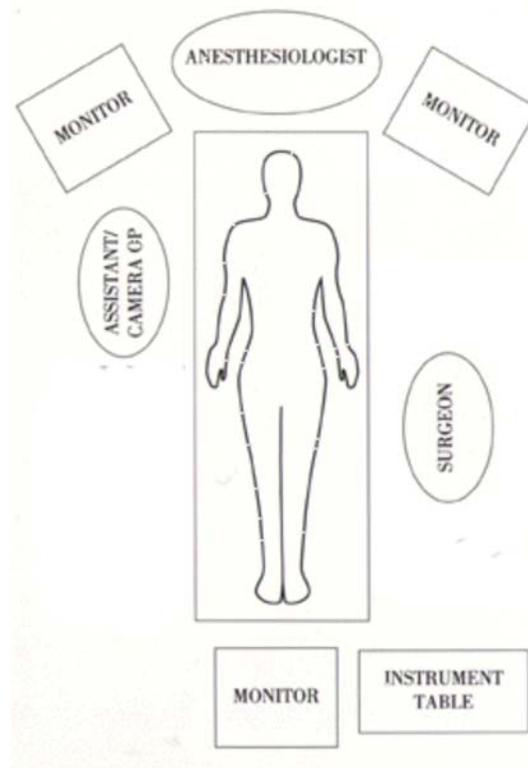

As previously mentioned, the number of laparoscopic common bile duct explorations performed on our surgical service has dramatically decreased over the past few years. These explorations are now rare and usually performed in post-cholecystectomy patients with Choledocholithiasis who have failed endoscopic retrieval. We strongly believe Choledocholithiasis is best treated by non-surgical methods such as an Endoscopic Retrograde Cholangiography and Papillotomy.

Two techniques are used to perform a common bile duct exploration via laparoscopy. These are

- 1) the cystic duct dilatation and retrieval and,
- 2) the anterior choledochotomy. Nowadays, we almost exclusively use the laparoscopic anterior choledochotomy.

Pre-exploration Work-up: A correct diagnosis should be made prior to the actual initiation of the procedure. An intraoperative cholangiogram or another imaging study should demonstrate common bile duct pathology unequivocally.

OPERATING ROOM SET-UP:

Additional Instruments and Hardware:

A second Storz Camera with a monitor

1 - 5 mm trocar (available)

Additional Instruments

1 Storz Ureteroscope- 3.0 mm or 3.5 mm with a 1.5 mm working channel

1 Phantom 5 Plus Balloon Catheter (Microvasive /75cm, 5 Fr./6 mm, 18 Fr.) with Catheter Introducer

1 LeVein Inflator 10 cc with Pressure Gauge

1 Glide Wire 0.35/150 cm with straight tip

1 Segura Stone Retrieval Stone Basket 2.4F Mini (120 cm)

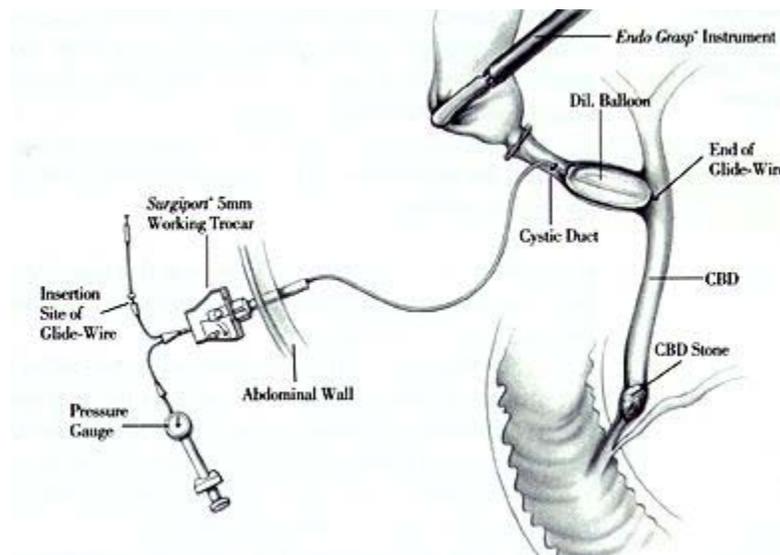

The Technique

STEP 1: THE INTRA-OPERATIVE CHOLANGIOGRAM

This technique is used at the time of a laparoscopic cholecystectomy. An operative cholangiogram has confirmed the presence of a common bile duct stone. At this point, a clip has been placed at the junction of the gallbladder and the cystic duct. The cholangio-catheter has been removed. The cystic duct should not be cut. An intact common bile duct is necessary to maintain sufficient tension for easy access into the cystic duct and the common bile duct.

STEP 2: CANNULATING THE CYSTIC DUCT

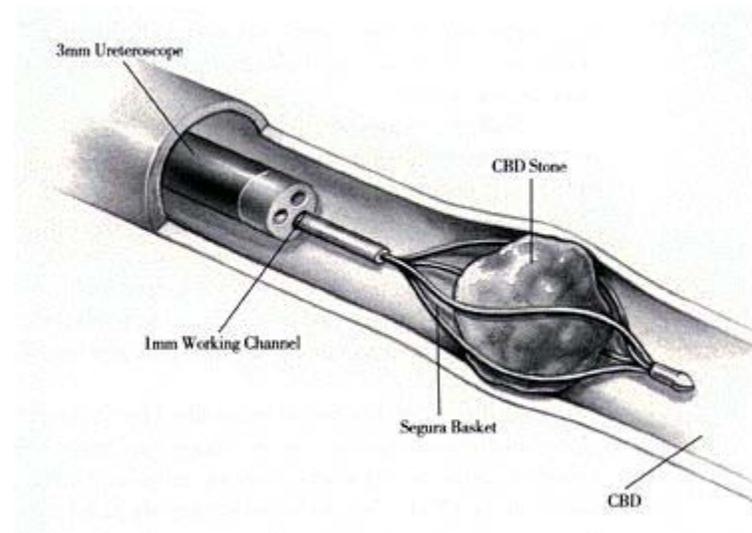

The Phantom 5 Plus Catheter is connected to the LeVeen Inflator with Pressure Gauge. The catheter is inserted via the lateral 5 mm trocar into the intraabdominal cavity. A long 4.5 mm sealed, steel shaft is used to minimize air leaks and to facilitate insertion of the catheter into the cystic duct.

A glide wire is inserted into the central channel of the Phantom 5 Plus Catheter. This glide wire is inserted into the Cystic duct and into the common bile duct using direct vision. The dilating catheter is then passed over the glide wire into the common bile duct. The balloon of the catheter entering the cystic duct is positioned at the entrance of the cystic duct. The balloon is inflated for five minutes at 12 atmospheres of pressure. The entrance of the cystic duct has now been dilated to accommodate a standard 3.0 mm ureteroscope.

STEP 3: INSERTING THE CHOLEDOCHOSCOPE

The Phantom 5 Plus Catheter is then removed and replaced by the ureteroscope. This scope is either connected to an additional camera and monitor, or to an additional camera with a image splitter. The ureteroscope is inserted into the cystic duct with a high pressure saline flow. It is pushed into the common bile duct which is visualized and fully explored.

STEP 4: RETRIEVING THE CBD STONES

Once a stone is seen, the tip of the ureteroscope is placed proximal to the stone. A Segura Basket is inserted into the working channel of the ureteroscope, advanced into the common bile duct and passed beyond the stone. It is then opened and slowly withdrawn under direct vision. When the stone is in the basket, the basket is closed and the stone grasped. The entire apparatus, including the ureteroscope and the wire basket, is pulled out of the common bile duct and the cystic duct. The stone is then released into the intraabdominal cavity and retrieved in the usual manner.

LAPAROSCOPIC COMMON BILE DUCT EXPLORATION: CHOLEDOCHOTOMY

Additional Instruments and Hardware:

A second Storz Camera with a monitor

1 - 5 mm trocar (available)

Biliary Fogarty Catheters (5, 6 F)

Zsabo-Berci Needle Driver or EndoStitch Instrument

Laparoscopic Sutures

T Tube (Sizes 12 - 18 should be available)

The Technique

This can be performed at the time of a laparoscopic cholecystectomy or in the post-cholecystectomy patient. In the latter group, the trocars used are the same as for a standard laparoscopic cholecystectomy.

STEP 1: EXPOSING THE CBD

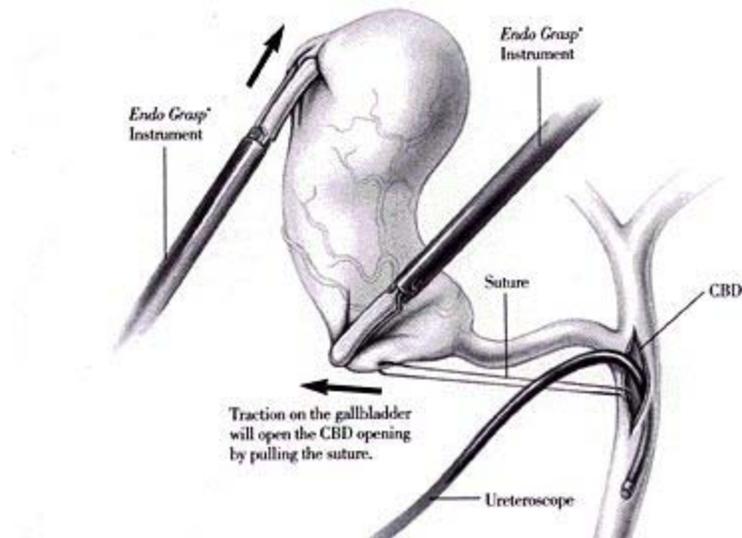

The common bile duct should be equivocally identified. We rarely proceed with a common bile duct exploration if the duct is 1cm or less in diameter. A confirmation of the diagnosis is imperative either via an intra-operative cholangiography or with an intra-operative sonographic study. A meticulous dissection of the common bile duct is performed using the ENDO SHEARS* Instrument and a non traumatic grasper from the hepatic bifurcation to the superior aspect of the pancreas. A section of the common bile duct of about 2 cm should be exposed. In some cases, the gallbladder is used to give additional retraction as demonstrated in the following picture. An endoscopic suture can be placed on the lower portion of the gallbladder and the lateral aspect of the common bile duct. In most cases however, we perform a choledochotomy without retraction sutures.

STEP 2: THE ANTERIOR CHOLEDOCHOTOMY

The anterior choledochotomy is performed by inserting the ENDO SHEARS* Instrument via the subxyphoid trocar, grasping the common bile duct with an ENDO DISSECT* Instrument (via the lateral trocar) and incising the CBD (15 to 20mm).

STEP 3: CLEARING THE CBD

Once the choledochotomy is done, the common bile duct is flushed using our high pressure irrigation device. A Biliary Fogarty Catheter is then used. It is inserted via the subxyphoid trocar and into the common bile duct, run proximally and distally. This step usually retrieves most of the common bile stones.

STEP 4: THE CHOLEDOCHOSCOPY

A Choledochoscopy is performed. An additional camera and monitor are used to connect the flexible 3 mm choledochoscope or ureteroscope. In this setting, larger ureteroscopes can be utilized as the choledochotomy can accommodate larger sizes. Stones are retrieved using a Secura Basket via the working channel of the telescope.

STEP 5: INSERTING THE T TUBE

Once the common bile duct is shown to be free of stones, a T Tube is inserted. The T Tube is usually inserted via the subxyphoid trocar after its limbs have been cut (each should be 1.0 cm in length). It is then inserted entirely into the intra-abdominal cavity. An additional 5 mm trocar is inserted in the RUQ. A grasper is inserted via this new trocar to grasp the long limb of the T Tube. The T Tube is then pulled through the anterior abdominal wall along with the trocar. The T Tube is then inserted into the common bile duct, using two graspers or ENDO DISSECT*. The common bile duct is sutured closed with endoscopic sutures. A completion Cholangiogram is then obtained.

SUBTOTAL OR ANTERIOR LAPAROSCOPIC CHOLECYSTECTOMY

Indications: Acute, severe, gangrenous Cholecystitis and the inability to complete a safe standard laparoscopic Cholecystectomy.

Operating Room Setup: Same as Standard LapChole

Hardware: Same as Standard LapChole

Instruments: Same as Standard LapChole

Additional Instruments: Two Blake drains with drainage reservoir

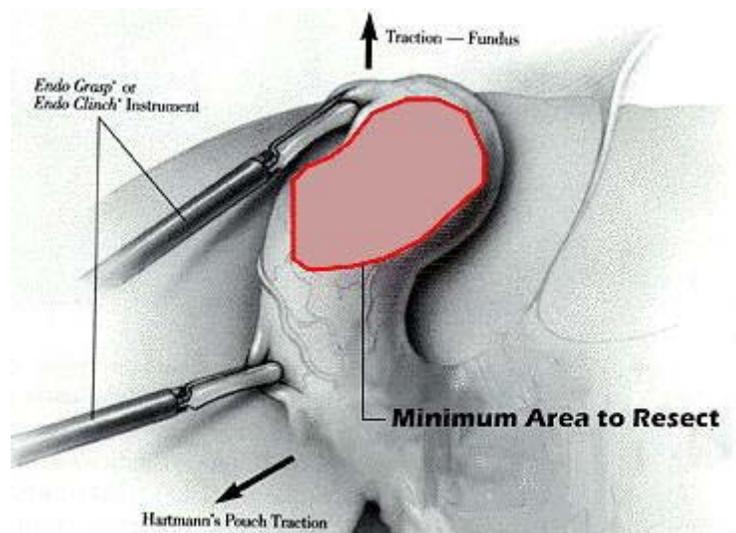

All patients are given Toradol (Roche Pharmaceuticals) and Cefizox (Fujisawa USA) during induction.

The Technique

A standard laparoscopic cholecystectomy has been initiated by the surgeon, at which time he assesses an anterior laparoscopic cholecystectomy should be performed.

Using the stationary or lateral 5 mm grasper, the tip of the fundus of the gallbladder is grasped and retracted cephalad. An ENDO SHEARS* Instrument is inserted via the sub-xyphoid trocar (with electrocautery connection). Using the other lateral grasper, the anterior aspect of the gallbladder is dissected meticulously. The dissection should be extended as low as possible toward the cystic duct without compromising the safety of the procedure.

Using the ENDO SHEARS* Instrument, the gallbladder is entered and the anterior wall of the gallbladder should be resected. Hemostasis should be controlled with the ENDO SHEARS* Instrument connected to an electrocautery source. Spilled gallstones should be retrieved and removed with a morcillator-type grasper (10 mm). The specimen should be removed via the sub-xyphoid trocar. The gallbladder fossa should be flushed thoroughly with normal saline.

Two Blake™ drains are inserted into the intra-abdominal cavity. The best method for the

insertion of these drains is to insert a 5 mm grasper via one of the lateral trocars into the intra-abdominal cavity and out through the sub-xyphoid trocar. The sub-xyphoid trocar is removed. The end of the Blake drain is grasped by the grasper outside the abdominal cavity and pulled back into the intra-abdominal cavity. The lateral grasper pulls it via the 5 mm trocar site. One drain is inserted into the open gallbladder fossa and the other into the sub-hepatic fossa.

The procedure is completed as usual.

Technical Notes

Postoperative Management: Postoperatively, the clinical behavior of these patients is the same as for all patients undergoing a minimally invasive procedure. The next day they usually are on a regular diet and ambulatory. Unless they have associated medical problems, most patients can be discharged within 48 hours. They are discharged with Blake drains in place. Interestingly, some patients will have a bile leak-drainage noticeable on postoperative day one, and others will not. This is most likely secondary to a blocked cystic duct secondary to an impacted gallstone. Nonetheless, these drains are to remain in place for two weeks or until they cease to drain.

Bile Leak-Drainage: Most patients will have significant bile drainage, as this procedure effectively creates a controlled bilio-cutaneous fistula. The average or mean bilious drainage is two days. The longest recorded drainage has been 21 days. As a rule, in the absence of a distal common bile duct obstruction, all bilious drainage or leaks will cease within three weeks.

Associated Complications: This procedure does not allow the performance of an intra-operative cholangiogram or the placement of a cystic duct cannula. One patient was found postoperatively to have a retained common bile duct stone requiring an Endoscopic Retrograde Cholangiography and Papillotomy. Another patient developed a sub-phrenic abscess and eventually required a laparotomy.

Impact of Anterior-subtotal Laparoscopic Cholecystectomy On the Conversion Rate: Prior to introducing this procedure, most conversions occurred in patients with acute, severe, and gangrenous cholecystitis. This procedure effectively decreased our conversion rate as soon as it was introduced. Actually, since its introduction, 896 LapCholes were done with only one conversion. This reduction in the conversion rate is probably the most significant advantage of this technique.

MANAGEMENT OF CHOLEDOCHOLITHIASIS WITH A CYSTIC DUCT CATHETER

Controversies in the Management of CBD Stones

In the United States, surgeons perform approximately 600,000 laparoscopic

cholecystectomies (LC) per year. LC's have largely superseded open cholecystectomies (OC) as the preferred method of gallbladder removal, accounting for 80% of such procedures in this country. One limitation of LC as compared to OC is the difficulty in dealing with common bile duct (CBD) stones. CBD stones are present in approximately 15% of patients, and are responsible for considerable morbidity and mortality (specifically pancreatitis and ascending cholangitis) which mandates the removal of such stones.

In OC, surgeons can routinely remove CBD stones via common bile duct exploration (CBDE), a natural extension of the operative procedure. In LC however, techniques for detection of CBD stones (intraoperative cholangiography or IOC) and subsequent removal are beset with pitfalls. IOC, performed by injection of dye via a cystic duct catheter placed surgically, adds significant time to the operative procedure. It also requires commitment of additional equipment and personnel to the operating room, and has a false positive rate of stone detection of up to 12%, sometimes resulting in unnecessary CBDE. Furthermore, the finding of stones on operative cholangiogram obligates the surgeon to perform CBDE, either laparoscopic or open. A laparoscopic CBDE is a time consuming, hardware intensive procedure, has a steep learning curve, is associated with up to a 50% failure rate, and risks injury to the CBD. Conversion to open CBDE negates the value of a laparoscopic procedure. Another alternative in patients with stones seen on IOC is to refer the patient postoperatively for ERCP, papillotomy, and stone removal. However, a technical failure rate of up to 15% in some series could lead to a second operative procedure, open CBDE.

A number of researchers have attempted to define parameters which could be useful in preoperative prediction of CBD stones. This includes the presence of any of several parameters: 1) Increased liver enzymes, 2) Preoperative pancreatitis, jaundice, or cholangitis, 3) A dilated CBD or intraductal stone on ultrasound, is predictive of CBD stones 25-48% of the time. Furthermore, stones can be present up to 8% of the time in the absence of such parameters or risk factors. Strategies to deal with possible CBD stones in patients with risk factors are complex. One strategy is to do preoperative ERCP with removal of stones (if present). The problem is that 50-75% of ERCP's performed because of the presence of a risk factor will show no stones. Thus, a large number of unnecessary ERCP's will be performed, with a complication rate of 5-10%, and a technical failure rate of up to 15% (i.e. failure to cannulate CBD). A second strategy is to do IOC on patients with risk factors, and to do intraoperative stone removal if stones are detected. The problem with this, as mentioned is that IOC, is time-consuming and associated with up to 12% false positive rate. Subsequent intraoperative stone removal is both time consuming and risky, and often subjects the patient to an open procedure. A third strategy is to do postoperative ERCP if the IOC shows stones. Again, the problem here is that up to a 15% failure risk associated with ERCP would subject the patient to another surgical procedure to remove the stones.

USING A CDC FOR A POST-OPERATIVE CHOLANGIOGRAM

We have developed a new and simple technique for cholangiography that we believe will largely supplant existing complicated algorithms for dealing with CBD stones. In this

laparoscopic technique, in lieu of performing IOC, we secure a standard ERCP catheter (Microvasive, tapered tip) in the cystic duct intraoperatively and leave the catheter in place after surgery.

Postoperatively, all patients undergo a cholangiogram in the x-ray department via the catheter. If no stones are demonstrated, then the catheter is pulled. If stones are present, then the endoscopist performs postoperative ERCP and papillotomy to remove the stones, and then pulls the transcystic catheter.

THE LAPCHOLE WITH CDC PLACEMENT

Operating Room Setup: Same as Standard LAPCHOLE

Hardware: Same as Standard LAPCHOLE

Instruments: Same as Standard LAPCHOLE

Additional Instruments:

- 1 Blake Drain with drainage reservoir
- 1 Ureteral 7 French Ureteral Catheter or
- 1 Fluoro Tip ERCP Cannula Tapered Tip
(210 cm - 5 French 1.7 mm with stainless steel stylet)

Technique

The procedure is initiated as described in the Standard LAPCHOLE Chapter.

1. Inserting the Cystic Duct Cannula in the Intraabdominal Cavity

The cystic duct is exposed and clipped at its junction with the gallbladder with an endoclip. Traction is maintained on Hartmann's pouch to expose the cystic duct. An anterior incision is made with the ENDO SHEARS* instrument.

The cystic duct cannula is inserted via the subxyphoid trocar site. First, the trocar is quickly removed from the subxyphoid site. The site is plugged with a finger and the cannula is inserted bluntly into the intraabdominal cavity under direct vision. When 10 to 15 cm of the cannula is in the intraabdominal cavity, the VERSAPORT* trocar is reinserted bluntly next to the cystic duct cannula. Both the cannula and the trocar are now side by side in the subxyphoid insertion site. The cannula can be advanced, withdrawn and manipulated very easily from the outside of the abdominal cavity.

2. Placing the Cannula in the Biliary Tree

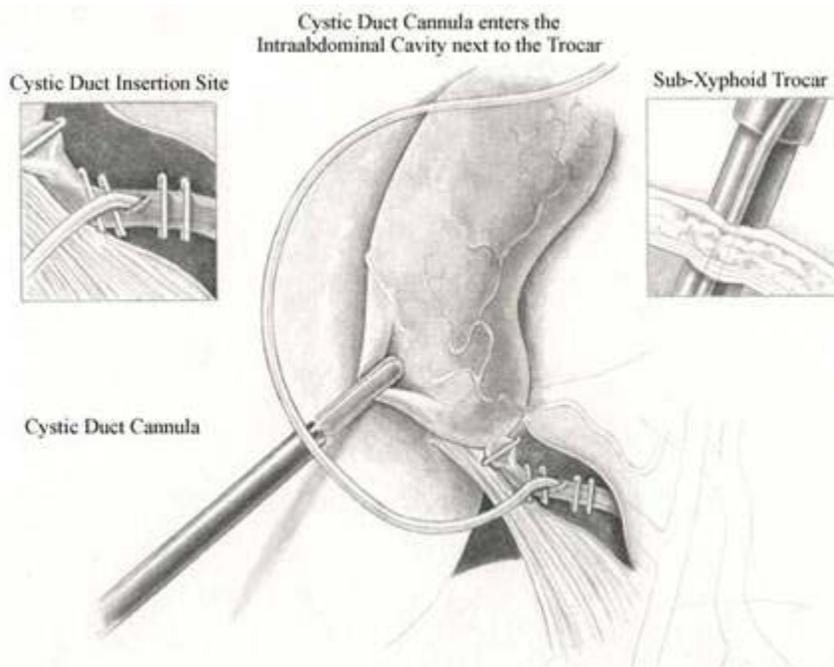

An ENDODISSECT* Instrument or an atraumatic grasper is inserted via the subxyphoid trocar and grasps the tip of the cystic duct cannula. It is inserted into the cystic duct under direct vision and advanced into the common bile duct.

We routinely advance the cannula for about 5-6 cm, and then withdraw the cannula to leave approximately 1.5 to 2 cm inside the cystic duct.

3. Securing the Cannula in the Cystic Duct

The ENDO DISSECT* or grasper is removed from the intraabdominal cavity and replaced with the ENDO CLIP* Applier. It is essential to use a USSC ENDO CLIP* or a SURGICON applier. They are the only instruments that will allow the performance of the next maneuver.

Two clips are placed on the cystic duct. It is essential NOT to close the entire clip around the cystic duct so as not to entirely obliterate the duct and cannula. The partial closing of the clip can only be performed with the USSC ENDO CLIP* applier. (The Ethicon clip Applier does not have this capability.) Another clip is tightly placed behind the cannula. If using the SURGICON clip applier, only one clip is used on the cannula and behind it.

The ENDO CLIP* applier is now replaced with the ENDO DISSECT* Grasper. The Cannula is grasped outside the cystic duct and pulled .5 cm to check that the cannula is not crushed or locked onto the cystic duct. Then additional cannula is inserted into the intraabdominal cavity to provide slack, so it can be placed laterally to allow for the completion of the laparoscopic cholecystectomy. A Blake Drain is inserted at the end of the procedure.

An intraoperative cholangiogram can be performed. If negative, the cannula is removed. We routinely do not perform an intraoperative cholangiogram. We order it a few hours after the procedure.

POST-OP ERCP

SCENARIO 1: CHOLEDOCHOLITHIASIS IS DEMONSTRATED ON THE TRANSCYSTIC CHOLANGIOGRAM: AN ERCP IS PLANNED.

ERCP Technique

The cystic duct catheter provides a portal through which a guidewire can be directed into the duodenum at the time of ERCP. The ability to place a guidewire greatly facilitates cannulation of the CBD during ERCP, especially in technically difficult cases.

Equipment

Pentax ERCP scope

Microvasive Ultratome XL

Zebra wire

Balloon Retrieval Catheters--8.5 mm. and 11 mm.(Microvasive Extractor XL)

Stone retrieval basket

Technique

STEP 1. A cholangiogram is first performed via transcystic catheter. This helps identify CBD and facilitates cannulation of papilla.

STEP 2. ERCP is then performed in the standard fashion.

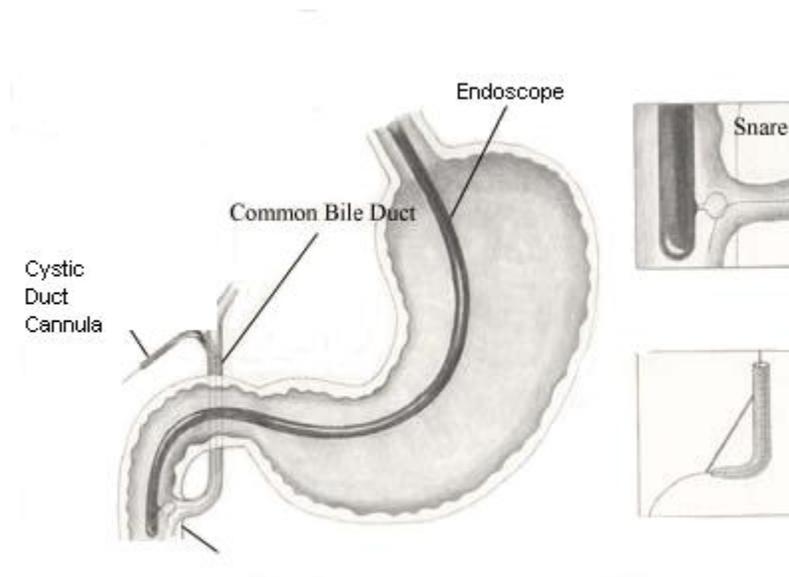

STEP 3. If cannulation takes longer than 15 minutes, then a 400 cm Zebra wire is advanced through the transcystic catheter and directed by fluoroscopy into the CBD and through the papilla.

STEP 4. The endoscopist passes a snare through the biopsy channel of the ERCP scope, snares the end of the Zebra wire, and pulls it out of the scope.

STEP 5. The papillotomy is flushed with saline and advanced over the wire, through the scope, and into position in the papilla and CBD.

STEP 6. Endoscopist performs papillotomy over the guidewire and removes guidewire/papillotomy assembly.

STEP 7. The duct is then swept with an 8.5 mm or 11 mm balloon or a stone retrieval basket to remove stone(s).

The transcystic cannula is removed by firmly pulling on it at the bedside or in the ERCP suite. The Blake drain is left in place and the patient is discharged. The Blake drain is then removed a few days later as an outpatient.

NOTE: There has been no reported leak following this protocol. However, the Blake drains are left in place should a bile leak occur.

SCENARIO 2: NO COMMON BILE DUCT STONE DEMONSTRATED.

The Cannula is removed by exerting firm traction. The Blake Drain is left in place and removed 48 hours later as an outpatient.

Advantages

This technique offers many advantages over existing strategies for dealing with CBD stones. First, ERCP's will be limited only to those patients who have a stone visualized on transcystic cholangiogram. For those surgeons or gastroenterologists who currently stratify patients' need for ERCP according to preoperative risk factors for CBD stones, the TCC approach will eliminate the need to perform ERCP on up to 80% of patients with positive risk factors but who have no stones (False Positives). The ERCP associated complications will thereby be eliminated. Second, the 15% risk of postoperative ERCP failure to cannulate or clear stones (even up to 10% in biliary referral centers) will be largely eliminated by the ability to place a transcystic, transpapillary guidewire. This safety valve will greatly facilitate endoscopic access to the bile duct, eliminate the need for a risky precut papillotomy to gain access to the CBD, and reduce the potential need for a second operation in patients in whom ERCP was a technical failure. Third, the TCC should eliminate the need for IOC and CBDE. Since the TCC/ERCP technique reduces the risks associated with ERCP and optimizes the chance of a successful outcome, the need for IOC and /or CBDE (laparoscopic or open) is greatly reduced (including those CBDE's done for false positive IOC's). Fourth, if this technique is applied to

all laparoscopic cholecystectomies, then all CBD stones will be detected including up to 8% of patients who have no preoperative risk factors for stones.

HERNIA

Hernia of the abdominal wall or external hernia (*herniae abdominalis externae*) is such surgical disease, which is characterized by outlet of the visceral organs from the place of their physiological placement through the natural channels or defects of the abdominal and pelvic wall. In such case all visceral organs covered by parietal peritoneum and skin cover are not damaged.

Internal hernia (*herniae abdominalis internae*) is such disease, visceral organs hit the peritoneum pouch. It formed in the place of natural peritoneum fold or recess and generally kept in the abdominal cavity.

Localizations of the abdominal wall hernias :1— Linea alba; 2—Umbilical; 3 —Spigelian li-nea; 4—Incisional hernia; 5—Direct inqualis hernia;6—Femoral hernia;7—Indirect inqualis hernia

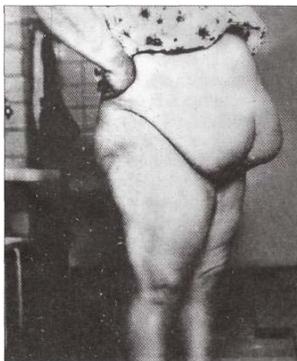

Etiology and pathogenesis

Hernias are divided into two main groups: congenital (*herniae congenitae*) and acquired (*herniae acquisitae*). The main reason of congenital hernias is malformation. Thus, inguinal hernia arose in case of noclosure of the process of peritoneum, which passes by inguinal channel during descending of the testis. On such hernias testis is located in the hernia pouch. Acquired inguinal hernia has hernia pouch and testis located outside it. Many factors are of great importance in the beginning and developing of the acquired hernia. One of them contributes, other - causes disease. The first are hereditary, anatomical inferiority of the abdominal wall, sex (inguinal area weakness in males and largeness internal femoral ring in females), age (atrophic processes in older age, anatomical inferiority of the abdominal wall in babies), weight loss, injury, postoperative scar, physical activity, pregnancy, during which abdominal wall stretched (for example, midline increased in 12 times).

Such reasons, as increased abdominal pressure and weakness of the abdominal wall, cause hernia. That arise after hard physical activity, continued cough, constipation, nerves palsy, which innervated abdominal wall, injury of muscles or aponeurosis of the abdomen.

Inguinal hernia

Postoperative hernia

Pathomorphology

Each abdominal hernia consists of hernia gate, hernia sac and hernia contents. Hernia sac forms by outpouching of parietal peritoneum and can contain any organ from abdominal cavity, but mostly – small intestine and omentum. Sometimes it contains other organs: large intestine, urinary bladder, ovary, and appendix.

The main parts of the hernia pouch are neck, body and fundus. Through the hernia's gate, peritoneum is outpouching. In the case of sliding hernia organ in the hernia pouch has mesoperitoneal disposition and not enclosed by peritoneum.

Classification

Hernia of the abdominal wall is divided:

- 1) Depends on anatomical localization: inguinal (indirect and direct), midline hernia, omphalocele, femoral hernia, lumbar hernia, sciatic hernia, (enterischiocele), lateral hernia, ischioanal [perineal] hernia (perineocele).
- 2) depends on etiology: congenital (*herniae congenitae*) and acquired (*herniae acquisitae*).
- 3) Depends on clinical presentations: complete and incomplete, reducible and nonreducible, traumatic and postoperative, complicated and noncomplicated.

Clinical management

The typical symptom of hernia is swelling, which arises on vertical position of the patient or during rise of intraperitoneal pressure. These can disappear in a state of dormancy, on vertical position of the patient or after applying small pressure. Such factors make it possible to confirm hernia.

In the case of hernia primary formation skin over the swelling almost not changed. Hernia is determined by finger examination of the inguinal channel. We can feel positive symptom of the "cough push", which is caused by cough or by the rise of intraperitoneal pressure. In the case of late stage of hernia developing evagination appear on changing body position from horizontal to vertical or after rising of the intraperitoneal pressure. If hernia sac contained small intestine than every next tension of the abdominal muscle inflated hernia sac by intestinal loop.

Symptom of the "cough push"

Diagnostics of the noncomplicated external abdominal hernias is easy. Anamnesis of patients and clinical data are enough. However, we should remember about nonreducible hernias. Such hernia's shape and dimension often does not change. Patients complicated for continuous pain in the hernia region, which irradiated to other abdominal organs. The main danger of the nonreducible hernias is jamming.

Clinical variants and complications

Inguinal hernias is developed in two ways: through the internal (middle) inguinal cavity and external (lateral). In the first case formed direct in other - indirect inguinal hernia.

Indirect hernias could be congenital and acquired. Direct hernias are only acquired and occur in older patients.

There are two main signs, which differentiate direct and indirect hernias. Direct hernia is always located medially from *a. epigastrica inf.* Indirect hernia is always located laterally from *a. epigastrica inf.* The other sign is: direct hernia located medially from deferent duct, indirect hernia located inside it
