Femoral hernias are such pathological formation, which is encountered 10-20 times more often in males than females. This is explained by anatomical peculiarity of the females' pelvis, wider interval between femoral vein and lacunar [Gimbernat's] ligament and inguinal [Poupart's] ligament weakness.

There are distinguished femoral hernias, vasculo-lacunar, rural pectineal [Cloquet's] hernia, Hesselbach's hernia.

In addition, there are some kinds of femoral hernias, which can be identified only during the operation:

- 1) Medial vascular-lacunar femoral hernia, most common;
- 2) Hernia, which passed through the middle part of vascular lacuna or through the vascular sheath;
- 3) Lateral vascular-lacunar hernia, which pass outside of the femoral vessels.

Besides, there is middle or prevascular hernia.

Medial vascular -lacunar femoral hernia has three stages of developing:

- 1) Beginning femoral hernia - swelling does not pass outside internal femoral ring;
- 2) Incomplete (interstitial) hernia - swelling does not pass outside of superficial fascia;
- 3) Complete femoral hernia - swelling passed through all anatomical part of the femoral channel and outgoing to the subcutaneous cellular tissue on the anterior femoral surface below inguinal [Poupart's]

ligament.

In spite of small size of the hernia sac, femoral hernia could contain omentum, small intestine and urinary bladder. It is more difficult to diagnose femoral hernia in overweight patients because of inexpressive clinical signs.

We should differentiate femoral hernias with inguinal hernias, increased or varicose changed lymphatic nodes. In those cases, we should determine external inguinal ring and inguinal ligament.

Midline [epigastric] hernia usually has males in giving age.

There are distinguished supraumbilical, umbilical and paraumbilical hernias.

Very often, such kind of the hernia has no clinical signs and can be determined on the medical examinations. The usual clinical signs are: swelling on linea alba and intermittent pain.

Umbilical hernias occur in 2 % from all kinds of hernia. The most frequent hernias in females (the ratio is 5:1), which is explained by anatomical peculiarity of the females' umbilicus after pregnancy. Such hernia often has two- and three-chambers hernia sacs, which could contain omentum, small intestine, and sometime stomach. Clinical signs depend on those contents. However, it always characterized by pain and swelling. In some patients swelling is very large.

Diagnosis of the umbilical hernia in typical case is not very difficult. Sometimes it is arduous to differentiate incarcerated umbilical hernia and umbilical metastasis of tumor. We should remember about umbilical evagination (without organs) in the patients with liver cirrhosis because of presence ascitic fluid in the abdominal cavity.

Lumbar hernias are abdominal wall or retroperitoneal outpouchings. It does not occur very often. The area of the hernia orifice includes the superior costolumbar triangle and the inferior iliolumbar triangle. Besides that, it could be in aponeurosis slit.

Lumbar hernias could be congenital and acquired. Congenital lumbar hernias are frequently the result of aponeurosis slit or enlargement of the Pt₁ triangle or Hrunfeld interval. Acquired lumbar hernias are usually result of injury those anatomical structure or after pyoinflammatory diseases.

The most frequent clinical sign is pain. The other signs depend on hernia content. The hernia contents may include any intra- and retroperitoneal structures, e.g., the kidney, small bowel, and omentum.

Diagnosis is made by clinical examination: in the horizontal patient position on healthy side, swelling disappeared, and on the vertical patient position appeared again.

Obturator hernia is the result of wide obturator channel. In those cases hernia sac formes inside pelvic cavity, and than passes through the obturator channel, and arises on internal femoral surface.

Diagnosis of the obturator hernias is not easy, especially in the patients without swelling on the hip. In such cases, patients have complaints for pain along obturator nerve with irradiation to knee joint or hip joint. Pain increases during leg rotation or abduction. Sometime pain irradiates to the foot.

Sciatic hernias is divided into two main types: hernia of the major sciatic foramen, which passes above and under piriform muscle and hernias of the small sciatic foramen, which passes under sciatic muscle. Patients complained for pain in the sciatic region, which increased during walking. Sometime pain irradiated along sciatic nerve.

Ischiorectal [perineal] hernia is formed in the urogenital diaphragm or in the perineum muscle. Anterior and posterior hernias are distinguished depending on whether the hernia is anterior or posterior to the transverse perineal muscle and sacrospinal ligament. Hernia ring formed by rectouterine [Douglas'] pouch in the female and by retrovesical pouch [Proust's space] in the male. Anterior hernias usually contained internal genital organs or urinary bladder. Posterior hernias usually contained omentum or small intestine loops.

Diagnosis of the anterior ischiorectal hernias, which passed to perineum, usually is not difficult. Diagnostic pitfall should be on the patients with posterior hernias, which is located under large sciatic muscle and looks like sciatic hernia. In such cases, we performed vaginal and rectal examination or X-Ray examination of the urinary bladder and intestine as required.

There are three types of the *lateral abdominal hernias*:

- 1) Acquired hernia of the rectus sheath;
- 2) Acquired hernias of the Spigelian line;
- 3) Congenital hernias because of congenital hypoplasia of the abdominal wall.

Clinical signs of lateral abdominal hernias are the same as for other types of hernias, so diagnosis is not very difficult.

The most common complications for all those hernias are incarceration.

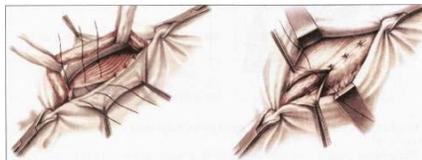

Diagnosis program

1. Anamnesis and physical examination.
2. Digital investigation of the hernia channel.
3. Sonography of the hernia pouch.
4. Common blood analysis.
5. Common urine analysis.

Tactics and choice of treatment method

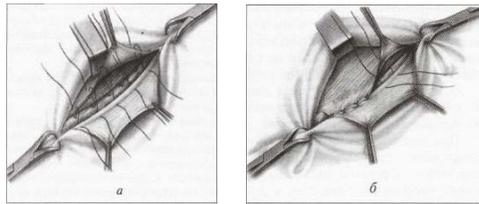

Inguinal hernia usually should be surgically repaired. On oblique inguinal hernias, we should strengthen anterior wall of the inguinal channel. On direct inguinal hernias, we should strengthen posterior wall of the inguinal channel. On recurrence hernias - we should strengthen anterior and posterior wall of the inguinal channel.

Bassini repair. After extraction of the hernia sac, we are taking spermatic duct on holders. Between the borders of transverse muscle, internal oblique muscle, transverse fascia and inguinal ligament interrupted sutures placed. Except that, couples sutures placed between border of abdominal rectus muscle sheath and pubic bone periosteum.

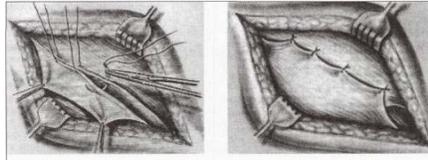

In such way, inguinal space closed and posterior wall strengthened. Spermatic duct placed on the new-formed posterior wall of the inguinal channel. Over the spermatic duct aponeurosis restored by interrupted sutures.

Girard in such kind of the operations propose to attach the edges of the internal oblique muscle and transversal muscle to the inguinal ligament over the spermatic duct. The aponeurosis of the external oblique muscle sutured by second layer of the suture. Excess of the aponeurosis is fixed to the muscle in the form of duplication.

Spasokukotsky proposed to catch the edges of the internal oblique muscle and transversus muscle with aponeurosis of the external oblique muscles by single-layer interrupted suture.

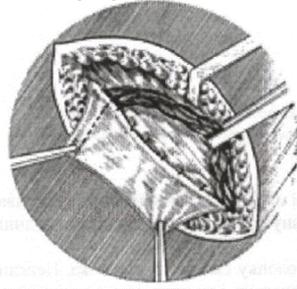

Martynov proposed the fixation to the Poupart's ligament only internal edge of the external oblique muscle aponeurosis without muscles. External edge of the aponeurosis sutured over internal in the form of duplication.

Kimbarovskyy, based on the principles of joining similar tissues, proposed special suture: Sutures placed on 1 cm from the edge of the external oblique abdominal muscle aponeurosis, grasped the part of the internal oblique and transversus muscle. After that, aponeurosis is sutured one more time from behind to the front and attached to the Poupart's ligament.

Kukudganov proposed to restore back wall of inguinal interval. Sutures are placed between the Couper's ligamentum, vagina of direct abdominal muscle and aponeurosis of the transversus muscle.

Postempysky proposed the deaf closing of inguinal interval with the lateral moving of spermatic duct.

The plastic narrowing of internal inguinal ring of to 0,8 cm is the important moment of this modification. On occasion, when internal and external inguinal rings are in one plane, a spermatic duct is displaced in lateral direction by transversal incision of the oblique and transversus muscles. Then edge of the vagina of direct muscle and aponeurosis of the internal and transversus muscles is fixed to the Couper's ligament.

FEMORAL HERNIA

The are some methods of surgical treatment of the **femoral hernia**, when the plastic are performed intraperitoneal from the side of thigh through the inguinal channel.

The Bassini method is attributed to "femoral". It is performed from a cut, that passes under inguinal fold. After removal of hernia sack a hernia gate is liquidated by suturing of inguinal to the pectineal ligament.

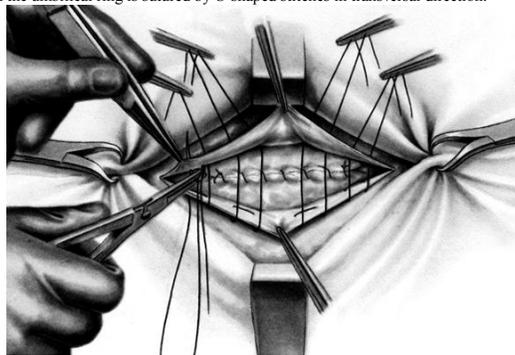

The Rudgi-Parlavecho Method. A cut passes parallel to the inguinal fold and higher it (the same as at inguinal hernia). A hernia sack is removed. After that the edges of the transversal and internal oblique muscles and inguinal ligament sutured to the periosteum of pubic bone.

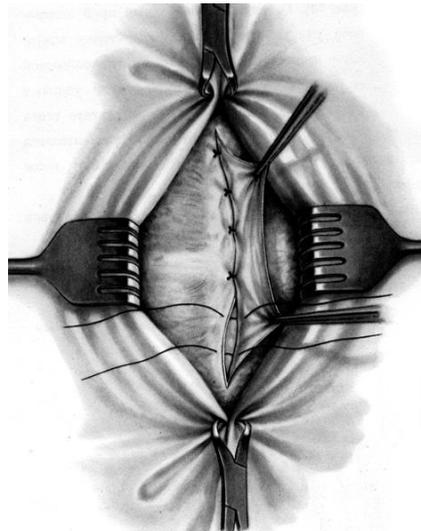

UMBILICAL HERNIA

For operative treatment of umbilical hernia a few methods are used. The Lexer operation is most widespread. It performed by imposition of sutures on an umbilical ring. After the *Meyo* method defect of anterior abdominal wall in the umbilical ring is sutured by U-shaped stitches in transversal direction.

Meyo method

Sapezhko proposed to form duplication of the abdominal white line by stitches in longitudinal direction.

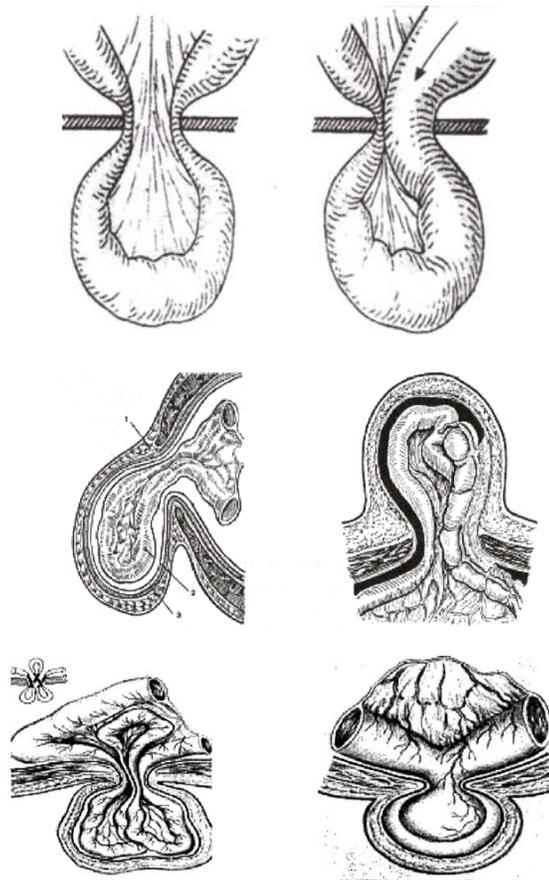

Sapezhko method

At surgical treatment of hernia of abdominal white line, abdominal lateral hernia, lumbar and obturator hernia, sciatic and ischio-rectal hernias after deleting of hernia sack it is needed to try to close a hernia orifice by suturing of fissures in aponeurosis and muscles.

INCARCERATED HERNIA

Incarcerated hernia is sudden pressing of hernia contents in a hernia orifice. Incarceration is the most frequent and most dangerous complication of hernia diseases.

Pic. Types of incarcerations

Etiology and pathogenesis

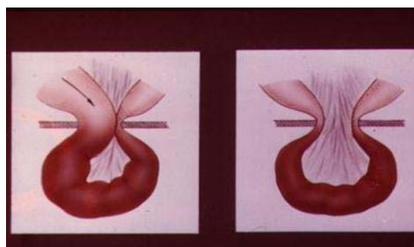

Depending on mechanism, the elastic and fecal incarceration is distinguished. At the *elastic incarceration*, after increasing intraabdominal pressure, one or a few organs relocated from an abdominal cavity to the hernia sack, where it is compressed with following ischemia and necrosis in the area of hernia gate. At the fecal incarceration in the intestinal loop which is in a hernia sack, plenty of excrement passed quickly. Proximal part of loop is overfilled, and distal is compressed in a hernia gate. So, arose its strangulation, as well as at the elastic incarceration.

Most often the loop of bowel is incarcerated. Thus three parts are distinguished in it: proximal, distal loop, central part. The heaviest pathological changes during incarceration takes place in a strangulated furrow in the central part of the incarcerated bowel.

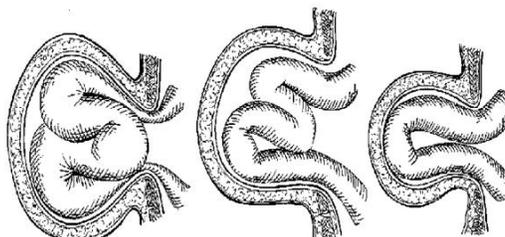

Pathomorphology

At incarcerated hernia an important role has all internal rings: inguinal, umbilical, "weak places" in a diaphragm, orifice of the omental bursa, numeral and "variant" folds of peritoneum.

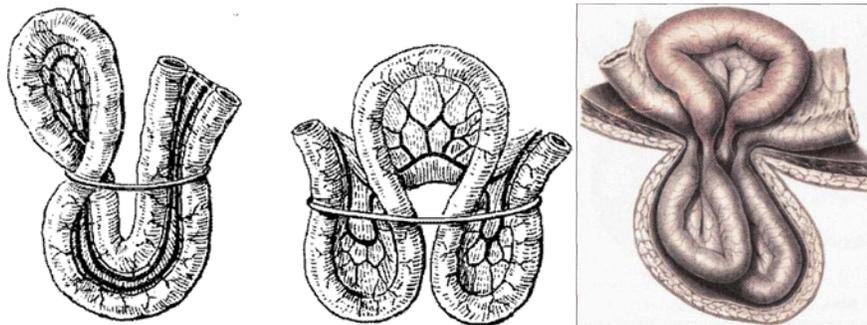

In the place of compressing of the bowels and mesentery, as a rule, it is possible to find a strangulation furrow. If circulation of blood changes, the wall of bowel cyanotic, with hemorrhages and necrosis of a different size. The loop of bowel which is located proximally the places of strangulation are extended, and distal loop mainly without changes.

Pic. Mechanizm of the incarceration.

Pic. Scheme of the incarceration.

Pic. Retrograde incarceration.

Classification of the incarcerated hernia

The incarcerated hernia is divided into the complete and incomplete. The other types of incarceration is partial (the Richter's hernia) and retrograde. The incarcerated hernia can be without the destructive changes of hernia contents and with the phlegmon of hernia sack.

Clinical management

The clinic of the incarcerated hernia depends on pulling in organ, character and duration of jamming. The clinical signs of the incarcerated hernia can be divided into three groups: 1) local changes; 2) common signs; 3) complication. From the most characteristic signs of local changes the most common is sharp pain, irreducible hernia, tension of hernia sack that and negative symptom of the "cough push".

Pain sometimes is so intensive that causes pain shock. In the case of intestinal obstruction a pain is attack-like. In case of occurring of peritonitis pain changes the character and becomes permanent.

It is necessary to mean that tensions of hernia sack and incarceration of the hernia, as signs of jamming, lose it value, if hernia was irreducible.

From other side, the isolation of hernia sack from an abdominal region during jamming is the reason of the *negative symptom of the "cough push"*.

The common signs at the incarcerated hernia has phase character. *Nausea and vomits* during first hours of disease has reflex reason, and on 2nd and 3rd days has toxic reason, that is consequence of antiperistaltic and reflux of intestinal contents to the stomach.

The *temperature of body* at first time is normal, and than rises, but usually low grade fever.

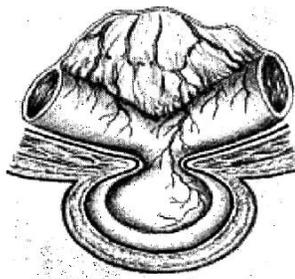

The clinic of acute intestinal obstruction and peritonitis develops at the protracted jamming of intestine. The phlegmon of hernia sack can develop in the area of the hernia swelling.

Clinical variants and complications

There are different forms of incarceration of internal organs, and accordingly — different clinical variants.

Retrograde incarceration. In such cases a hernia sack contains no less than two loops of intestine. But these loops are damaged less, than loop which is in an abdominal cavity. At this variant of jamming peritonitis arose quicker. So, surgeon during operation must always remember about the necessity of careful revision of the incarcerated loops of bowel.

Parietal incarceration (the Richter's hernia). Unlike retrograde, which has wide hernia gate, a similar pathology arises in case of narrow hernia gate. In a hernia sack in such patients located part of bowel wall, opposite it mesentery edge.

Thus, as a rule, patency of bowel is not broken. Such variant of jamming is dangerous, because there are no evident clinical signs or some of them are quite absent and intestinal patency almost is always present. Necrosis of bowel wall comes quickly and in 2-3 days the perforation with subsequent development of peritonitis begins after jamming.

The Litre's hernia. Jamming of Meckel's diverticulum can come at oblique inguinal hernia. Clinical signs of this pathology reminds the parietal incarceration. Sometimes is possible to palpate dense, short, thick tension bar in a hernia sack.

Incarceration at sliding hernia. It is observed at patients with inguinal hernia. At sliding hernia of colon, as a rule, there is the fecal incarceration. A bowel is the external wall of hernia sack in such cases. About it is necessary to remember during opening of hernia sack. Jammings of urinary bladder meet enough rarely, mainly at older-men at oblique sliding hernia of inguinal channel. It is necessary to ask before the operation, whether a patient had disorders of urination before jamming. Frequent urges, or, opposite, the reflex delay of urination is arose at the beginning of jamming already, and in urine expose macro- or microhematuria. If during operation at opening of hernia sack it medial wall has dense, doughy consistency, it is an urinary bladder.

At the incarcerated hernia the contents of hernia sack can be also omentum, appendages of colon, internal female genital organs. Sometimes combination of the incarcerated inguinal hernia with different pathological changes of testicle and deferent duct can take place.

Rough manual reduction of the incarcerated hernia can bring to pseudoreduction. Then the local signs of the incarcerated hernia disappear, and jamming of organs and its consequences is kept. There are five variants of the pseudoreduction: 1) at multicompartiment hernia sacks there is the possible moving of strangulated organs from one chamber in other, that located more deep or in a preperitoneal adipose tissue; 2) separation and reduction of hernia sack together with it content in an abdominal cavity or in a preperitoneal adipose tissue; 3) abruption of the neck from other part of hernia sack and reduction it together with content in an abdominal cavity or in a preperitoneal adipose tissue; 4) abruption of the neck from a hernia sack and from a parietal peritoneum with reduction of the incarcerated organs in an abdominal cavity; 5) break of the incarcerated bowel at the rough reduction of hernia.

Untimely operative at the incarcerated hernia, usually, is complicated by the gangrene of bowel, peritonitis or phlegmon of hernia sack. Such complications considerably worsen clinical status of patient and require other surgical tactic.

Diagnosis program

1. Anamnesis examination.

2. Physical examination.
3. Blood analysis and urine analysis.
4. Digital investigation of the rectum.
5. Survey X-Ray of abdominal cavity organs.

Differential diagnostics

As experience shows, the incarcerated hernia we should differentiate with irreducible, which as a rule, is not tense, positive symptom of the "cough push", painful on palpation. A patient complained for long duration of the disease. The incarcerated hernia needs to be differentiated with coprostasis. In such patients disorder of bowel loop patency, that is in a hernia sack, creates accumulation of excrement. Coprostasis mostly found at fecal hernia in older people, that suffer from intractable constipation. Clinically it develops gradually and slowly. The hernia swelling almost not painfully, some tense, a positive symptom of the "cough push". Beginning of coprostasis is unconnected with physical tension. Application of cleansing siphon enema washed of excrement and liquidated coprostasis.

Unreal jamming of hernia. In clinical practice there are often such situation, when during the acute surgical diseases of organs of abdominal cavity free external abdominal hernia becomes irreducible, painfully and tense, and looks like incarcerated. This is the unreal jamming of hernia, which can be observed at the acute surgical diseases of organs of abdominal cavity, ascites. During examination of such patients it is necessary to remember, that at the unreal jamming abdominal pain, vomiting, worsening of the general condition and signs of the intestine obstruction come earlier, than changes in a hernia sack.

In addition, during the operation in patients with incarcerated hernia, it is needed to make sure, whether there is a strangulation furrow, or organ, that is in a hernia sack, fixed in a hernia gate. When these signs are absent, it is possible to consider that jamming is unreal.

The incarcerated femoral hernia must be differentiated with inguinal lymphadenitis, by varicose expansion of large hypodermic vein, varicose knot and their thrombophlebitis, tumor and abscess.

From such pathology without surgical procedure it is possible to differentiate only varicose expansion of veins (varicose knot), for which the positive Valsalva test — at horizontal position of patient with the leg heaved up a knot is empty.

The incarcerated inguinal hernia needs to be differentiated also with hydrocele and orchiepididymitis, cyst of deferent duct, cyst of round ligamentum of uterus, Bartholinitis. Patients, who have with such diseases, a process usually does not spread higher external ring of inguinal channel. Also, absence of testicle in scrotum can be cryptorchidism sign.

The common clinical signs of the internal incarcerated hernia is abdominal pain and symptoms of the intestinal obstruction. A final diagnosis is set during the operation.

Differential diagnostics and clinical variants

Acute appendicitis is an inflammation of vermiform appendix caused by festering microflora.

Most frequent causes of acute appendicitis are festering microbes: intestinal stick, streptococcus, staphylococcus. Moreover, microflora can be in cavity of appendix or get there by hematogenic way, and for women — by lymphogenic one.

Factors which promote the origin of appendicitis, are the following: a) change of reactivity of organism; b) constipation and atony of intestine; c) twisting or bends of appendix; d) excrement stone in its cavity; e) thrombosis of vessels of appendix and gangrene of wall as a substance of inflammatory process (special cases).

Simple (superficial) and destructive (phlegmonous, gangrenous primary and gangrenous secondary) appendicitises which are morphological expressions of phases of acute inflammation that is completed by necrosis can be distinguished.

In simple appendicitis the changes are observed, mainly, in the distant part of appendix. There are stasis in capillaries and venule, edema and hemorrhages. Focus of festering inflammation of mucus membrane with the defect of the epithelium covering is formed in 1–2 hours (primary affect of Ashoff). This characterizes acute superficial appendicitis. The phlegmon of appendix develops to the end of the day. The organ increases, it serous tunic becomes dimmed, sanguineous, stratifications of fibrin appear on its surface, and there is pus in cavity.

In gangrenous appendicitis the appendix is thickened, its serous tunic is covered by dimmed fibrinogenous tape, differentiating of the layer structure through destruction is not succeeded.

Four phases are distinguished in clinical passing of acute appendicitis: 1) epigastric; 2) local symptoms; 3) calming down; 4) complications.

The disease begins with a sudden pain in the abdomen. It is localized in a right iliac area, has moderate intensity, permanent character and not irradiate. With 70 % of patients the pain arises in an epigastric area — it is an epigastric phase of acute appendicitis. In 2–4 hours it moves to the place of appendix existence (the Kocher's symptom). At coughing patients mark strengthening of pain in a right iliac area — it is a positive cough symptom.

Together with it, nausea and vomiting that have reflex character can disturb a patient. Often there is a delay of gases. The temperature of body of most patients rises, but high temperature can occur rarely and, mainly, it is a low grade fever. The general condition of patients gets worse only in case of growth of destructive changes in appendix.

During the examination it is possible to mark, that the right half of stomach falls behind in the act of breathing, and a patient wants to lie down on a right side with bound leg.

Painfulness is the basic and decisive signs of acute appendicitis during the examination by palpation in a right iliac area, tension of muscle of abdominal wall, positive symptoms of peritoneum irritation. About 100 pain symptoms characteristic of acute appendicitis are known, however only some of them have the real practical value.

The Blumberg's symptom. After gradual pressing by fingers on a front abdominal wall from the place of pain quickly, but not acutely, the hand is taken away. Strengthening of pain is considered as a positive symptom in that place. Obligatory here is tension of muscles of front abdominal wall.

The Voskresenskyy Symptom. By a left hand the shirt of patient is drawn downward and fixed on pubis. By the taps of 2–4 fingers of right hand epigastric area is pressed and during exhalation of patient quickly and evenly the hand slides in the direction of right iliac area, without taking the hand away. Thus there is an acute strengthening of pain.

The Bartomier's symptom is the increase of pain intensity during the palpation in right iliac area of patient in position on the left side. At such pose an omentum and loops of thin intestine is displaced to the left, and an appendix becomes accessible for palpation.

The Sitkovsky's symptom. A patient, that lies on left, feels the pain which arises or increases in a right iliac area. The mechanism of intensification of pain is explained by displacement of blind gut to the left, by drawing of mesentery of the inflamed appendix.

The Rovsing's symptom. By a left hand a sigmoid bowel is pressed to the back wall of stomach. By a right hand by ballotting palpation a descending bowel is pressed. Appearance of pain in a right iliac area is considered as a sign characteristic of appendicitis.

The Obrazcov's symptom. With the position of patient on the back by index and middle fingers the right iliac area of most painful place is pressed and the patient is asked to heave up the straightened right leg. At appendicitis pain increases acutely.

The Rozdolsky's symptom. At percussion there is painfulness in a right iliac area.

The general analysis of blood does not carry specific information, which would specify the presence of acute appendicitis. However, much leukocytosis and change of formula to the left in most cases can point to the present inflammatory process.

Acute appendicitis in children. With children of infancy acute appendicitis can be seen infrequently, but, quite often carries atypical character. All this is conditioned, mainly, by the features of anatomy of appendix, insufficient of plastic properties of the peritoneum, short omentum and high reactivity of child's organism. The inflammatory process in the appendix of children quickly makes progress and during the first half of days from the beginning of disease there can appear its destruction, even perforation. The child, more frequent than an adult, suffers vomiting. Its general condition gets worse quickly, and already the positive symptoms of irritation of peritoneum can show up during the first hours of a disease. The temperature reaction is also expressed considerably acuter. In the blood test there is high leukocytosis. It is necessary to remember, that during the examination of calmless children it is expedient to use a chloral hydrate enema.

Acute appendicitis of the people of declining and old ages can be met not so often, as of the persons of middle ages and youth. This contingent of patients is hospitalized to hospital rather late: in 2–3 days from the beginning of a disease. Because of the promoted threshold of pain sensitiveness, the intensity of pain in such patients is small, therefore they almost do not fix attention on the epigastric phase of appendicitis. More frequent are nausea and vomiting, and the temperature reaction is expressed poorly. Tension of muscles of abdominal wall is absent or insignificant through old-age relaxation of muscles. But the symptoms of irritation of peritoneum keep the diagnostic value with this group of patients. Thus, the sclerosis of vessels of appendix results in its rapid numbness, initially-gangrenous appendicitis develops. Because of such reasons the destructive forms of appendicitis prevail, often there is appendiceal infiltrate.

With pregnant women both the bend of appendix and violation of its blood flow are causes of the origin of appendicitis. Increased in sizes uterus causes such changes. It, especially in the second half of pregnancy, displaces a blind gut together with an appendix upwards, and an overdistended abdominal wall does not create adequate tension. It is needed also to remember, that pregnant women periodically can have a moderate pain in the abdomen and changes in the blood test. Together with that, psoas-symptom and the Bartomier's symptom have a diagnostic value at pregnant women.

Clinical passing of acute appendicitis at the atypical placing (not in a right iliac area) will differ from a classic vermiform appendix (Pic. 3.3.1).

Appendicitis at retrocecal and retroperitoneal location of appendiceal appendix can be with 8–20 % patients. Thus an appendix can be placed both in a free abdominal cavity and retroperitoneal. An atypical clinic arises, as a rule, at the retroperitoneal location. The patients complain at pain in lumbus or above the wing of right ilium. There they mark painfulness during palpation. Sometimes the pain irradiates to the pelvis and in the right thigh. The positive symptom of Rozanov — painfulness during palpation in the right Pti triangle is characteristic. In transition of inflammatory process on an ureter and kidney in the urines analysis red corpuscles can be found.

Appendicitis at the pelvic location of appendix can be met in 11–30 % cases. In such patients the pain is localized above the right Poupard's ligament and above pubis. At the very low placing of appendix at the beginning of disease the reaction of muscles of front abdominal wall on an inflammatory process can be absent. With transition of inflammation on an urinary bladder or rectum either the dysuric signs or diarrhea develops, mucus appears in an excrement. Distribution of process on internal genital organs provokes signs characteristic of their inflammation.

Appendicitis at the medial placing of appendix. The appendix in patients with such pathology is located between the loops of intestine, that is the large field of suction and irritation of peritoneum. At these anatomic features mesentery is pulled in the inflammatory process, acute dynamic of the intestinal obstruction develops in such patients. The pain in the abdomen is intensive, widespread, the expressed tension of muscles of abdominal wall develops, that together with symptoms of the irritation of peritoneum specify the substantial threat of peritonitis development.

For the subhepatic location of appendix the pain is characteristic in right hypocondrium. During palpation painfulness and tension of muscles can be marked.

Left-side appendicitis appears infrequently and, as a rule, in case of the reverse placing of all organs, however it can occur at a mobile blind gut. In this situation all signs which characterize acute appendicitis will be exposed not on the right, as usually, but on the left.

Among complications of acute appendicitis most value have appendiceal infiltrates and abscesses.

Appendiceal infiltrate is the conglomerate of organs and tissue not densely accrete round the inflamed vermiform appendix. It develops, certainly, on 3–5th day from the beginning of disease. Acute pain in the stomach calms down thus, the general condition of a patient gets better. Dense, not mobile, painful, with unclear contours, formation is palpated in the right iliac area. There are different sizes of infiltrate, sometimes it occupies all right iliac area. The stomach round infiltrate during palpation is soft and unpainful.

At reverse development of infiltrate (when resorption comes) the general condition of a patient gets better, sleep and appetite recommence, activity grows, the temperature of body and indexes of blood is normalized. Pain in the right iliac area calms down, infiltrate diminishes in size. In this phase of infiltrate physiotherapeutic procedure is appointed, warmth on the iliac area.

In two months after resorption of infiltrate appendectomy is conducted.

At abscessing of infiltrate the condition of a patient gets worse, the symptoms of acute appendicitis become more expressed, the temperature of body, which in most cases gains hectic character, rises, the fever appears. Next to that, pain in the right iliac area increases. Painful formation is felt there. In the blood test high leukocytosis is present with the acutely expressed change of leukocyte formula to the left.

Local abscesses of abdominal cavity, mainly, develops as a result of the atypical placing of appendix or suppuration. More frequent from other there are pelvic abscesses. Thus a patient is disturbed by pain

beneath the abcupula, there are dysuric disorders, diarrhea and tenesmus. The temperature of body rises to 38,0–39,0oC, and rectal — to considerably higher numbers. In the blood test leukocytosis, change of formula of blood is fixed to the left.

During the rectal examination the weakened sphincter of anus is found. The front wall of rectum at first is only painful, and then its overhanging is observed as dense painful infiltrate.

A subdiaphragmatic abscess develops at the high placing of appendix. The pain in the lower parts of thorax and in a upper quarter of abcupula ofn to the right, that increases at deep inhalationis except for the signs of intoxication, is characteristic of it. A patient, generally, occupies semisitting position. Swelling in an epigastric area is observed in heavy cases, smoothing and painful intercostal intervals. The abcupula ofn during palpation is soft, although tension in the area of right hypochondrium is possible. Painfulness at pressure on bottom (9–11) ribs is the early and permanent symptom of subdiaphragmatic abscess (the Krukov's symptom).

Roentgenologically the right half of diaphragm can fall behind from left one while breathing, and there is a present reactive exudate in the right pleura cavity. A gas bubble is considered the roentgenologic sign of subdiaphragmatic abscess with the horizontal level of liquid, which is placed under the diaphragm.

Interloop abscesses are not frequent complications of acute appendicitis. As well as all abscesses of abdominal cavity, they pass the period of infiltrate and abscess formation with the recreation of the proper clinic.

The poured festering peritonitis develops as a result of the timely unoperated appendicitis. Diagnostics of this pathology does not cause difficulties.

Pylephlebitis is a complication of both appendicitis and after-operative period of appendectomy.

The reason of this pathology is acute retrocecal appendicitis. At it development the thrombophlebitis process from the veins of appendix, passes to the veins of bowels mesentery, and then on to the portal vein. Patients complain at the expressed general weakness, pain in right hypochondrium, high hectic temperature of body, fever and strong sweating. Patients are adynamic, with expressed subicteritiousness of the scleras. During palpation painfulness is observed in the right half of abcupula ofn and the symptoms of irritation of peritoneum are not acutely expressed.

In case with rapid passing of disease the icterus appears, the liver is increased, kidney-hepatic insufficiency makes progress, and patients die in 7-10 days from the beginning of disease. At gradual subacute development of pathology the liver and spleen is increased in size, and after the septic state of organism ascites arises.

Acute appendicitis is differentiated with the diseases which are accompanied by pain in the abcupula ofn.

Food toxicoinfection. Complaints for pain in the epigastric area of the intermittent character, nausea, vomitings and liquid emptying are the first signs of disease. The state of patients progressively gets worse from the beginning. Next to that, it is succeeded to expect that a patient used meal of poor quality. However, here patients do not have phase passing, which is characteristic of acute appendicitis, and clear localization of pain. Defining the symptoms of irritation of peritoneum is not succeeded, the peristalsis of intestine is, as a rule, increased.

Acute pancreatitis. In anamnesis in patients with this pathology there is a gallstone disease, violation of diet and use of alcohol. Their condition from the beginning of a disease is heavy. Pain is considerably more intensive, than during appendicitis, and is concentrated in the upper half of abcupula ofn. Vomiting is frequent and does not bring to the recovery of patients.

Perforative peptic and duodenum ulcer. Diagnostic difficulties during this pathology arise up only on occasion. They can be in patients with the covered perforation, when portion of gastric juice flows out in an abdominal cavity and stays too long in the right iliac area, or in case of atypical perforations. Taking it into account, it is needed to remember, that the pain in the perforative ulcer is considerably more intensive in epigastric, instead of in the right iliac area. On the survey roentgenogram of organs of abdominal cavity under the right cupula of diaphragms free gases can be found.

The apoplexy of ovarya more frequent is with young women and, as a rule, on 10-14 day after menstruation. Pain appears suddenly and irradiate in the thigh and perineum. At the beginning of disease there can be a collapse. However, the general condition of patients suffers insignificantly. When not enough blood was passed in the abdominal cavity, all signs of pathology of abdominal cavity organs calm down after some time. Signs, which are characteristic of acute anaemia, appear at considerable hemorrhage. Abdomen more frequent is soft and painful down, (positive Kulenkampff's symptom: acute pain during palpation of stomach and absent tension of muscles of the front abdominal wall).

During paracentesis of back fornix the blood which does not convolve is got.

Extra-uterine pregnancy. A necessity to differentiate acute appendicitis with the interrupted extra-uterine pregnancy arises, when during the examination the patient complains at the pain only down in the stomach, more to the right. Taking it into account, it is needed to remember, that at extra-uterine pregnancy a few days before there can be intermittent pain in the lower part of the abdomen, sometimes excretions of "coffee" colour appear from vagina. In anamnesis often there are the present gynaecological diseases, abortions and pathological passing of pregnancy. For the clinical picture of such patient inherent sudden appearance of intensive pain in lower part of the abdomen. Often there is a brief loss of consciousness. During palpation considerable painfulness is localized lower, than at appendicitis, the abdomen is soft, the positive Kulenkampff's symptom is determined. Violations of menstrual cycle testify for pregnancy, characteristic changes are in milk glands, vagina and uterus. During the vaginal examination it is sometimes possible to palpate increased tube of uterus. The temperature of body more frequently is normal. If hemorrhage is small, the changes in the blood test are not present. The convincing proof of the broken extra-uterine pregnancy is the dark colour of blood, taken at puncture of back fornix of vagina.

Acute cholecystitis. The high placing of vermiform appendix in the right half of abdomen during its inflammation can cause the clinic somewhat similar to acute cholecystitis. But unlike appendicitis, in patients with cholecystitis the pain is more intensive, has cramp-like character, is localized in right hypochondrium and irradiate in the right shoulder and shoulder-blade. Also the epigastric phase is absent. The attack of pain can arise after the reception of spicy food and, is accompanied by nausea and frequent vomiting by bile. In anamnesis patients often have information about a gallstone disease. During examination intensive painfulness is observed in right hypochondrium, increased gall-bladder and positive symptoms Murphy's and Ortner's.

Right-side kidney colic. For this disease tormina at the level of kidney and in lumbus is inherent, hematuria and dysuric signs which can take place at the irritation of ureter by the inflamed appendix. Intensity of pain in kidney colic is one of the basic differences from acute appendicitis. Pain at first appears in lumbus and irradiate downward after passing of ureter in genital organs and front surface of the thigh. In diagnostics urogram survey is important, and if necessary — chromocystoscopy. Absence of function of right kidney to some extent allows to eliminate the diagnosis of acute appendicitis.

As experience of surgeons of the whole world testifies, in acute appendicitis timely operation is the unique effective method of treatment.

Access for appendectomy must provide implementation of operation. McBurney's incision is typical.

When during operation the appendix without the special difficulties can be shown out in a wound, antegrade appendectomy is executed. On clamps its mesentery is cut off and ligated. Near the basis the appendix is ligated and cut. Stump is processed by solution of antiseptic and peritonized by a purse-string suture (Pic. 3.3.2).

If only the basis of appendix is taken in a wound, and an apex is fixed in an abdominal cavity, more rationally retrograde appendectomy is conducted (Pic. 3.3.3). Thus the appendix near basis is cut between two ligatures. Stump is processed by antiseptic and peritonized. According to it the appendix is removed in the direction from basis to the apex. According to indication operation is concluded by draining of abdominal cavity (destructive appendicitis, exudate in an abdominal cavity, capillary hemorrhage from the bed). In recent years the laparoscopy methods of appendectomy are successfully performed.

In patients with appendiceal infiltrate it is necessary to perform conservative-temporizing tactic. Taking it into account, bed rest is appointed, protective diet, cold on the area of infiltrate, antibiotic therapy. According to resorption of infiltrate, in two months, planned appendectomy is executed.

Treatment of appendiceal abscess must be only operative. Opening and drainage of abscess, from retroperitoneal access, is performed. To delete here the appendix is not necessary, and because of denger of bleeding, peritonitis and intestinal fistula — even dangerously.

Intestinal obstruction is a complete or partial violation of passing of maintenance by the intestinal tract.

The principal reasons of intestinal obstruction can be:

- 1) commissures of abdominal cavity after traumas, wounds, previous operations and inflammatory diseases of organs of abdominal cavity and pelvis;
- 2) long mesentery of small intestine or colon, that predetermines considerable mobility of their loops;
- 3) tumours of abdominal cavity and retroperitoneal space.

Such principal reasons can cause violation of passing of intestinal maintenance, disorder of suction from the intestine and loss of plenty of electrolytes both from vomiting and in the intestine cavity as a result of disorders of bloodflow in its wall.

The morphological signs of dynamic intestinal obstruction are: small thickening of wall (at considerable paresis is thinning), friability of tissue (the bowel breaks easily) and presence of liquid maintenance and gases in cavity of bowel. At mechanical obstruction it is always possible to expose the obstacle: strang, commissures, tumours, jamnings of hernia, cicatricial strictures, wrong entered drainages, tampons and others like that. In place of compression strangulation is exposed. The bowel loop higher strangulation is extended, and distally — collapsed. In case of released invagination on small distance two strangulation furrows are observed, and distally from the second ring cylinder expansion of bowel lumen is observed.

Beginning of clinical signs of intestinal obstruction is sudden — in 1–2 hours after taking the meal. The pain in the abdomen has the intermittent character and is met in all forms of mechanical intestinal obstruction. However, some types of strangulated intestinal obstruction (node formation, volvulus of thin and colons) can be accompanied by permanent pain. It is needed to mark that at spike intestinal obstruction, invagination and obturation cramp-like pain can be considered as pathognomic sign of disease. For paralytic intestinal obstruction more frequent is inherent permanent pain which is accompanied by the progressive swelling of abdomen. At spastic obstruction of intestine the pain is mainly acute, the abdomen is not blown away, sometimes pulled in.

Nausea and vomiting are met in 75–80 % patients with the heaviest forms of high level of intestinal obstruction (node formation, volvulus of small intestine, spike obstruction). At obturation obstruction and invagination they are observed not so often.

There is a characteristic thirst which can be considered as an early symptom. Besides, the higher intestinal obstruction, the greater the thirst.

Swelling of abdomen, the delay of emptying and gases are observed in 85–90% patients, mainly, with the high forms of obstruction (volvulus of small intestine, spike intestinal obstruction).

Together with that, for invagination emptying by liquid excrement with the admixtures of mucus and blood are more characteristic.

In patients during palpation the soft abdomen is observed, sometimes — with easy resistance of front abdominal wall, and at percussion — high tympanitis. At auscultation at the beginning of disease increased peristaltic noises are present, then gradual fading of peristalsis is positive (the Mondor's symptom, "noise of beginning, quietness of end").

There are other symptoms pathognomic for intestinal obstruction.

The Vala's symptom is the limited elastic sausage-shaped formation.

The Sklarov's symptom is the noise of intestinal splash.

The Kywul's symptom is the clang above the exaggerated bowel.

The Schlang's symptom is the peristalsis of bowel, that arises after palpation of abdomen.

The Spasokukotsky's symptom is "noise of falling drop".

The Hoehenegg's symptom — incompletely closed anus in combination with balloon expansion of ampoule of rectum.

At survey roentgenoscopy or -graphy of the abdominal cavity in the loops of bowels liquids and gas are observed — the Klobjer's bowl (Pic. 3.3.4).

Strangulated obstruction. The ischemic component is the characteristic feature of this form of intestinal obstruction, that is investigation of squeezing of mesentery vessels, which determines the dynamics of pathomorphologic changes and clinical signs of disease, and the basic place among them belongs to the pain syndrome. Consequently, sudden appearance of disease, acuteness of pain syndrome and ischemic disorders in the wall of bowel cause necrosis changes of area of bowel pulling in a process. It is accompanied by the making progress worsening of the patient condition and origin of endotoxiosis.

Obturation intestinal obstruction, unlike strangulated, pass not so quickly. In its clinical picture on the first place there are the symptoms of violation of passage on the intestine (protracted intermittent pain, flatulence), instead of symptoms of bowel destruction and peritonitis.

For high, especially strangulated, intestinal obstruction progressive growth of clinical signs of disease and violation of secretory function of intestine is inherent. Thus the volume of circulatory blood diminishes, the level of haematocrit rises and leukocytosis grows. There are also deep violations of homeostasis (hypoproteinemia, hypokalemia, hyponatremia, hypoxia and others like that). In patients with low intestinal obstruction above-named signs are less expressed, and their growth is related to more protracted passing of disease. Invagination of bowel which can be characterized by the triad of characteristic signs is

the special type of intestinal obstruction with the signs of both obturation and strangulation: 1) periodicity of appearance of the intermittent attacks of pain in the abdomen; 2) presence of elastic, insignificantly painful, mobile formation in an abdominal cavity; 3) appearance of blood in the excrement or its tracks (at rectal examination).

The special forms of obturation intestinal obstruction is the obstruction caused by gall-stones. The last are got in the small intestine as a result of bedsores in the walls of gall-bladder and bowel, that adjoins to it. It is needed to mention that intestinal obstruction can be caused by concretum with considerably more small diameter than bowel lumen. The mechanism of such phenomenon is related to irritating action of bilious acids on the bowel wall. The last answers this action by a spasm with the dense wedging of stone in the bowel lumen.

Development of intestinal obstruction caused by gall-stones the attack of colic and clinic of acute cholecystitis precede always. Characteristically, that in the process of development of disease the pain caused by acute cholecystitis calms down, whereupon the new pain characteristic of other pathology — intestinal obstruction appears.

Dynamic intestinal obstruction is divided into paralytic and spastic. Paralytic obstruction often arises after different abdominal operations, inflammatory diseases of organs of abdominal cavity, traumas and poisonings. The reason of spastic intestinal obstruction can be the lead poisonings, low-quality meal, neuroses, hysterias, helminthiasis and others like that. Clinic of dynamic intestinal obstruction is always variable in signs and depends on a reason, that caused it. Disease is characterized by pain in the abdomen, delay of gases and emptying. During palpation the abdomen is blown away, painful, however soft. To diagnose this form of intestinal obstruction is not difficult, especially, if its etiology is known.

Hemostatic intestinal obstruction develops after embolism or thromboses of mesenteric arteries and thromboses of veins, there can be mixed forms. Embolism of mesenteric arteries arises in patients with heart diseases (mitral and aortic failings, heart attack of myocardium, warty endocarditis) and declared by damaging, mainly, upper mesentery arteries. Beginning of disease, certainly, is acute, with nausea, sometimes — vomiting. At first there is a picture of acute abdominal ischemic syndrome, that is often accompanied by shock (frequent pulse, decline of arterial and pulse pressure, death-damp, cyanosis of mucus membranes and acrocyanosis). Patients become excitative, uneasy, occupy the forced knee-elbow position or lie on the side with bound legs.

During the examination the abdomen keeps symmetry, abdominal wall is soft, the increased peristalsis is heard from the first minutes during 1–2 hours (hypoxic stimulation of peristalsis), which later goes out gradually (“grave quiet”). According to the phenomena of intoxication peritonitis grow quickly. At the beginning of disease the delay of gases and emptying is observed, later there is diarrhea with the admixtures of blood in an excrement. When the last is heavy to set macroscopically, it is needed to explore scourage of intestine.

Intestinal obstruction must be differentiated with the acute diseases of organs of abdominal cavity.

The perforation of gastroduodenal ulcer, as well as intestinal obstruction, passes acutely with inherent to it by sudden intensive pain and tension of muscles of abdomen. However, in patients with this pathology, unlike intestinal obstruction, the abdomen is not exaggerated, and pulled in with “wooden belly” tension of muscles of front abdominal wall. There is also characteristic ulcerous anamnesis. Roentgenologic and by percussion pneumoperitoneum is observed. Certain difficulties in conducting of differential diagnostics of intestinal obstruction can arise at atypical passing and in case of the covered perforations.

Acute pancreatitis almost always passes with the phenomena of dynamic intestinal obstruction and symptoms of intoxication and repeated vomiting, with rapid growth. During the examination in such patients, unlike intestinal obstruction, rigidity of abdominal wall and painfulness is observed in the projections of pancreas and positive Korte's symptom and Mayo-Robson's. The examination of diastase of urine and amylase of blood have important value in establishment of diagnosis.

Acute cholecystitis. Unlike intestinal obstruction, patients with this pathology complain for pain in right hypochondrium, that irradiate in the right shoulder-blade, shoulder and right subclavian area. Difficulties can arise, when the symptoms of dynamic intestinal obstruction appear on the basis of peritonitis.

The clinic of kidney colic in the signs and character of passing are similar to intestinal obstruction, however, attacks of pain in the lumbar area with characteristic irradiation in genital parts, the thigh and dysuric disorders help to set the correct diagnosis. Certain difficulties in conducting of differential diagnostics also can arise in difficult patients, at frequent vomiting which sometimes can be observed in patients with kidney colic.

During the first 1,5–2 hours after hospitalization of patient complex conservative therapy which has the differential-diagnostic value and can be preoperative preparation is conducted.

It is directed on warning of the complications related to pain shock, correction of homeostasis and, simultaneously, is the attempt of liquidation of intestinal obstruction by unoperative methods.

1. The measures directed for the fight against abdominal pain shock include conducting of neuroleptanalgesia, procaine paranephric block and introduction of spasmolytics. Patients with the expressed pain syndrome and spastic intestinal obstruction positive effect can be attained by epidural anaesthesia also.

2. Liquidation of hypovolemia with correction of electrolyte, carbohydrate and albuminous exchanges is achieved by introduction of salt blood substitutes, 5–10 % solution of glucose, gelatin, albumen and plasma of blood. There are a few methods suitable for use in the urgent surgery of calculation of amount of liquid necessary for liquidation of hypovolemia. Most simple and accessible is a calculation by the values of hematocrit. If to consider 40 % for the high bound of hematocrit norm, on each 5 % above this size it is needed to pour 1000 ml of liquids.

3. Correction of hemodynamic indexes, microcirculation and disintoxication therapy is achieved by intravenous infusion of Reopolylukline and Neohemodes.

4. Decompression of intestine tract is achieved by conducting of nasogastric drainage and washing of stomach, and also conducting of siphon enema. It is needed to underline that technically the correct conducting of siphon enema has the important value for the attempt of liquidation of intestinal obstruction by conservative facilities, therefore this manipulation must be conducted in presence of a doctor. For such enema the special device is used with the rectal tip, by a PVC pipe by a diameter of 1,5–2,0 cm and watering-can of very thin material. A liquid into the colon is brought to appearance of the pain feeling, then drop the watering-can below the level of patient who lies. The passage of gases and excrement is looked after. As a rule, this manipulation is to repeat repeatedly with the use of plenty of warm water (to 15–20 and more litres).

Liquidating of the intestinal obstruction by such conservative facilities is succeeded in 50–60 % patients with mechanical intestinal obstruction.

Patients with dynamic paralytic intestinal obstruction are expedient to stimulation of peristalsis of intestine to be conducted, besides, necessarily after infusion therapy and correction of hypovolemia. A lot of kinds of stimulation of intestine peristalsis are offered. Most common of them are:

1) hypodermic introduction of 1,0 ml of 0,05 % solution of proserin; 2) through 10 min — 60 ml intravenously stream of 10 % solution of chlorous sodium; 3) hypertensive enema.

Surgical treatment of intestinal obstruction must include such important moments:

1. According to middle laparotomy executed the novocaine blockade of mesentery of small and large intestine and operative exploration of abdominal cavity organs during which the reason of intestinal obstruction and expose viability of intestine is set.

The revision at small intestine obstruction begins from the Treitz' ligament to iliocecal corner. At large intestine obstruction the hepatic, splenic and rectosigmoid parts are observed intently. Absence of pathological processes after revision needs the examination of places of cavity and jamming of internal hernia: internal inguinal and femoral rings, obturator openings, pockets of the Treitz' ligament, Winslow's opening, diaphragm and periesophageal opening.

2. Liquidation of reasons of obstruction (scission of connection, that squeezes a bowel, violence of volvulus and node formation of loops, desinvagination, deleting of obturative tumours and others like that).

It is needed to mark that the unique method of liquidation of acute intestinal obstruction does not exist. At the lack of viability of bowel the resection of nonviable area is executed with 30–40 cm of afferent and 15–20 cm of efferent part with imposition of “side-to-side” anastomosis (Pic. 3.3.5) or “end-to-end” (Pic. 3.3.6).

3. Intubation. Decompression of intestine foresees conducting in the small intestine of elastic probe by thickness of 8–9 mm and length of 3–3,5 m with the plural openings by a diameter 2–2,5 mm along all probe, except for part, that will be in the oesophagus, pharynx and outwardly. A few methods of conducting of probe are offered in a bowel (nasogastric, through gastrostomy, ceco- or appendicostoma). Taking it into account, such procedure needs to be executed individually and according to indications.

Each of them has the advantages and failings. In connection with the threat of origin of pneumonia, entering an intubation probe to the patients of old ages is better by means of gastrostomy. Most surgeons avoid the method of introduction of probe through ceco- or appendicostoma because of technical difficulties of passing in a small intestine through a Bauhin's valve. Today the most wide clinical application has intubation of intestine extracted by the nasogastric method with the use of other thick probe as explorer of the first (by L.J. Kovalchuk, 1981). Such method not only simplifies procedure of intubation but also facilitates penetration through the piloric sphincter and duodenojejunal bend, and also warns passing of intestinal maintenance in a mouth cavity and trachea. Thus probe is tried to be conducted in the small intestine as possible farther and deleted the next day after appearance of peristalsis and passage of gases, however not later than on 7th days, because more protracted sign of probe carries the real threat of formation of bedsores in the wall of bowel.

4. Sanation and draining of abdominal cavity is executed by the generally accepted methods of washing of antiseptic. Draining of the abdominal cavity it is needed from four places: in both iliac areas and both hypochondrium, better by the coupled synthetic drainpipes.

Crohn's disease is an unspecific inflammatory process of submucosal membrane of gastrointestinal tract with propensity to the segmental lesions and recurrent passing. The local signs of disease exist in different areas of digestive tract organs, however, most frequent and most intensive they are in the distal segment of small intestine, therefore it was named terminal ileitis.

The reason of origin of the Crohn's disease for today is not finally found out. An infection and allergy are infringement factors. Together with that, granuloma, which is exposed at histological examination with present in its lymphocytic and protoplasmatic infiltrations, grounds to consider that the defined value in the origin of the Crohn's disease have immune factors. Thus inflammation begins in the submucosal membrane, and afterwards engulfs all bowel walls. The mucus membrane acquires the crimson colouring, there are deep cracks and ulcers. Combination of the damaged areas of mucus membrane with healthy creates a picture similar to the roadway. In future granuloma appears, an inflammatory process goes out outside the wall of bowel and gets to the contiguous organs (large and small intestines, urinary bladder, abdominal wall). In the eventual result there are infiltrate, abscesses and fistula. Finally, it is needed to mark that the people of young ages mainly are ill by terminal ileitis.

The morphological changes are concentrated, mainly, in the terminal part of iliac bowel, anal segment of rectum and appendix. Internal surface is hilly, thickened, swelling, deep ulcers are intermittent with the unchanged areas of mucus. The serous tunic is covered by plural, similar on tuberculosis, knots. Mesentery is sclerosed, regional lymphatic knots are hyperplastic, of whiter-rose color. By the most characteristic microscopic sign of Crohn's disease is presence of unspecific sarcoid granuloma. Hyperplasia of lymphoid elements of submucosal membrane and formation of fissured ulcers is observed also.

The Crohn's disease begins from the insignificant signs as a general weakness, increase of temperature of body, intermittent pain, that arises after the reception of meal, diarrhea without some visible features or with the admixture of blood. As this process strikes the terminal segment of small intestine, pain is concentrated in the right iliac area. Together with that, at localization of pathological focus in a colon with an anal segment pain is concentrated by its passing to the anal opening. A granuloma process takes place in the area of oesophagus, abdomen or duodenum, pain can arise up in the area of lesions. With progress of disease on endoscopy examination (proctosigmoidoscopy, fiberoptic colonoscopy, fiberoptic gastroscopy) hyperemia and deep cracks of mucus membrane, ulcers, symptom of “roadway” and stenosis are observed. At roentgenoscopy survey of organs of abdominal cavity in patients with the perforation it is possible to expose pneumoperitoneum, and at contrasting sciagraphy — stenosis of initial part of stomach, presence of ulcers or granuloma in the oesophagus. The examination of the passage on the small intestine enables to eliminate or confirm stenosis (Pic. 3.3.7). Irrigoscopy determines the defect of filling.

At acute passing of terminal ileitis, the pain appears acute in the right iliac area, sometimes intermittent, accompanied by nausea, vomitings, emptying by a liquid excrement with the admixture of blood or delay of emptying. During the examination of patient the abdomen can be exaggerated, tension of muscles and positive symptoms of irritation of peritoneum, high temperature is observed. In the general analysis of blood leukocytosis is present with the change of leukocyte formula to the left. In such difficult situation often only laparotomy helps to specify the diagnosis. The swollen segment of iliac bowel is thus observed with increased mesentery lymphatic knots. The changed area of bowel can perforate in the free abdominal cavity or penetrate in the contiguous loops of large or small intestine. It causes forming of inflammatory infiltrate, and in future — abscess formation. The unoperated abscesses are always inclined to the independent opening in surrounding organs with subsequent formation of fistula ducts.

The disease with the lesions of other parts of small and large intestine passes acutely (granulomatous enteritis, colitis). By palpation in these patients painful infiltrate is exposed, which by the character remind the clinic of invagination. Only the meticulous examination and present data analysis enable to set correct diagnosis. At granulomatous proctitis the plural cracks of mucus membrane without the signs of spasm of sphincter appear often, on the basis of which afterwards there are ulcers, that badly granulate. The same changes can develop on skin round the anal opening.

The chronic forms of disease often pass with insignificant symptoms. From the beginning of disease to establishment of diagnosis sometimes 1–2 years and more pass. Such patients periodically complain for pain, diarrhea, weight loss, increase of body temperature, nausea, vomitings and bleeding from a rectum.

Objectively in the abdominal cavity painful infiltrate is determined, and at laboratory examination — anaemia and hypoproteinemia.

Complications of the Crohn's disease can be divided into local and general. Among local, formations of fistula which arise on the front abdominal wall between the damaged bowel and surrounding organs are most characteristic (ileoileal fistula, entero-entero, enterovesical fistula). Sometimes fistulas are opened in the area of scars after the operations on the lateral wall of abdomen or in the area of anus. Next to that, stenosis inflammatory infiltrate of bowel can be transformed in acute or chronic intestinal obstruction. Some patients have the obvious threat of perforation of the changed wall of bowel or intestinal bleeding. The protracted passing of disease can be also complicated by malignization. The aphthous ulcers of tongue, node erythema, arthritises and chronic lesions of liver are general complications.

The Crohn's disease must be differentiated with the unspecific ulcerous colitis and cancer of colon.

An unspecific ulcerous colitis mainly initially strikes the mucus membrane of all colon. The disease is accompanied by the excreta with the excrement of plenty of blood and mucus. For Crohn's disease languid passing of disease is characteristic. Acute passing of disease is met considerably rarer, than chronic. The modern methods of endoscopic examination with the biopsy of mucus membrane, which helps to specify diagnosis, are helpful in differential diagnostics.

The cancer of colon is mostly accompanied by formation of deep ulcers and infiltrate. However, for the cancer process slowly progressive passing without the periods of remission is more inherent, thus the disease more frequently ends with the phenomena of intestinal obstruction. At roentgenologic examination on the background the relatively unchanged colon the lonely defect of filling is observed, and during colonoscopy — thrusting out in the lumen of bowel with an erosive surface or signs of disintegration. Histological examination of biopsy material enables to expose cancer cells.

Conservative treatment. The diet of patient, generally, must be ordinary, except for products with bad intestinal uptake. The medicine of the first row is 5-ASK (aminosalicylic acid, sulfasalazone and glucocorticoid). The medicines of the second row are: 6- mercaptopurine, azatiopurine and metronidazole. At diarrhea diphenoxilate is used — 5 ml peroral three times per days, loperamide — 2 mg peroral 3–4 times per days, smecta — 1 pack 3 times per days. At the expressed anaemia, to the considerable loss of weight, system complications, relapse of disease after operation prednisolone is applied — for 40–60 mg peroral every day during 1–2 weeks. After that its day's dose is diminished to 10–20 mg during 4–6 weeks and, in the end, stopped. For patients which are irresponsive to steroid, asatioprine is appointed (2 mg/kr) peroral. Metronidazole in a dose of 400 mg twice a days is used in the case of granulomatous disease of perineum.

The presence of external and internal fistula, stenosis of bowel, perforation and recurrent bleeding is an indication to operative treatment. The method of choice of operation is the segmental resection of the pathologically changed bowel in the distance of 30–35 cm of proximal and distal from the damaged area. The regional lymph nodes is also deleted. In case of the perforation of bowel with poured peritonitis, it is recommend not to perform primary anastomosis because of possible insolvency of stitches after the resection. In this connection, afferent and efferent loops exteriorizes on the wall of abdomen as two-channel stoma (Pic. 3.3.8). The passage by an intestine (liquidation of stoma) is restored in 2–4 months after liquidation of the peritonitis signs.

An unspecific ulcerous colitis is a diffuse inflammatory process that is accompanied by the ulcerous-necrosis changes in the mucus membrane of colon and rectums.

Etiology of unspecific ulcerous colitis to this time is not finally found out. This disease is suffered by people in the age from 20 to 40 years. An infectious factor in development of disease for today is not confirmed. However, as the exception of meal of food allergens (milk, eggs) results in the improvement of passing of disease, it is possible to consider that allergy assists to development of inflammatory process. Important significance in genesis of this pathology is also attached to immunological violations. In the blood of patient sensibilizing on the antigen of mucus membrane of colon specifically lymphocytes and immune complexes are found. The antigen-antibody reaction can cause colitis. In most patients with the chronic recurrent unspecific ulcerous colitis a stress situation causes the process of acuteing. In future, obviously, there are violations of microcirculation and cellular structures, and also the transport system of cells membranes suffers, that carries potassium and sodium ions. Taking it into account, the timely exposure of disease in which the process is localized and has a reverse tendency, can result in the positive therapeutic effect.

In patients with an unspecific ulcerous colitis the relatively isolated damages of rectum and sigmoid colon, sigmoid colon and transverse colon, so total colitis are met. The necrosis component prevails as the acute form. The wall of bowel in such cases is swollen, hyperemic, with plural erosions and ulcers of irregular form. Its infiltration by lymphocytes, plasmocytes and eosinophils with characteristic formation of granulation, crypt and abscesses are microscopically observed. In patients with a chronic process prevail, mainly, reparative-sclerotic processes. A bowel is deformed, dense, segmentally narrowed. As a result of the disfigured regeneration plural granulomatous and adenomatous pseudopolypuses appear.

Pain in the abdomen and diarrhea is one of basic signs of unspecific ulcerous colitis with emptying from 3 to 20 and more times per days. Thus during defecation the mixture of liquid excrement, mucus and blood are observed. As far as progress of disease the pain has the intermittent character and is localized by the passing of colon. By palpation it is spastic and painful. Frequent diarrhea is brought to dehydration, loss of electrolytes, albumen and anaemia. Patients are weak, there are the strongly expressed signs of intoxication, the temperature of body rises to 40 oC and the psyche is repressed. Characteristic also are tachycardia, decline of arterial pressure, avitaminosises and edema. Hypochromic anaemia is exposed in the general analysis of blood, leukocytosis, change of leukocyte formula to the left and increased ESR. In plasma of blood the decline of maintenance of potassium and sodium ions and level of general protein, especially albumen are marked. In future there are the progressive degenerative changes of parenchymatous organs.

At endoscopic examination (proctoscopy, fiberoptic colonoscopy) hyperemia of mucus membrane, swollen, contact bleeding, plural erosions, ulcers, festering and necrosis stratifications, are observed. At heavy passing of disease fiberoptic colonoscopy or irrigoscopy always has the danger of perforation or acute bowel dilatation, therefore more rationally it is to conduct it in the period of calming down of inflammatory process. During roentgenoscopy survey of organs of abdominal cavity in case of disease, complicated of acute toxic dilatation, the extended (from 10 to 20 cm and more) pneumatized bowel is exposed. During the perforation of bowel signs of pneumoperitoneum are present (air under the right cupula of diaphragm). Contrasting irrigoscopy examination in such patients enables to establish the presence of "water-pipe" symptom. Thrusting out of tailings of well-kept mucus membrane on the background of plural ulcers and cicatricial changes of bowel walls at pseudopolyposis creates roentgenologic reality of "shot target through" symptom (Pic. 3.3.9). Often in case of transformation of ulcerous colitis in the cancer on roentgenograms, stenosis cavity of bowel or defect of filling is observed (Pic. 3.3.10).

Acute, especially fulminant form of the unspecific ulcerous colitis passes the heaviest, so the prognosis is always doubtful. Taking it into account, death can come in the first days of disease. Thus an inflammatory process will strike all colon. During 1–2 days the heavy clinical picture is observed with frequent diarrhea with mucus, blood and pus, vomiting, dehydration and loss of weight of body. Next to that, deep intoxication, darkened consciousness, and the temperature of body rises to 39–40 oC is present. The expressed anaemia, tachycardia and hypovolemia are observed. The loss of albumens causes the decline of oncotic pressure and causes dehydration. The disbalance of electrolytes grows with progress of disease, microcirculation gets worse and day's diuresis goes down. In most cases this form of disease requires urgentoperative treatment (absolute indications).

A chronic recurrent unspecific ulcerous colitis is characterized by the periods of acuteing and remission. Thus in patients with the total lesions of colon in the period of acuteing the heavy degree of disease is observed, and in the period of remission — middle or even easy degree of disease, thus, such "calming down" can last 6 months and more.

A chronic continuous unspecific ulcerous colitis at the total lesions of intestine in most patients passes as middle heavy degree, and in the period of worsening the disease takes heavy shape. The easy form is met, mainly, at presence of inflammatory process in the rectum and sigmoid colon, considerably rarer it is at the lesions of left half of colon and quite rarely — at the total lesions in the period of calming down of the process. Conventionally, the unspecific ulcerous colitis begins from the rectum and engulf all parts of colon. Thus emptying are 2–3 times per days with the admixtures of mucus, sometimes blood. Thus, diarrhea can be intermittent with constipation. The temperature of body remains within the limits of norm. From the side of global and biochemical analysis of blood noticeable changes do not arise. Weight of body does not diminish. At endoscopic examination hyperemia of mucus membrane, contact bleeding, expressed vascular picture, erosions, point hemorrhages and superficial ulcers are observed. It is needed also to mark that in this situation the presence of erosions must be equated with an ulcerous process.

The middle heavy form of disease of the unspecific ulcerous colitis can be met in patients with the ulcerous colitis and proctosigmoiditis in the period of process acuteing. Thus there are the subjective feelings with considerable expression of tenesmus and heartburns.

The chronic forms of unspecific ulcerous colitis both at total and at the left-side lesions of colon, pass at the level of middle heavy degree. Frequency of emptying reaches to 5–10 times with mucus, blood and pain. Low grade fever, general weakness, nausea and loss of appetite appear, and weight of body diminishes on 5–8 kg. Moderate anaemia is exposed in the general analysis of blood, leukocytosis, increased ESR. Among the biochemical indexes of blood hypoproteinemia and hypokalemia are marked. At endoscopic examination of colon there is a considerable hyperemia and edema of mucus membrane, plural erosions, contact bleeding and superficial ulcers.

The heavy form of unspecific ulcerous colitis is at the total lesions, especially with acute, and also chronic recurrent passing of disease. The temperature of body in such patient rises to 39–40 oC, there is diarrhea (more than 10 times per days) with mucus, blood and pus, vomitings, heavy intoxication grows, weight loss on 25–30 kg, acutely expressed anaemia, leukocytosis with the change of leukocyte formula to the left, considerable changes of albuminous and electrolyte exchanges. At endoscopic examination of colon the blood is exposed in its cavity, slid, pus, fibrin incrustation, often pseudopolypuses and almost complete absence of mucus membrane. Roentgenologically some signs of complications of unspecific ulcerous colitis are confirmed.

The complications are divided into local and general. Local complications are: profuse intestinal bleeding, perforation, acute toxic dilatation, stenosis and malignization. To general the following are included: damage of liver (hepatitis, cirrhosis), stomatitis, ulcer of lower extremities, lesions of joints, eyes and skin.

Acute dysentery passes with bloody diarrheas, increased temperature of body, pain in the abdomen. Bacteriological examination of excrement enables to expose dysenteric bacillus and specify diagnosis.

Crohn's disease (granulomatous colitis) is this local process, that begins from the submucosal layer of bowel and distributes outside of walls with subsequent formation of infiltrate, abscesses and fistula. Exposure of granulomas, and during microscopic examination — accumulation of lymphocytes, neutrophils, protoplasmatic cells and the Pyrohov-Lunghans' cells are confirmed diagnosis.

The cancer of colon, in particular its enterocolitis and toxicoanaemic forms, also often can simulate an unspecific ulcerous colitis. Irrigoscopy, fiberoptic colonoscopy with biopsy and subsequent histological examination almost always help to diagnose cancer process.

Treatment of unspecific ulcerous colitis, certainly, begins with application of conservative facilities. Thus patients with easy and middle heavy forms must be under protracted conservative treatment.

The leading role is taken to the parenteral feed of patients with heavy common exhaustion (hydrolyzate of casein, aminopeptid, amynsol, vamin, alvesin, moriamin, intralipid, lipofundin, glucose and others like that). Electrolytes (chloride of sodium, sulfate of magnesium, chloride of potassium, panangin) and vitamins are entered (B6, B12, C, K, PP and others). Intensity and methods of conservative therapy always must depend on the phase of disease:

- moderately expressed passing of disease or proctitis — corticosteroid enema and sulfasalazone peroral;
- at heavy passing is parenteral introduction of liquids, nutritives, blood transfusion, system use of corticosteroids, surgical treatment;
- at chronic passing is corticosteroids peroral, asatioprine, surgical treatment;
- at remission is preparations of 5-aminosalicylic acid peroral, examination for the exception of cancer of colon.

The heavy form of passing of disease is absent of effect from the conducted conservative treatment during two weeks and progress of process testifies to the necessity of surgical treatment.

The conservative treatment must include antibacterial agent, antidiarrheal preparations, steroid hormone.

A diet is considered an important factor in treatment of such patient (diet № 4). Thus it is recommended to take a meal to 6 times per days by small portions, withdrawing milk, fruit, vegetables, wheat and rye bread from it. It is possible to appoint unfat meat and fish. Parenteral introduction of vitamins B, C, A, folic acid are helpful.

The basic antiinflammatory facilities are: sulfasalazopreparations (sulfasalazone, salazopirine), salicylazosulfanilamide (salazosulfa-pyridine, salazodimetoxine) and corticosteroids. Practice showed that sulfasalazone was one of the best antirecurrent facilities.

In patients with easy and middle heavy forms (distal or left-side lesions of colon) sulfasalazone is applied in a dose about 5 g per days, and salazopiridazine and salazodimetoxine — about 2 g during that time. The course of treatment must proceed 1–2 months. For local steroid therapy prednisolone is used as powder in a dose 60–80 mg or hydrocortisone — to 125 mg. It is dissolved in 100 ml physiologic saline and entered rectal dropwise one time per days during 3–4 weeks.

At erosive proctitis and proctosigmoiditis 5% (100,0 ml) solution of kolargole or extract of camomile in microclyster is applied.

At the heavy forms of ulcerous colitis with fulminant passing and frequent vomiting the treatment is needed to begin with intravenous introduction of 350–380 mg hydrocortisone per day. Thus procedures must proceed to appearance of positive clinical effect and realization of possibility of transition on enteral treatment. Such period lasts on the average of 6–7 days. In future it is recommended to adopt prednisolone peroral.

Sulfasalazopreparations is used in the same dose, as at the middle heavy form of flow of disease. As in patients at this form of disease water-electrolyte and albuminous exchanges are considerably violated,

there are the expressed intoxication and anaemia, it is expedient to conduct adequate therapy (intravenously - NaCl solution, glucose, chlorous potassium, albumen, hemodes, protein, whole blood), and also hemodialysis and oxygenotherapy is used.

An absolute indication for surgical treatment is the presence of such complications of unspecific ulcerous colitis as: perforation of wall of bowel, acute toxic dilatation, stenosis, profuse bleeding and malignization. By the choice of method of operation at such pathology it is needed to count coloproctectomy with exteriorization of ileostomy.

However, during the perforation of colon or toxic dilatation the operative treatment can be limited to colectomy because proctectomy will be conducted as the next stage.

For patients with total ulcerous colitis with chronic heavy passing and without the tendency to the visible improvement expedient radical operative treatment — coloproctectomy with exteriorization of ileostomy. At such tactic postoperative lethality is diminished in 5-6 times, comparative with palliative operations which were conducted earlier.

In Western Europe and North America colorectal cancer (CRC) is one of most widespread malignant neoplasm. Morbidity in these regions exceeds 20,0 on a 100000 of population. In Japan, South America, Africa and countries of Asia this tumour is met rarer (6,0:100000). There is an annual increase of frequency of cancer of colon approximately by 3 % in the developed countries. Morbidity of population of Ukraine by malignant neoplasm in 1995 was 16,3:100000.

Approximately 85 % of patients for CRC are of over 50 years old, with age frequency of cancer is increased.

The nutrition by fat and albuminous food promotes the elimination to the intestine of bile. Under the act of bacterial flora there is transformation of primary bilious acids to the secondary, which has the carcinogenic and mutagenic activity. A meal with vitamins A, C and that which contains plenty of vegetable cellulose has a braking carcinogenic influence.

The factors of risk which predetermine the origin of cancer of bowel are:

- 1) diffuse (family) polyposis, which is considered obligate precancer;
- 2) plural and single adenomatous polypses;
- 3) chronic unspecific ulcerous colitis (anamnesis more than 10 years);
- 4) Crohn's disease (granulomatous colitis).

Localization. A tumour is mostly localized in sigmoid (35–40 % cases) and blind (20–25 % cases) bowels.

Macroscopic forms. Exophytic tumours grow in the lumen of bowel as a polypus or knot and at disintegration have the appearance of ulcer with a dense bottom that is swelling by edges which come forward above the surface of the damaged mucous (saucer-shaped cancer). The endophytic (infiltrate) cancer grows in walls of bowel. The tumour spreads on the perimeter of bowel and engulfs it circular, causing narrowing of its lumen. In the right half of colon exophytic tumours grow, as a rule, in left — endophytic tumours.

Histological structure. Cancer of colon in 95 % cases has the structure of adenocarcinoma. Metastasis takes place by lymphatic and hematogenic ways in regional retroperitoneal lymphatic knots, liver, lungs.

The symptoms of cancer of colon are so numerous and various, that many authors group them in such clinical forms: toxico-anemic, dyspeptic, enterocolitic, obturation, pseudoinflammatory and tumular.

A toxico-anemic form shows up by indisposition, weakness, rapid fatigability, increase of temperature, progressive anaemia. Characteristic for the cancer of right half of colon.

The enterocolitic form is characterized by symptom of complex intestinal disorders: diarrhea, constipation, swelling, grumbling, pain.

The dyspeptic form is characterized by functional disorders of gastrointestinal tract.

An obturation form shows up by intestinal obstruction.

A pseudoinflammatory form is characterized by the symptoms of inflammatory process in the abdominal cavity.

A tumour form passes asymptomatic. A tumour is exposed by chance by a patient or doctor.

Obturation and enterocolitic forms more characteristic for the cancer of left half, other ones — of the right. For the cancer of right half of colon tendency to gradual progress is characteristic, and the tumours of left half often show up suddenly by intestinal obstruction.

Intestinal obstruction, germination in neighbouring organs and tissue, perforation, bleeding are considered as the most frequent complications of colon cancer.

Depending on the clinical signs of colon cancer, a differential diagnosis is to be conducted with appendiceal infiltrate, by different chronic specific and unspecific diseases of colon, and also other organs of abdominal cavity and retroperitoneal space (gall-bladder, pancreas, kidneys, genital organs and others like that), with the tumours of other organs of abdominal cavity and retroperitoneal space.

Radical treatment. Operative treatment is the unique method of radical treatment of colon cancer. The choice of method of operation depends on localization of tumour (Pic. 3.3.11). At cancer of right half of colon right hemicolectomy, (deleting of all right half of colon, including right third of transversal colon and distal segment of iliac bowel by length 20–25 cm) is conducted. In patients with tumours of left half of colon left hemicolectomy (segment from middle or from left third of transversal colon to overhead part of sigmoid is resected) is executed. At cancer of transversal colon, middle and distal parts of sigmoid bowels the resection of the damaged area is conducted, stepping back 5-6 cm from the edge of tumour. In patients who are hospitalized in an urgent order with the signs of intestinal obstruction, perforations and peritonitis, after intensive preoperative preparation the Hartmann operation is executed (at tumours of left half of colon). It is the resection of the damaged area of intestine and exteriorization of proximal segment on a front abdominal wall as colostomy. A distal end is sutured and is remained in the abdominal cavity. Through half-year there is a possibility of reconstructive operation. To the patients with the damage of right half of colon operation in a radical volume can be executed (right hemicolectomy).

During treatment with palliative purpose (at presence of solitary metastases) operations in a radical volume with removing of metastatic knot (in a liver) or subsequent chemotherapy (by 5- fluorouracil) can be used.

In recent years for the improvement of remote results treatment is applied by the adjuvant chemotherapy and intensive preoperative gamut-therapy.

The remote results of treatment of patients on the initial stages of CRC are fully satisfactory. At I stages the five-year survival is 85-100 %, at II — 65–70 %, at III — 25–30 %. On the whole at the I-III stages the five-year survival is 45 %.

Persons who refused from operative treatment perish in a short time. The combined treatment improves remote results approximately on 15–20%.

The gastric ulcer is the chronic disease with polycyclic passing. The main typical of peptic ulcer is the presence of ulcerous defect in a mucous tunic. One of basic places belongs among the gastroenterology diseases to this pathology. Such phenomenon explained by not only considerable distribution of disease but also those dangerous complications which always accompany gastric ulcers.

Frequency of morbidity on the peptic ulcer among the adult population is about 4 %. More frequent age in patients with gastric ulcers is 50–60 years.

To development mechanism of disease is still not enough studied. From a plenty of different theories in relation to genesis of peptic ulcer no one able to explain the disease. So, each of such factors as neurogenic, mechanical, inflammatory, vascular is present in the mechanism of development of peptic ulcer. Consider for today, that disturbance between the factors of aggression and defense of mucous tunic arose peptic ulcer. To the first factors belong: hydrochloric acid, pepsin, reverse diffusion of ions of hydrogen, products of lipid hyperoxidizing. To the second: mucus and alkaline components of gastric juice, property of epithelium of mucous tunic to permanent renewal, local blood flow of mucous tunic and submucous membrane.

In the terminal stage of mechanism of origin of gastric ulcers important role has the peptic factor and disturbance of trophism of gastric wall as a result of local ischemia. It confirmed by decreasing of blood flow in the wall of stomach at patients with ulcers on 30–35 % compared to the norm. It is proved, that a local and functional ischemia more frequent arises up on small curvature of stomach in the areas of ectopy of the antral mucous tunic in acid-forming. Exactly there ulcers appear.

Important part in ulcerogenesis is acted by duodenogastric reflux and gastritis. Also, gastrostasis can provoke hypergastrinaemia and hypersecretion and formed gastric ulcers.

Numeral scientific developments of the last years testify to the important infectious factor in the mechanism of origin of peptic ulcer conditioned, mainly, by helicobacter pylori.

Such stages of disease are distinguished: erosion, acute and chronic ulcers.

Erosions, mainly, are plural. Their bottom as a result of formation of mucriatic haematin is black, edges — infiltrated by leucocytes. A defect usually does not penetrate outside muscular tissue of the mucous tunic. If necrosis gets to more deep layers of wall of stomach, a acute ulcer develops. It has a funnel-shaped form. Bottom is also black, edges is swelled. Chronic ulcers are mainly single, sometimes arrive to the serous layer. A bottom is smooth, sometimes hilly, edges is like elevation, dense.

For today the most known classification of gastric ulcers by Johnson (1965). There are three types of gastric ulcers are distinguished: I – ulcers of small curvature (for 3 cm higher from a goalkeeper); II – double localization of ulcers simultaneously in a stomach and duodenum; III – ulcers of goalkeeper part of stomach (not farther as 3 cm from a goalkeeper). In the area of small curvature of body of stomach is localized 70,9 % ulcers, on a back wall, nearer to small curvature — 4,8 %, in the area of cardiac part — 12,9 %, in a goalkeeper part — 11,4 %. The ulcers of large curvature of stomach are casuistry and meet infrequently.

The complaints of patients with the gastric ulcer always give valuable information about the disease. The detailed analysis of their anamnesis allows to pay attention to the possible reasons of origin of ulcer, time of the first complaints, to the changes of symptoms.

Pain. A pain symptom in the peptic ulcer disease is very important. There are typical passing for this disease: hunger – pain – food intake – facilitation – again hunger – pain – food intake – facilitation (so during all days). Night pain for the gastric ulcer is not typical. The such patients rarely wake up in order to take a food. For diagnostics of ulcer localization it is important to know the time of appearance of pain. Between acceptance of food and appearance of pain it is the shorter, than the higher placed gastric ulcer. Thus, at patients with a cardiac ulcer pain arises at once after the food intake, with the ulcers of small curvature — in 50–60 minutes, at pyloric localization — approximately in two hours. However this feature it is enough relative and some patients in general do not mark dependence between food intake and pain. In other patients the pain attack is accompanied by the salivation.

A epigastric region near the xiphoid process is typical localization of pain. The irradiation of pain is not usual for gastric ulcers. Irradiation occur in patients with penetration and depended from organ, in which an ulcer penetrates.

At the examination of ulcerous patient it is expedient to determine the special pain points: Boas (pain at pressure on the left of the X–XII pectoral vertebrae), Mendel (pain at percussion on the left to epigastric region).

Vomiting, the sign of disturbance of motility function of stomach, is the second typical symptom of gastric ulcer. More frequent gastrostasis arises as a result of failure of stomach muscular, it atony which can be effect of organ ischemia. Vomiting could arises both on empty stomach and after food intake.

Heartburn is one of early symptoms of gastric ulcer, however at the prolonged passing of disease it can be hidden or quite disappear. Often it precedes of pain arising (initial heartburn) or accompanies a pain symptom. Mostly heartburn arises after the food intake, but can appear independently. It is observed not only at hypersecretion of the hydrochloric acid, but at normal secretion, even reduced acidity of gastric juice.

The belching at gastric ulcers is examined rarely, more frequent in patients with cardiac and subcardial ulcers. It is necessary to bind to disturbance of function of cardiac valve.

The general condition of patients with the uncomplicated gastric ulcer usually satisfactory, and in a period between the attacks — even good. However for most patients lost of the body weight and pallor are typical. In a epigastric region hyperpigmental spots are examined after the prolonged application of hot-water bottle. At palpation of stomach in this area sometimes appears local painful. It is needed also to check up “noise of splash”, the presence of which can be the sign of possible gastrostasis.

At the examination of mouth cavity a tongue has whiter-yellow incrustation. In patients with penetration ulcers and disturbances evacuations from a stomach examined dryness of tongue.

Stomach, as a rule, regular rounded shape, however during the pain attack is pulled in. There is antiperistalsis arises during the pylorostenosis.

The increased secretion of hydrochloric acid in patients with gastric ulcer observed rarely and, mainly, at prepyloric ulcer localizations. Mostly secretion is normal, and in some patients is even reduced.

X-Ray examination. The direct signs of ulcer at X-Ray examinations are: symptom of “Haudek's niche” (Pic. 3.2.1), ulcerous billow and convergence of folds of mucous tunic. Indirect signs: symptom of “forefinger” (circular spasm of muscles), segmental hyperperistalsis, pylorospasm, delay of evacuation from a stomach, duodenogastric reflux, disturbance of function of cardiac part (gastroesophageal reflux).

Gastroscopy can give important information about localization, sizes, kind of ulcer, dynamics of its cicatrization, and also allow to perform biopsy with subsequent histological examination.

The gastric ulcer passing can be acute and chronic. Acute ulcers arise as answer for the stress situations, related to the nervous overstrain, trauma, loss of blood, some infectious and somatic diseases. By a

diameter ulcers has from a few millimeters to centimeter, a round or oval form with even edges. Thus in most cases clinically observed clear ulcerous clinical signs. If complications is absent (bleeding, perforation) such ulcers treated and mostly heal over.

G.J. Burchynskyy (1965) such variants of clinical flow distinguished:

1. Chronic ulcer which does not heal over long time.
2. Chronic ulcer which after the conservative therapy heals over relatively easily, however inclined to the relapses after the periods of remission of a different duration.
3. Ulcers, which localization are had migrant character. Observed in people with acute ulcerous process of stomach.
4. Special form of gastric ulcer passing after the already carried disease. Passed with the expressed pain syndrome. Characterized by the presence in place of ulcerous defect of scars or deformations and absence of symptom of "niche".

There are such complications can develop in patients with gastric ulcer: penetration, stenosis, perforation, bleeding and malignization.

Chronic gastritis, as well as at a gastric ulcer, characterized by the pain syndrome, that arises after the food intake. In such patients it is possible to observe nausea and vomiting by gastric content, heartburn and belch. However, unlike an gastric ulcer, for gastritis typical symptom of "quick satiation by a food". Unsteady emptying, diarrhea also more inherent to gastritis. At gastric ulcer more frequent the delays are observed, constipation for 4–5 days.

The cancer of stomach, it is comparative with an gastric ulcer, has considerably more short anamnesis. The most typical clinical signs of this pathology are: absence of appetite, weight loss, rapid fatigability, depression, unsociability, apathy. In such patients X-Ray examination expose the "defect of filling", related to exophytic tumor and deformation of walls of organ. A final diagnosis is set after the results of multiposition biopsy of shady areas of mucous tunic of stomach.

Differential diagnostics also needs to be conducted with the so called precancerous states: gastritis with the achlorhydria; chronic, continuously recurrence ulcers, poliposis and Addison-Biermer anemia.

Conservative treatment of gastric ulcer always must be complex, individually differentiated, according to the etiology, pathogeny, localization of ulcer and character of clinical signs (disturbance of functions of gastroduodenal organs, complication, accompanying diseases).

Conservative therapy must include: a) anticholinergic drugs (atropine, methacin, platyphyllin) and myolitics (papaverine, halidor, nospanum); antacid drugs — in accordance with the results of pH-metry; b) H2- blocker histamine receptor (ranitidine) — 150 mg in the evening, famotidine — 40 mg at night, roxatidine — 150 mg in the evening, c) reparative drugs (dalargin, solcoseryl, actovegin) — for 2 ml 1–2 times per days; d) antimicrobial drugs (de-nol, metronidazole, semisynthetic antibiotic); e) vitamins of group B and symptomatic medicine.

Treatment of patient with a gastric ulcer must continues not less than 6–8 weeks.

Surgical treatment must performed in cases:

- a) at the relapse of ulcer after the course of conservative therapy;
- b) in the cases when the relapses arise during supporting antiulcer therapy;
- c) when an ulcer does not heal over during 1,5–2 months of intensive treatment, especially in families with "ulcerous anamnesis".
- d) at the relapse of ulcer in patients with complications (perforation or bleeding);
- e) at suspicion on malignization ulcers, in case of negative cytological analysis.

The choice of method of surgical treatment of gastric ulcer depended from localization and sizes of ulcer, presence of gastro- and duodenostasis, accompanying gastritis, complications of peptic ulcer (penetration, stenosis, perforation, bleeding, malignization), age of patient, general condition and accompanying diseases. In patients with cardial localization of ulcer the operation of choice is the proximal resection of stomach, which, from one side, allows to remove an ulcer, and from other — to save considerable part of organ, providing it functional ability (Pic. 3.2.2). In case with large cardial ulcers, when the vagus nerves pulled in the inflammatory infiltrate and it is impossible to save integrity even one of them, operation needs to be complemented by pyloroplasty. It will give possibility to warn pylorospasm and gastrostasis, which in an early postoperative period can be the reason of anastomosis insufficiency and other complications.

At the choice of method of surgical treatment of gastric ulcers with subcardial localization on small curvature without duodenostasis it is better to apply the methods of stomach resection with saving of passage through a duodenum.

For this purpose we are developed the method of segmental resection of stomach with addition selective proximal vagotomy. The redistribution of gastric blood flow between the functional parts of stomach as reply to medicinal vagotomy (intravenous introduction 1,0 ml 0,1 % solution of atropine of sulfate) is studied. Hyperemia of acid-forming part of stomach comes after introduction of preparation. The functional scopes of stomach parts are determined. The border between acid-forming and antral parts are the most frequent localization of gastric ulcers.

During this operation middle laparotomy is performed, intravenously entered 1,0 ml 0,1 % solution of atropine, then the scopes of functional stomach parts are identified and by stitches-holders is marked a intermedial segment. Selective proximal vagotomy is performed. After mobilization of large curvature of stomach within the limits of intermedial segment it resection is performed. After that gastro-gastro anastomosis "end-to-end" is formed (Pic. 3.2.3).

The analysis of supervisions of the patients operated by such method in postoperative period has good results. It allows to recommend this operation for clinical practice, in case of gastric ulcers of subcardial localizations, without duodenostasis, penetration, malignization or nerves Latarjet damaging.

The operation of choice in patients with subcardial ulcers and duodenostasis is gastric resection by Billroth II.

At the choice of method of surgical treatment of ulcers which are localized in upper and middle third of stomach, it is necessary to consider such factors, as absence of penetration in a small omentum and absence of the duodenostasis. In such patients is performed segmental resection of stomach with ulcer removing with selective proximal vagotomy. In case of penetration ulcer in a small omentum with involvement in infiltrate Latarjet nerves, such operation is impossible because of future spasm of pylorus and gastrostasis. If duodenostasis is absence than better to apply pylorus-saving resection by Maki-Shalimov. In patients with duodenostasis better to apply gastric resection by Billroth II.

At the border of gastric resection near pyloric sphincter can be spasm and gastrostasis in a postoperative period. Avoiding such complication is possible, if this border of gastric resection passes no more than 1,5 cm from a pyloric sphincter (M.M. Risaev, 1986). So, at a resection, that passes higher than 2,0 cm from a pylorus, integrity of both loops is kept.

Patients with antral ulcers without the duodenostasis performed the gastric resection by Billroth I (Pic. 3.2.6), and on presence of duodenostasis — Billroth II.

Prepyloric ulcers is similar to the ulcers of duodenum. Such localization of gastric ulcers without malignization allow to perform selective proximal vagotomy. However, at large prepyloric ulcers with penetration without duodenostasis is better to perform the gastric resection by Billroth I and on presence of duodenostasis — by Billroth II.

By contra-indication to operations with saving of food passing through the duodenum are also decompensated pylorostenosis, functional gastrostasis and duodenostasis. In such patients it is better to perform gastric resection by Billroth II.

The duodenal ulcer is the chronic recurrent disease which characterized by ulcerous defect on a mucous tunic of duodenum. Pathology often makes progress with complications development.

There are some etiologic factors of the duodenal ulcer: Helicobacter pylori, emotion tension and neuropsychic stress overstrain, heredity and genetic inclination, presence of chronic gastroduodenitis, disturbance of diet and harmful habits (alcohol, smoking). In pathogenesis of peptic ulcer a leading role is played disturbance of equilibrium between aggressive and projective properties of secret of stomach and it mucous tunic. The aggressive factors are vagus hyperfunctioning and hypergastrinemia; hyperproduction of hydrochloric acid and pepsin, and also reverse diffusion of the ions H⁺, action of bilious acids and isoleucine, toxins and enzymes of helicobacter pylori (HP). There are factors which are contribute to ulcerogenic action: disturbance of motility of stomach and duodenum, ischemia of duodenum, and metaplasia of the epithelium.

Morphogenesis of duodenal ulcer fundamentally does not differ from ulcer in a stomach. Chronic ulcers are mainly single, is localized on the front or back wall of bulb (bulbar ulcer) and only in 7–8 % cases — below it (postbulbar ulcer). The plural ulcers of duodenum are met in 25 % cases.

Pain in the epigastric region is the most expressed symptom of duodenal ulcer, often with displacement to the right in the projection area of bulb of duodenum and gall-bladder. Also for this pathology is typical the pain, that arises in 1,5–2 hours after food intake, "hungry" and nightly pain. As a rule, it is acute, sometimes unendurable, and is halted only after the use of food or water. Such patients complains for the seasonal exacerbation, more frequent in spring and in autumn. However exacerbation can be also in winter or in summer. In the acute period of disease heartburn often increases. However heartburn is the frequent symptom of cardial insufficiency and gastroesophageal reflux. For an duodenal ulcer the acute burning feeling of acid in a esophagus, pharynx and even in the cavity of mouth is especially typical. Often are belch by air or sour content, excessive salivation. Vomiting is not a typical symptom for duodenal ulcer. More typical sign is nausea. Sometimes for facilitation patients wilfully cause vomiting. These symptoms, arises in the late periods of passing of duodenal ulcer.

Intensity of pain and dyspepsia syndromes depends both on the depth of penetration and from distribution of ulcerous and perulcerous processes. Superficial ulceration within the mucous tunic, as a rule, does not cause the pain because it does not have sensible receptors. However, more deep layers of wall (muscular and especially serous) have plural sensible vegetative receptors. Therefore, on deepening and distribution of process arises visceral pain. At evident perulcerous processes and penetration of ulcers to neighboring organs and tissues, usually, a parietal peritoneum, that has spinal innervation, is pulled in. Pain becomes viscerosomatic, more intensive. A such pain syndrome (with an irradiation in the back) is typical for low postbulbar ulcers and bulbous ulcers of back wall, which penetrates in a pancreas and hepato-duodenal ligament. Usually such patients has good appetite. Some of them limit themselves in acceptance of ordinary food, go into to the dietary feed by small portions, and some — even hold back from a food, being afraid to provoke pain, and as a result of it weight is lost. Some of patients feeds more intensive and often.

The psychical status of patients often are changed as a asthenoneurotic syndrome: irritates, decline of working capacity, indisposition, hypochondria, abusiveness.

An inspection, as a rule, gives insignificant information. In many cases on the abdominal skin it is possible to notice hyperpigmentation after application of hot-water bottle. During the pain attack patients often occupy the forced position. At superficial palpation on the abdominal wall determined hyperesthesia in ulcer projection. In the epigastric region, during deep palpation, it is possible to define pain and muscular tension, mostly moderate intensity. There is important symptom of local percussion painful (Mendel's symptom): percussion by fingers in the symmetric epigastric areas provoke pain in the ulcer, which is increased after the deep breath. The roentgenologic and endoscopic are main diagnostic methods. The symptom of ulcerous "niche" is a classic roentgenologic sign. It is depot of contrast agent, which is corresponded to ulcerous defect, with clear contours and light bank to which converged fold mucus. Cicatricial deformation of bulb of duodenum as a shamrock, butterfly, narrowing, tube, diverticulum and other forms is the important sign of chronic ulcerous process. A roentgenologic method is especially important for determination of configuration and sizes of stomach and duodenum, and also for estimation of motility functions. X-Ray examination is the main method at the peptic ulcer complicated by stenosis, with disturbance of evacuation, duodenostasis, duodenal-gastric reflux, gastroesophageal reflux, diverticulum. But by X-Ray examination is difficult to diagnose small superficial ulcers, acute ulcers, erosions, gastritis and duodenitis. The most informing method in such cases it endoscopy.

During endoscopy examination it is possible to define localization, form, sizes and depth of ulcer. During bleeding grumes, trickle or pulsating of blood are observed. By irrigation by stypic solutions, by cryocoagulation, by laser coagulation endoscopy allows to secure hemostasis. Endoscopy allows to perform the biopsy of ulcer tissues for determination of possible malignization.

In patients with low postbulbar ulcers the clinical signs are more expressed. It characterized by late (in 2–3 hours after food intake) and intensive "hungry" and nightly pain, that often irradiate to the back and to the right hypochondrium. The postbulbar ulcers are inclined to more frequent exacerbation, and also to more frequent complications, such, as penetration, stenosis and bleeding.

The are more frequent ulcerous bleeding (the bulbous happen in 20–25 % cases, postbulbar — in 50–75 %), perforations (10–15 % cases). Penetration, stenosis and malignization in patients with duodenal ulcers are observed rarely.

Penetration is frequent complication of "low" and postbulbar ulcers of duodenum, which are placed on posterior, posterior superior and posterior inferior walls. Penetrates, usually, deep chronic ulcers, by passing through all layers of duodenum in neighboring organs and tissues (head of pancreas, hepato-duodenal ligament, small and large omentum, gall-bladder, liver). Such penetration is accompanied by development of inflammatory process in the neighboring organs and surrounding tissues and forming of cicatricial adhesions. A pain syndrome becomes more intensive, permanent and often pain irradiated in the back. Sometimes in the area of penetration it is possible to palpate painfully infiltrate.

The duodenal ulcer must be differentiated from acute and chronic cholecystitis, pancreatitis, gastroduodenitis. Endoscopy is help to diagnose duodenal ulcer.

Conservative treatment. In most patients after conservative treatment an ulcer heals over in 4–6 weeks. Warning of relapses can be carried out by only supporting therapy during many years.

The best therapy of duodenal ulcer is associated with a helicobacter infection, there is the use of antagonists of H₂- receptors of histamine (renitidine— 300 mg in the evening or 150 mg twice for days; famotidine— 40 mg in the evening or 20 mg twice for days; nizatidine — 300 mg in the evening or 150 mg twice for days; roxatidine — 150 mg in the evening) in combination with sucralfate (venter) — for 1 r three times for days and antacid (almagel, maalox or gaviscon —1 dessert-spoon in a 1 hour after food intake). To this complex it is needed to add antibacterial preparations (De-nol – 1 tabl. 4 times per a day during 4–6 weeks + oxacylline for 0,5 g 4 times per a day — 10 days + Tryhopol (metronidazole) for 0,5 g 4 times per a day — 15 days).

In treatment of duodenal ulcer used cholinotics and miolitics (atropine, methacin, platyphyllin), and also mesoprostol (200 mg 4 times per days) and omeprazole (20 or 40 mg on days).

Such treatment of patients with the duodenal ulcer must be 4–6 weeks. If complications absents there is no necessity in the special diet.

Because of appearance of new pharmaceutical preparations and modern therapeutic treatment, indication to the operative methods narrowed. But the number of acute complications of duodenal ulcer does not go down, especially bleeding and perforations which require the urgent surgery.

Indications to the elective operation:

1. Passing of duodenal ulcer with the frequent relapses which could not treated conservatively.
2. Repeated ulcerous bleeding.
3. Stenosis of outcome part of stomach.
4. Chronic penetration ulcers with the pain syndrome.
5. Suspicion for malignization ulcers.

Methods of surgical treatment.

At patients with the duodenal ulcer three types of operations are distinguished:

- organ-saving operations;
- organ-sparing operations;
- resection.

From them the better are: organ-saving operations with vagotomy, excision of ulcer and drainage operation.

Types of vagotomy: trunk (TrV) (Pic. 3.2.7), selective (SV) (Pic. 3.2.8), selective proximal (SPV) (Pic. 3.2.9). Selective proximal vagotomy is optimal in the elective surgery of duodenal ulcer. However in urgent surgery a trunk, selective or selective proximal is often used in combination with drainage operations.

Drainage of the stomach operations are: Heineke-Mikulicz pyloroplasty, Finney pyloroplasty, submucous pyloroplasty by Diver-Barden-Shalimov, gastroduodenostomy by Jaboulay, gastroenteroanastomosis.

It is necessary to mark that “clean isolated” SPV, performed in patients with duodenal ulcer, often (in 15–20 % cases) results in the relapses. The considerably less number of relapses (8–10 %) is observed after SPV in combinations with drainage operations. Especially dangerous is the relapses of the ulcers placed in the projection of large duodenal papilla, after gastroduodenostomy by Jaboulay.

The least number of relapses of duodenal ulcer is observed after organ-saving operations, that combine SPV and ulcer excision.

If ulcer localized on the anterior surface of duodenal bulb it can be performed by the method Jade (Pic. 3.2.13) with subsequent to the pyloroplasty by Heineke-Mikulich.

At patients with decompensate stenosis and expressed dilatation and by the atony of stomach it is needed to apply the classic resection of stomach depending on possible damping-syndrome by Billroth -I or Billroth -II.

The choice of subtotal resection of stomach needs to be done at suspicion for malignization or at histological confirmed malignization ulcers. In a duodenum this process happens very rarely.

Ulcerous stenosis is complication of Peptic ulcer or duodenum, which characterized by narrowing.

Stenosis of outgoing part of stomach and duodenum of ulcerous origin arises as a result of scarring and common morphological changes around an ulcer. Narrowing, disturbance of the coordinated motility of goalkeeper come as a result of it and creates the obstacle to the even moving of stomach content to the duodenum.

Such pathology in the compensation stage arises hypertrophy of the stomach walls. The pyloric ring has a 0,5–0,7 cm in diameter. The mucous tunic of pyloric part of stomach is thickened, with rough folds. Muscular fibers are hypertrophied and solid. Histological hyperplasia of pyloric glands is observed.

During decompensation the muscular layer of stomach higher stenosis becomes thinner, tone of him goes down, and a pyloric ring narrows to a few millimetres. Microscopically present atrophy of mucous tunic and muscular fibers, vessels sclerosis. A stomach collects the form of the stretched sack which goes down to the level of small pelvis.

The first signs of stenosis can be exposed already in eight-ten years from the beginning of the peptic ulcer disease.. Mainly, this is narrowing and rigidity and disturbance of retractive activity of goalkeeper, which create a barrier for transition of stomach content to the duodenum.

In the stage of the compensated stenosis hypertrophy of wall of stomach develops and tone of muscular shell rises. Hereupon gastric content, slowly, but passes through the narrowed area of stomach output. In this stage patients, usually, complained about feeling of plenitude in an epigastric area after food intake, periodic vomitings by sour gastric content. On empty a stomach by a stomach pump 200–300 ml gastric content is removed.

In the subcompensated stage muscular layer of stomach becomes thinner. Tone of him goes down, a peristalsis relaxes, and it looks like the stretched sack. Evacuation disorders is increased. Fermentation and rotting developed in stagnant gastric content. On this stage of disease development patients, usually, complain for the permanent feeling of weight in epigastric region and regurgitation with an unpleasant “rotten” smell of sulphuretted hydrogen.

Vomiting becomes systematic (once or twice on a day) up to half of liter per day. On empty a stomach it possible to aspirate from it more 500 ml of content with the food used the day before.

In the decompensation stage of the clinical signn make progress quickly. There are heavy disturbances of the general condition of patient, considerable loss of weight (to 30–40 %), acutely expressed dehydration of organism, hypoproteinemia, hypokalemia, azotemia and alkalosis. In case of the protracted neglected disease, as a result of progress of disturbances of metabolism, there can be a convulsive syndrome (gastric tetany). Vomiting in this stage not always can be considered by a typical sign, in fact patients often renounce to adopt a food, and a stomach acquires considerable sizes, overdistension form, it tone is violated and atrophy of wall comes. In such patients in an epigastric area it is possible to define the contours of the stretched stomach, with a slow peristalsis.. In the distance it is possible to hearken the splash. By a probe from a stomach to 1.5-2 litres of food with a putrid smell are removed. There can be gastric tetany at considerable disturbances of electrolyte metabolism.

A diagnosis is set according to a typical syndrome, results of sounding of stomach, rontgenoscopy, at which by contrasting of a barium expose stenosis of initial part of stomach or duodenum, determines it origin and estimate a degree.

Roentgenologically in the compensation stage stomach in normal sizes, it peristalsis deep, increased, evacuation of content proceeds no more than 6 hours. In the stage of subcompensation a stomach is megascopic, a peristalsis is loosened, evacuation stays too long to 24 hours. During decompensation a stomach is considerably extended as a sack, deformed, the waves of antiperistalsis can take place, a contrast stays too long more than 24–48 hours. The method of the double contrasting by a barium and air considerably facilitates diagnostics.

Determination of stomach motility has not only diagnostic but also prognostic value for the choice of method of operation.

In the stage of compensation motility of stomach is well-kept, often even increased. With the increasing the degree of stenosis the motility disturbance increased, up to gastroplegia.

In the biochemical blood test is marked the decline of content of albumen to 54–48 g/l; potassium — to 2,9–2,5 mmol/l; chlorides — to 85–87 mmol/l. The changes of such indexes are most expressed at patients with gastrogenous tetany.

The study of secretory function of stomach allows to define the degree of compensation of stenosis and important at the choice of adequate method of operation.

Gastroscopy with a biopsy is the enough informing method of examination of such patients. By this method is possible to determine a reason and degree of stenosis, and also state of mucous tunic of stomach.

Stenosis of the output part of stomach and duodenum of ulcerous origin it is needed to differentiate with functional gastrostasis and narrowing of tumour and chemical genesis.

Functional gastrostasis more frequent meets at women. Basic, that distinguishes it from other pathologies, there is absence of some organic changes in the area of pyloric part of stomach or in a duodenum, that can be exposed during fibergastroscopy.

Differential diagnostics of stenosis of tumour genesis, as a rule, also does not cause the special difficulties. A diagnosis is finally confirmed by histological examinations of the biopsy material taken during endoscopy.

Postburn stenosis of piloroantral area of stomach observed, from data of statistics, more than in 25 % cases of patients with the burn of esophagus. In anamnesis in each of such patients takes place by mistake or the intentionally taken an a swig at acid, alkali or other chemical matter. Some diagnostic difficulties can arise up at the isolated postburn stenosis of pyloric part of stomach. The however attentively collected anamnesis and professionally conducted endoscopic examination enable to set a correct diagnosis.

Treatment of ulcerous stenosis of piloroantral part of stomach and duodenum must be exceptionally operative. A method depend on many factors: degree of stenosis, these secretory and motility functions of stomach, age of patient, presence of accompanying diseases and others like that. In the compensated and subcompensated stages of stenosis and at enough well-kept functions of stomach it is possible to perform of organ-saving operations (vagotomy with drainage stomach operations, economy resection of stomach). At growth of the signs of stenosis and disturbance of basic functions of stomach, the volume of operation must be increased up resection by the Billroth's second method.

At the patients and older age persons with heavy accompanying pathology is performed minimum surgery —gastroenteroanastomosis.

Preoperative preparation must be strictly individual.

At patients with insignificant disturbances of gastric motor activity (stage of compensation, subcompensations) and with good level of metabolism indexes it is better to shorten preoperative preparation in time. Such patients, usually, operated on 3–4 day. Preparation before operation at patients with decompensated piloroostenosis must be directed for the correction of metabolism disturbances. Such patients must receive transfusion of liquid up to 2,5–3 l per day with content of the ions K⁺, Na⁺, Ca⁺⁺, amino acid and glucose; plasma, albumen. Twice on days performed decompensation and washing of stomach and anti-ulcerous therapy. Effective preoperative preparation in such patients requires 5–7 days, sometimes more.

The typical perforation of gastric or duodenum ulcer is strengthening of necrosis process in the area of ulcerous crater with subsequent disturbance of integrity of wall, that result to the permanent effluence of gastroduodenal content and air in a free abdominal cavity.

In 50,7 % cases perforates the ulcers of duodenum, in 42,8 % are ulcers of pyloric part of stomach, in 4,8 % are ulcers of small curvature of body of stomach and in 0,7 % are cardiac ulcers.

Ulcers, which lie on the front wall of stomach and duodenum more frequent give the perforation with general peritonitis, while ulcers on a back wall — perforation with adhesive inflammation.

The reasons of ulcers perforation are: exacerbation of peptic ulcer, harmful habits, stresses, professional, athletic overexertion, faults in the feed and abuses by strong waters.

In pathogeny of acute perforation important: progressive necrosis processes in the area of ulcerous crater with activating of virulent infection; hyperergic type of local vaculo-stromal reaction with the thrombosis of veins of stomach and duodenum; local manifestation of autoimmune conflict with accumulation of sour mucopolysaccharides on periphery of ulcer and high coefficient of plasmationization of mucous tunic (K.I. Mishkin, A.A. Frankfurt, 1971).

The clinical picture of perforation is very typical and depends on distribution of inflammatory process and infection of abdominal cavity. In clinical passing of the perforations distinguish three phases: shock, “imaginary prosperity” and peritonitis (Mondor, 1939).

For the phase of shock (to 6 hours last) typical very acute pain in epigastric region (Delafua compares it to pain from the stab with a dagger) with an irradiation in a right shoulder and collar-bone, a face is pale, with expression of strong fear, lines become (facies abdominalis) acute, a death-damp irrigates skin covers. A pulse is at first slow (vagus pulse), later becomes frequent and less filling. Sometime observed the reflex vomiting and delay of gases. Arterial pressure is reduced. On examination stomach is pulls in, does not take part in the act of breathing. At palpation is “wooden belly stomach”, especially in an upper part, where, usually, there is most pain. Positive Blumberg's sign. At percussion is disappearance of hepatic dullness (the Spizharny symptom). At rectal examination expose painful in the area of rectouterine or

rectovesical pouch (the Kulenkampf's symptom).

The phase of shock changes by the phase of "imaginary prosperity", when the reflex signs go down: the general condition of patient gets better, a pulse becomes normal, arterial pressure rises, a stomach-ache diminishes partly. However observed tension of muscles of front abdominal wall, positive Blumberg's sign.

The phase of "imaginary prosperity" in 6–12 hours from the moment of perforation changes by the phase of peritonitis: a pulse is frequent, a stomach is swollen through growing flatulence, intestinal noises are not listened, a face acquires the specific kind — facies Hippocratica — the eyes fall back, lips turn blue, a nose becomes sharp, a tongue becomes dry and furred, breathing superficial and frequent, a temperature rises.

Covered perforation (A.M. Shnieler, 1912). At this pathology the perforative hole after a perforation is closed by a fibrin, by an omentum, by the fate of liver, sometimes — piece of food. After that some amount of stomach content and air gets in an abdominal cavity. After the protection a stomach-ache diminishes, but proof tension of muscles of front abdominal wall, especially overhead quadrant of stomach is kept. At percussion hepatic dullness is doubtful. During x-Ray examination it is not always possible to mark gas in right hypocondrium (Pic. 3.2.14).

Consequences of passing of the covered perforation: the repeated perforation with development of classic clinical signs can come; at separation of process from a free abdominal cavity a subdiaphragmatic or subhepatic abscess is formed; complete closing of defect by surrounding tissue with gradual convalescence of patient.

The atypical perforation is the perforation, at which gastric or intestinal content gets not to the abdominal cavity, but in retroperitoneal space (ulcers of back wall of duodenum), large or small omentum (ulcers of small curvature of stomach), hepato-duodenal ligament.

In such patients during a perforation pain is not acutely expressed. During palpation observed insignificant rigidity of muscles of front abdominal wall. On occasion, especially on the late stages of disease, there can be hypodermic emphysema and crepitation.

The diagnosed perforated gastric and duodenal ulcer is an absolute indications to operation. Preoperative preparation must include: in I phase are antishock action; in the II and III phases — reanimation preparations, introductions of antibiotics for 2–3 hours before operation, liquidation of hypovolemia by salt blood substitutes (solution of chlorous sodium), solutions of dextran (polyhukline, reopolihukline, hemodes). Amount of liquid necessary for correction of hypovolemia, calculate after hematokrit by central vein pressure. Taking for the norm of hematokrit 40 %, on each 5 % higher norms need to be poured 1000,0 ml liquids.

Conservative treatment (method of Tejlor, 1946) can be justified at the refusal of patient from operation or in default of conditions for its implementation.

It must include:

- permanent nasogastral aspiration of gastric content;
- introduction of preparations which brake a gastric secretion (atropine, H₂- blockers and others like that);
- introduction of antibiotics;
- correction of metabolism;
- laparocentesis with drainage and closed lavage of the abdominal cavity.

In the decision of question about the choice of method of operative treatment of perforated gastroduodenal ulcers the important value has the following factors: localization of ulcer, clinico-morphological description of ulcer (perforation of acute or chronic ulcer), connected with the perforation such complications of ulcer, as bleeding, cicatricial-ulcerous stenosis, penetration, degree of risk of operation and feature of clinical situation.

Operative treatments at a perforated ulcer divide into palliative and radical.

Palliative operations are: closure of the perforative hole of ulcer, tamponade of the perforative hole by a omentum on a leg by B.A. Ooppel - P.N.Polikarpov - M.A.Pidhorbunskyy (1896, 1927, 1948) (Pic. 3.2.15). Indications and terms for their implementation are:

- perforation of acute duodenal ulcer in youth and young age without anamnesis;
- perforation of acute ulcer in the II–III phases of passing;
- perforation of callous gastric ulcer in the II–III phases of passing;
- expressed and high degrees of risk of operation.

The radical operations at perforated ulcers are: resection of stomach and excision of the perforative hole of ulcer in combination with pyloroplasty and StV, SV or SPV.

Indications and terms for implementation of resection of stomach are:

- perforation of callous gastric ulcer in I phase of clinical passing;
- repeated perforation of ulcer;
- perforation of ulcer in I phase of clinical passing in combination with stenosis and bleeding of ulcer;
- perforation of duodenal ulcer in I phase of passing in combination with a gastric ulcer;
- unexpressed and moderate degree of risk of operation;
- sufficient qualification of surgeon and material resources of operating-anaesthetic brigade.

Indications for implementation of operation of excision of the perforative hole of ulcer with pyloroplasty, StV, SV and SPV are: perforation of ulcer of front wall of duodenum or pyloric part of stomach in the I–II phases of passing;

- perforation of ulcer of front wall of duodenum in the I–II phases of passing in combination with the bleeding ulcer of back wall;
- perforation of duodenal ulcer in the I–II phases of passing in combination with the compensated stenosis of outgoing part of stomach;
- increased gastric secretion;
- insignificant and moderate degree of risk of operation;
- sufficient qualification and technical preparedness of surgeon.

Bleeding gastroduodenal ulcers are outpouring of blood in the gastrointestinal tract cavity as a result of strengthening and distribution of necrosis process in the ulcer area to vessels with the subsequent melting of their walls.

Complication of peptic or duodenal ulcer by bleeding is critical situation which threatens to life of patient and requires from the surgeon of immediate and decisive actions for clarification of reasons of bleeding and choice of tactic of treatment. The ulcerous bleeding has 60 % of the acute bleeding from the upper parts of gastrointestinal tract.

The origin of the gastrointestinal bleeding at patients with a gastric or duodenal ulcer almost is always related to exacerbation of ulcerous process. The reason of bleeding is a erosive vessel, that is on the bottom of ulcer. The expressed inflammatory and sclerotic processes round the damaged vessel embarrassed its contraction, that diminishes chances on the spontaneous stop of bleeding.

Gastric ulcers, compare with the ulcers of duodenum, complicated by bleeding more frequent. Bleeding at gastric ulcers are more expressed, profuse, with heavy passing.

At the duodenal ulcer bleeding more frequent complicate the ulcers of back wall, which penetrates in the head of pancreas.

At the men ulcer is complicated by bleeding twice more frequent, than at women. It costs to mark that 80 % patients which carried bleeding from an ulcer and treated oneself by conservative preparations, are under the permanent threat of the recurrent bleeding.

Strengthening of necrosis process are leading factors in the origin of the ulcerous bleeding in the area of ulcerous crater with distribution of this process to a vessel and subsequent melting of vascular wall; activation of fibrinolysis in tissues of stomach and duodenum; ischemia of tissues of wall of stomach.

At patients with an peptic ulcer disease, bleeding pops up, mainly at night. Vomiting can be the first sign of it, mostly, at gastric localization of ulcers. Vomiting masses, as a rule, looks like "coffee-ground". Sometimes they are as a fresh red blood or its grume.

The black tar-like emptying are the permanent symptom of the ulcerous bleeding, with an unpleasant smell ("melenä"), that can take place to a few times per days.

Bloody vomiting and emptying as "melenä" is accompanied by worsening of the general condition of patient. A acute weakness, dizziness, noise in a head and darkening in eyes, sometimes — loss of consciousness. A collapse with the signs of hemorrhagic shock can also develop. Exactly with a such clinical picture the such patients get to the hospital. It is needed to remember, that for diagnostics anamnesis is very important. Find out often, that at a patient an peptic ulcer was already diagnosed once. It appears sometimes, that bleeding is repeated or surgery concerning a perforated ulcer took place in the past. At some patients a gastric or duodenal ulcer is was not diagnosed before, the however attentively collected anamnesis exposed, that at a patient had a stomach-ache. Thus it communication with acceptance of food and seasonality is typical (more frequent appears in spring and in autumn). Patients tell, that pain in overhead part of abdomen which disturbed a few days prior to bleeding suddenly disappeared after first its displays (the Bergmann's symptom).

At patients with the ulcerous bleeding there are the typical changes of hemodynamic indexes: a pulse is frequent, weak filling and tension, arterial pressure is mostly reduced. These indexes need to be observed in a dynamics, as they can change during the short interval of time.

There is the pallor of skin and visible mucous tunics at a examination. A stomach sometimes is moderately exaggerated, but more frequent is pulled in, soft at palpation. In overhead part it is possible to notice hyperpigmental spots — tracks from the protracted application of hot-water bottle. Painful at deep palpation in the area of right hypocondrium (duodenal ulcer) or in a epigastric area (gastric ulcer) it is possible to observe at penetrated ulcers. Important symptom of Mendel also — painful at percussion in the projection of piloroduodenal area.

At the examination of patients with the gastrointestinal bleeding finger examination of rectum is obligatory. It needs to be performed at the first examination, because information about the presence of black excrement ("melenä") more frequent get according to a patient anamnesis, that can result in erroneous conclusions. Finger examination of rectum allows to expose tracks of black excrement or blood. In addition, it is sometimes possible to expose the tumour of rectum or haemorrhoidal knots which also are the source of bleeding.

The deciding value in establishment of diagnosis has the endoscopic examination. Fiber-gastroduodenoscopy enables not only to deny or confirm the presence of bleeding but also, that it is especially important, to set its reason and source. Often embarrassed the examination of stomach and duodenum present in it blood and content. In such cases it is necessary to remove blood or content, by gastric lavage, and to repeat endoscopic examination. During the examination often exposed the bleeding with fresh blood from the bottom of ulcer or ulcerous defect with one or a few erosive and thrombosed vessels (stopped bleeding). The bottom of ulcer can be covered by the package of blood.

Important information about such pathology is given by haematological indexes also. Diminishment of number of red corpuscles and haemoglobin of blood, decline of haematocrit is observed in such patients. However always needed to remember, that at first time after bleeding haematological indexes can change insignificantly. Conducting of global analysis of blood in a dynamics in every a few hours is more informing.

It is necessary always to remember that complication of peptic ulcer by bleeding happens considerably more frequent, than is diagnosed. Usually, to 50–55 % moderate bleeding (microbleeding) have the hidden passing. The massive bleeding meet considerably rarer, however almost always run across with the brightly expressed clinical signs which often carries dramatic character. In fact profuse bleeding with the loss 50–60 % to the volume of circulatory blood could stop the heart and cause the death of patient.

The clinical signs and passing of disease depend on the degree of blood (O.O. Shalimov and V.F.Saenko, 1987).

For lost of blood I degree typical there is a frequent pulse to 90–100, decline of arterial pressure to 90/60 mm Hg. The excitability of patient changes by lethargy, however clear consciousness is, breathing some frequent. After the stop of bleeding and in absent of hemorrhage compensation the expressed disturbances of circulation of blood does not observe.

At patients with the II degree of hemorrhage the general condition needs to be estimated as average. Expressed pallor of skin, sticky sweat, lethargy. Pulse — 120–130 per min., weak filling and tension, arterial pressure — 90–80/50 mm Hg. At first hours the spasm of vessels (centralization of circulation of blood) comes after bleeding, that predetermines normal or increased, arterial pressure. However, as a result of the protracted bleeding compensate mechanisms of arterial pressure are exhausted and can acutely go down at any point. Without the proper compensation of hemorrhage the such patients can survive, however

almost always there are considerable disturbances of blood circulation with disturbance of functions of liver and kidneys.

The III degree of hemorrhage characterizes heavy clinical passing. There is a pulse in such patients — 130–140 per min., and arterial pressure — from 60 to 0 mm Hg. Consciousness is almost always darkened, acutely expressed adynamy. Central vein pressure is low. Oliguria is observed, that can change by anuria. Without active and directed correction of hemorrhage a patient can die.

But, not always weight of bleeding which is conditioned by the degree of hemorrhage correspond the general condition of patient. On occasion the considerable loss of blood during the set time is accompanied by the relatively satisfactory condition of patient. And vice versa, moderate hemorrhage can bring to the considerable worsening of general condition. It can depend both on compensate possibilities of organism and from the presence of accompanying pathology.

It is needed to remember, that the ulcerous bleeding can accompanying with the perforation of ulcer. During perforation ulcers are often accompanied by bleeding. Correct diagnostics of these two complications has the important value in tactical approach and in the choice of method of surgical treatment. In fact simple suturing of perforated and bleeding ulcer can complicated in postoperative period by the profuse bleeding and cause the necessity of the repeated operation.

At wide introduction of gastroduodenoscopy of question of differential diagnostics of bleeding lost the actuality. However much a problem arises up at impossibility to execute this examination through the heavy general condition of patient or taking into account other reasons. Differential diagnostics is conducted with bleeding of ulcerous origin, which arise up in different parts of digestive tract.

For bleeding from the varicose extended veins of esophagus during portal hypertension at patients with the cirrhosis of liver the acute beginning without pain is characteristic, like during exacerbation of ulcerous disease. These bleeding differ by the special massiveness and considerable hemorrhage. Vomiting by fresh blood, expressed tachycardia, falling of arterial pressure are observed. In such patients it is possible to find the signs of cirrhosis of liver and portal hypertension (“head of jelly-fish”, hypersplenism, ascites, often is icterus).

Sliding hernia of the esophagus opening of diaphragm can be accompanied by formation of ulcers in the place of clench of the stomach by the legs of diaphragm and bleeding from them. However for this pathology are more typical microbleeding, that is hidden. In such patients often the present protracted anaemia which can achieve the critical values. Sometimes in them observe more expressed bleeding with “classic” vomiting “coffee-grounds” and melena. During the roentgenologic examination with barium is possible to expose the signs of sliding hernia of the esophagus opening: the obtuse cardial angle, absence or diminishment of gas bubble of stomach or “ringing symptom”.

The cancer tumour of stomach in the destruction stage can be also complicated by bleeding. However, such bleeding are massive, and chronic character is carried mostly with gradual growth of anaemia. For this pathology there are the inherent worsenings of the general condition of patient, loss of weight of body, decline of appetite and waiver of meat food. At the roentgenologic examination the “defect of filling” is exposed in a stomach.

The gastric bleeding can be related to the diseases of the cardio-vascular system (atherosclerosis, hypertensive disease), however such happens mainly in the older years people. Clearly, that in such patients during the endoscopic examination the source of bleeding exposing is not succeeded.

Among other diseases, with which it is necessary to differentiate the ulcerous bleeding, it is needed to remember the Mallory-Weiss syndrome, benign tumours of stomach and duodenum (more frequent leiomyoma), hemorrhagic gastritis, acute (stress) erosive defects of stomach, arteriovenous fistula of mucous tunic.

Often differential diagnostics performed according to the level of localization of source of bleeding in different parts of gastrointestinal tract. For the upper parts of digestive tract (esophagus and stomach) typical there is vomiting by grume or “coffee-grounds” content and emptying by “melena”. The farther aboral placed source of bleeding, the bloody emptying changes the more so. During the bleeding from a thin bowel excrement looks as “melena”. In case of such pathology of colon (polypuses, tumours, unspecific ulcerous colitis) emptying have the appearance of fresh red blood, mostly as packages.

The conservative therapy indicated to patients with the stopped bleeding of I degree and bleeding of the II–III degrees at patients which have heavy accompanying pathology, because of operative risk.

Conservative therapy must include:

- prescription of hemostatic preparations (intravenously the aminocaproic acid 5 % — 200–400 ml, chlorous calcium 10 % — 10,0 ml, vicasol 1 % — 3,0 ml);
- addition to the volume of circulatory blood (gelatin, poliglukine, salt blood substitutes);
- preparations of blood (fibrinogen — 2–3 r, cryoprecipitate);
- blood substitutes therapy (red corpuscles mass, washed red corpuscles, plasma of blood);
- antiulcerous preparations — blocker of H₂-receptor (ranitidine, roxatidine, nasatidine— for 150 mg 1–2 times per days);
- antacid and adsorbents (almagel, phosphalugel, maalox— for 1–2 dessert-spoons through 1 hour after food intake).

It is expedient to apply washing of stomach by water with ice and the use 5 % solution of aminocaproic acid inward for to a 1 soupsoon in every 20–30 minutes.

The endoscopic methods of stop of bleeding are used also. Among them most effective is a laser and electro-coagulation.

Absolute indications to surgical treatment are: 1) lasting bleeding I degree; 2) recurrent bleeding after hemorrhage I degree; 3) bleeding of the II–III degrees; 4) stopped bleeding with hemorrhage of the II–III degrees at the endoscopically exposed ulcerous defect with a presence on the ulcer bottom thrombosed vessels or erosive vessels covered by the package of blood.

The choice of method of surgical treatment always needs to be decided individually. On today the best tactic which gives advantage to organ-saving and organsparing methods of operations. The removing ulcer as sources of bleeding must be an obligatory condition. The methods of sewing of bleeding vessels or edging of ulcer and bandaging of vessels which feed a stomach and duodenum did not justify itself through the real threat of relapse of bleeding already in an early postoperative period (9–12 days).

Palliative operations (cutting of ulcer, forming of roundabout anastomosis) can be justified only taking into account the general condition of patient and on a necessity as possible quick and least traumatically to make off operation.

At the bleeding ulcers of duodenum it is better to apply excision of ulcer or it enteritization after methods, developed by V.Zajtsev and Velihotsky. Operation complemented by one of types of vagotomy, it is better by a selective proximal with piloroplastic. The resection of stomach on the second or first method of Biltroth can be realized only in the stable general condition of patient. During the resection of stomach in case of low bleeding duodenal ulcers it is better to execute mobilization of duodenum and suturing of its stump on transcholedoch drainage which formed as transcholedoch duodenotomy (Lapey, 1942). This method warns the possible intraoperative damages of choledoch, that are the possible at low duodenal ulcers. Transcholedoch duodenotomy by performing the decompression of stump of duodenum, warns insufficiency of its stitches, that can arise up in an early postoperative period.

In case of bleeding gastric ulcers, the resection methods of operations are also usable. Only on occasion, when patients has the grave general condition, it is possible to assume the wedge cutting of ulcer.

The origin of acute linear breaks of mucous tunic of esophagus and cardial part of stomach, which are accompanied by bleeding of a different degree of weight to the gastrointestinal tract lumen, is named the Mallory-Weiss Syndrome. First described by K. Mallory and C. Weiss in 1929. As the reason of the gastroduodenal bleeding observed in 10 % cases. Men are ill mainly in age 30–50 years.

The predetermining factors of origin of syndrome are: protracted whooping, attacks of cough, physical overstrain after the surplus food intake, alcohol with vomiting, chronic diseases of stomach, with the acute increase of intragastric pressure as a result of disordinated function of cardial and pyloric sphincter, especially at older patients with atrophy gastritis. The increase of intragastric pressure causes change of blood flow in the wall of the stretched stomach. Spontaneous break of mucous tunic of cardial part of stomach, is accompanied by bleeding in the gastrointestinal tract lumen. The break takes not only mucous tunic but also muscular layer, that weight of bleeding is predetermined. Most often the breaks are localized on small curvature, on the back wall of stomach and esophagus.

The main symptom of syndrome is “bloody” vomiting which the dyspeptic signs preceded: nausea and “unbloody” vomiting. Sometimes patients complain for pain in a epigastric area, in the lower part of thorax, which is related to sudden cardial and lower part of esophagus distension.

Weight of bleeding depends on length and depth of breaks and caliber of the damaged vessels. In one case at first the some dark blood is excreted and only at the repeated vomiting is a lot of bright red blood. In other case at once there is vomiting by a bright red blood. Sometimes bleeding looked as the tar-like emptying. The degree of hemorrhage and its weight is determined after the generally accepted chart.

Taking into account that a syndrome arises up after acceptance of a plenty of alcohol and food, the clinical forms of passing are distinguished: simple, delirious, with the signs of acute hepatic insufficiency, without the signs of acute hepatic insufficiency, that matters very much for the choice of medical tactic.

Urgent esophagogastrosopy is the basic method of diagnostics of syndrome. During it in the cardial part of stomach or esophagus single or plural fissures are diagnosed by length 0,5–4,0 cm, by width 0,5–0,8 cm which pass longitudinally, bleeding. The edges of mucus round a fissures swelled, elevated, covered by a fibrin. Often the muscular layer of stomach or esophagus is the bottom of fissure.

Conservative treatment of the Mallory-Weiss syndrome is indicated at the small rupture of mucus stomach, to the stop of bleeding, absence of bleeding. Treatment of patients is begun with active conservative therapy, which includes blood transfusion, infusion of hemostatic, application of antacid, Meulengracht's diet. At the rupture of the I–II degrees indicated endoscopy by a monopolar electrocoagulation of the fissure and covering of aerosol film-forming preparation Lifusol. The conservative method of stop of bleeding in such patients is especially perspective, because most of them has the delirious state or acute hepatic insufficiency.

Operative treatment is indicated at the deep large ruptures of mucus and muscular layers, cardial part of stomach, which are complicated by bleeding. In such cases conduct gastrotomy and suturing of ruptures by interrupted suture or 8-shaped stitch, applying nonabsorbable filaments. Sewings of ruptures of mucus stomach often supplement with vagotomy with pyloroplasty. At deep, especially plural ruptures which are accompanied by the edema of tissues, sewing of ruptures is supplement with bandaging of left gastric artery.

Hemorrhagic erosive gastritis is diffuse bleeding from mucous tunic stomach as a result of single or plural superficial defects (erosions) of mucous tunic. The gastrointestinal bleeding during erosive gastritis meet in a clinic in 13–17 % cases of acute hemorrhage in a gastrointestinal tract and take first place among bleeding of ulcerous etiology. The disease is met both at men and at women, but more frequent observe in declining years.

The spasm of large vessels in the deep layers of gastric wall, which results in disturbance of local microcirculation, hypoxia and increases of permeability of vascular wall, matters in etiology and pathogenesis of hemorrhage erosive gastritis. The local reaction causes strengthening of reverse diffusion of hydrogen ions, liberation of pepsin, histamine. Such process often is consequence of local damaging factor — action of medicinal or toxic factors for the vessels of mucus. Damaging factor could be the matters which violate a blood flow in mucus stomach (aspirin, reserpine, hormones of adrenal glands cortex). The large value in formation of erosions is had by the anatomic features of blood flow of stomach in a cardial part on small curvature. In connection with absence of submucosal vascular plexus, eventual vessels on small curvature are disposed in relation to mucus tangentially. It results in shelling of epithelium, origin of erosions. Veins damaged at first, that predetermines a hemorrhage and then bleeding. In the origin of acute hemorrhage gastritis matter also acute damage of mucus stomach by mechanical, chemical (burns) and other factors, accompanying diseases (uremia and others like that).

For hemorrhage erosive gastritis there are typical two clinical syndromes: ulcerous and hemorrhagic. The ulcerous syndrome is the most frequent sign of hemorrhage gastritis. “Typical ulcerous pain” is observed in such patients. A hemorrhagic syndrome shows up by the repeated gastric bleeding and moderately increasing anaemia. Bleeding are capillary and are not such catastrophic, as at gastric ulcers.

The clinical picture of hemorrhage gastritis is characterized by dull pain in a epigastric area, which appears at faults in a food, reception of alcohol. Patients disturbs vomiting like “coffee-grounds”, “melena”, which arise up among a complete health, symptoms of hemorrhage (dizziness, general weakness, acceleration of pulse, decline of arterial pressure). The decline of amount of red corpuscles is observed in the blood test, haemoglobin, haemathokrits, leukocytosis. During the roentgenologic examination observed the thickened winding folds of mucus stomach with the small depots of barium. At endoscopic diagnostics of bleeding the presence of single or plural erosions on mucus up to 5–7 mm in diameter are noticed, symptom of “morning dew” (“weeps” all mucus stomach).

Treatment of hemorrhage erosive gastritis, mainly, is conservative. Washing of stomach an effective by cold water or by 5 % solution of aminocaproic acid with subsequent irrigation of mucous tunic by film-forming preparations through endoscope and introduction of hemostatic. It is important the neutralization of hydrochloric acid in a stomach (antacid, additional introduction of atropine of sulfate, aspiration of gastric content), setting of preparations which stimulate reparative processes in a mucous tunic (methyluracil, sayotek, sea-buckthorn oil), antihelicoacter preparation (de-nol). If under the endoscopy control effect from conservative treatment is absent and it is the obvious threat of life of the patients, operative treatment is indicated.

Surgical treatment must be minimum. Sewing and edging of bleeding areas, selective vagotomy with pyloroplasty in most cases is effective. Only at bleeding from arising acute erosions after submucosal telangiectasia, indicated resection of stomach. It is needed to remember, that the additional focus of bleeding can be in fundal and cardial part of stomach. Without their edging and local hemostasis operation can not be radical. At the considerable damage of stomach by an erosive process, for a patient indicated resection of stomach or gastrectomy.

The hereditary hemorrhagic telangiectasia, Rendu-Osler-Weber Disease — hemorrhage angiopathy, which is characterized by focus microvascular expansion by the type of telangiectasia and angiomas with the break of which possible bleeding. Meets rarely, inherited after a autosomal-dominant type, sometimes arises up sporadically.

Teleangiectasia and angiomata develops as a result of thinning and expansion of shallow vessels. At the same time local hemostasis is violated as a result of hypoplasia of subendothelium and collagen deficiency. Bleeding is related to small resistance and easy vulnerability of vascular wall, by weak stimulation in these areas of aggregation of thrombocyte and blood coagulation. Teleangiectasia is disposed on the mucous tunics of mouth cavity, rarer is mucus of the trachea, bronchial tubes, gastrointestinal tract, urinary bladder and liver.

The disease is characterized by the frequent nose-bleeds which appear in early child's age, teleangiectasias and angiomata with certain localization. The gastrointestinal bleeding can be profuse and result in lethal termination, chronic, with the expressed anaemia. At differential diagnostics of bleeding it is necessary to observe the skin and mucous tunics. Teleangiectasias and angiomata is characterized by expansion of granulomatous vessels and is disposed, mainly, on a head, skin, mucus of the mouth, nose, on hands, finger-tips, genital organs.

Treatment of the Rendu-Osler-Weber disease is conservative, symptomatic, including hemostatic therapy. There is the indicated blood transfusion at considerable hemorrhage. Often during recrudescence and profuse gastrointestinal bleeding the resection of stomach is indicated. It is represents a problem for a surgeon, because teleangiectasias after the decline of arterial pressure, become pale and unnoticeable. A prognosis is often unfavorable, because not always it is possible to expose teleangiectasias in other organs.

Menetrier syndrome is pseudotumor gastritis. The disease rarely. Etiology and pathogenesis is unknown. During disease observed the increasing of folds of mucus stomach by the height up to 3 cm and thickness up to 2 cm. Deep cracks, which the massive bleeding are from, appear between folds. Diagnostics of bleeding is confirmed by endoscopy. Treatment is conservative, including the hemostatic therapy. If conservative treatment are ineffective, indicated resection of stomach. During operation round a stomach the megascopic lymphatic knots with soft consistency are observed.

Hemobilia is bleeding from biliary ways and liver to the intestine. Meets in 0,01 % all gastric bleeding of ulcerous genesis.

The most frequent reason of hemobilia is the traumas of liver. Among other reasons are inflammatory processes of liver, external biliary ways (abscesses, cholangitis), vascular anomalies as aneurism of hepatic artery and vein gate.

The typical signs of hemobilia: attack-like pain in right hypochondrium, moderate icterus, anaemia, presence of grume in vomiting masses and in the excrement which looks like a pencil or worm (imprints of biliary ducts). Bleeding have cyclic passing (repeat oneself in 6–8 days). A diagnosis is based on the clinical signs, information of endoscopy, at which founded the blood flow to the duodenum from a general biliary duct or bloody clot in the papilla Vateri. The most diagnostic value has selective angiography of the hepatic artery and cholangiography, which allow to expose the flowline of contrasting matter in tissues of liver.

Bleeding from biliary tracts during the damage of large vessels can be severe. So, operation is the unique treatment method in such cases. In patients with hemobilia performed opening, draining and tamponade of the haematomas with obligatory draining of general biliary channel for decompression of biliary tracts. The most radical method some surgeons count opening of haematoma with bandaging of bleeding vessel and biliary channel or resection of liver. Bandaging of hepatic artery after angiographic study of the intraorgan arterial vessels is sometimes recommended only. Better to bandage that branch of hepatic artery from which observed bleeding.

The particle of the rare extragastric diseases complicated by the acute gastrointestinal bleeding is 2 %. Among them the diseases of blood are met, blood vessels, system diseases (leukosis, haemophilia, autoimmune thrombocytopenia, hemorrhagic vasculitis, the Werlhof's disease and others like that).

Leukosis are tumours which developed from hemopoietic cells. Etiology and pathogenesis to this time is not exposed. Patients with a leukosis with the gastrointestinal bleeding is 1 % of all patients with the un ulcerous bleeding.

During leukosis in the process of extramedullary hematosis the cells of vascular wall and vessel are pulled in and from the circulatory changed into hemopoietic, that results in disturbance of permeability of vessel wall. In development of hemorrhage diathesis large part is acted the changes of thrombocytopenia, declines of growth of tissue's basophiles, which produce heparin, that shows up by wide hemorrhages in a gastrointestinal tract. Bleeding can be both insignificant and threatening to life of patient. In establishment of diagnosis sometimes there is enough simple examination of blood (hyperleukocytosis), to suspect leukosis bleeding. During endoscopy in such patients observe the presence of flat, superficial defects of mucus stomach. A final diagnosis is based on the results of biopsy and haematological examination of bone marrow.

Treatment includes complex application of hemostatic, preparations of blood and cytostatic agents, that results in the stop of bleeding and even to bring a patient into remission.

Haemophilia is the innate form of bleeding which caused by the deficit of one of three antihemophilic factors (VIII, IX, XI). The gastrointestinal bleeding is observed in 6–24 % patients with haemophilia. Absence or insufficient content in the blood of antihemophilic globulin lies in basis of disease. At diminishment of it level below 30 % there is bleeding. Haemophilia is inherited, men are ill more frequent.

Pointing in anamnesis on bleeding from babyhood allow to suspect haemophilia. Roentgenologic information and results of fibergastroscopy does not expose the substantial changes in a gastrointestinal tract. Main in diagnostics of haemophilia — examination of the system of blood coagulation. Time of blood coagulation continued to 10–30 minutes, sometimes a blood does not coagulate by hours.

Treatment is directed on compensation of insufficient components of the of blood coagulation system. In patients with haemophilia A, for which typical deficit of antihemophilic globulin, fresh blood transfusion is indicated, because in a banked blood a antihemophilic globulin collapses during a few hours. At haemophilia B and C are used dry and native plasma, cryoprecipitate, banked blood, because factors IX, XI, which predetermine the form of haemophilia, is kept in them long. ordinary hemostyptic preparation (vicasol, the C vitamin, chloride of calcium and others like that) does not give the effect. So, if form of haemophilia does not established, the treatment is necessary to begin from fresh blood transfusion, antihemophilic plasma and antihemophilic globulin transfusion.

Autoimmune thrombocytopenia, or idiopathic thrombocytopenic purpura, is accompanied by the gastrointestinal bleeding and is arisen up in 0,5–2 % patients. Often bloody vomiting and black excrement conditioned by swallowing of blood from a nose and gums.

The disease shows up by plural hypodermic hemorrhages and hemorrhages into submucous membrane. At girls and women the uterine bleeding is often observed. Thrombocytopenia on very low numbers and it is the most pathognomonic sign of disease. Typical acute increase of duration of bleeding, especially in the period of acute hemorrhage.

Fresh blood and thrombocyte mass transfusion is the most effective treatment in the case of the gastrointestinal bleeding during autoimmune thrombocytopenia. Other hemostatic preparations are indicated also. During operative treatment performed splenectomy. The absolute indications to it are frequent and protracted bleeding, threat of hemorrhage in a brain.

The Schonlein-Henoch disease is hemorrhagic vasculitis, which caused by plural microfocus microthrombovasculitis. The gastrointestinal bleeding at the Schonlein-Henoch disease is observed in 0,5–1 % cases and accompanied with great pain in a epigastric area like "abdominal colic". For this disease typical presence of purpura which has the symmetric location on the external surface of feet, legs, shoulders, buttocks, also joint syndrome with pain and edema in large joints, kidney syndrome by the type of acute or chronic glomerulonephritis. Women have the possible uterine bleeding. The intestinal bleeding can be accompanied by the edema of wall of intestine, that results in invagination or perforation of wall of bowel.

The basic and pathogenetic treatment method of patients is early application of heparin with blood transfusion, introduction of heparinized blood under the control of blood coagulation, which after adequate therapy must be increased in two times, comparative with a norm. For a patient in the initial form of disease indicated introduction of antibiotics of wide spectrum of action, hormones of adrenal glands cortex.

The diseases of the operated stomach (postgastroectomy and postvagotomy syndromes) are the diseases which arise up after surgical treatment of peptic or duodenum ulcer or other pathology of these organs.

Dumping syndrome is frequent complication of operations which are related to deleting or disturbance of function of goalkeeper (resection of stomach, vagotomy with antrectomy, vagotomy with drainage operations). It takes place in 10–30 % patients.

The rapid receipt (dumping) is considered the starting mechanism of dumping syndrome. During this concentrated, mainly carbohydrate, food passed from a stomach in an empty bowel.

In the phase changes of motility of thin bowel during dumping syndrome important part is acted by the hormones of thin bowel. In endocrine cells of APUD-системи on during dumping-syndrome observed degradation and presence of hormones of mothiline, neurotensin and enteroglucagon.

The inadequate mechanical, chemical and osmotic irritation of mucous tunic of thin bowel by chymus results for the acute increase of blood flow in a bowel. The last is accompanied by the considerable redistribution of blood, especially in heavy case of dumping syndrome: blood supply of head, lower extremities is diminishes, a blood flow in a liver is multiplied.

The numeral examinations resulted in creation of osmotic theory — the principal reason of dumping syndrome is the decline of volume of circulatory plasma as a result of coming a plenty of liquid into the lumen of thin bowel from an of circulatory system and intercellular space.

For the clinical finding of dumping syndrome typical there is the origin of attacks of general weakness during acceptance of food or during the first 15–20 minutes after it. The attack begins from feeling of plenitude in a epigastric area and is accompanied by the unpleasant feeling of heat, that "spills" in the overhead half of trunk or on all body. Thus is acutely multiplied sweating. Then there is a fatigue, appear somnolence, dizziness, noise in ears, shaking of extremities and worsening of sight. These signs sometimes achieve such intensity, that patients forced to lie down. Loss of consciousness could be in the first months after operation. The attacks are accompanied by tachycardia, sometimes by the shortness of breath, headache, paresthesia of upper and lower extremities, polyuria and vasomotor rhinitis. At the end of attack or after it patients often notice grumbling in a stomach and diarrhea.

A milk or carbohydrate food is the most frequent provoking factor of dumping syndrome. In a period between the attacks patients complain about rapid fatigueability, weakening of memory, decline of working capacity, change of mood, irritates, apathy. During roentgenologic examination after 5–15 minutes observed the increased evacuation of barium mixture through anastomosis by a wide continuous stream, expansion of efferent loop and rapid advancement of contrasting matter in the distal parts of thin bowel (Pic. 3.2.16).

By the expression of symptoms dumping syndrome is divided into three degrees of weight:

I degree is easy. Patients have the periodic attacks of weakness with dizziness, nausea, that appear after the use of carbohydrates and milk food and last no more than 15–20 min. During the attack a pulse becomes more frequent on 10–15 per min., arterial pressure rises or sometimes goes down on 1.3–2 KPa (10–15 mm Hg), the volume of circulatory blood diminishes on 200–300 ml. The deficit of mass of body of patient does not exceed 5 kg. A working capacity is well-kept. Medicinal and dietary treatment gives a good effect.

II degree — middle weight. Attacks of weakness with dizziness, pain in the region of heart, hyperhidrosis, diarrhea. Such signs last, usually, 20–40 min., arise up after the use of ordinary portions of some food. During such state a pulse becomes more frequent on 20–30 per min., arterial pressure is rises (sometimes goes down) on 2–2,7 KPa (15–20 mm Hg), the volume of circulatory blood diminishes on 300–500 ml. The deficit of mass of body of patient achieves 5–10 kg. A working capacity is reduced. Conservative treatment sometimes has a positive effect, but brief.

The III degree is hard. Patients are disturbed by the permanent, acutely expressed attacks with the collaptoid state, by a fainting fit, by diarrhea, which do not depend on character and amount of the accepted food and last about 1 hour. During the attack is multiplied frequency of pulse on 20–30 per 1 min; arterial pressure goes down on 2,7–4 KPa (20–30 mm Hg), the volume of circulatory blood diminishes more than on 500 ml. The deficit of mass of body exceeds 10 kg. Patients, as a rule, are disabled. Conservative treatment is ineffective.

The problem of treatment of patients with dumping syndrome is not easy. Before the surgical treatment, as a rule, must precede conservative. Patients with the disease of easy and middle degrees respond to conservative treatment, mainly with an enough quite good effect. At the heavy degree of disease such treatment more frequent serves as only preparation to operative treatment. If a patient does not give a consent for operation or at presence of contra-indications to operative treatment (disease of heart, livers, kidneys), conservative therapy is also applied. Such treatment must include dietotherapy, blood and plasma transfusion, correction of metabolism, hormonal preparations, symptomatic therapy, electro-stimulation of motility function of digestive tract.

The dietotherapy: using of high-calorie, various food rich in squirrel, by vitamins, by mineral salts, with normal content of fats and exception from the ration of carbohydrates which are easily assimilation (limitation of sugar, sweet drinks, honey, jam, pastry wares, kissel and fruit compotes). All it is needed to use by small portions (5–6 times per days). If the signs of dumping syndrome appear after a food, such patients it is needed to lie down and be in horizontal position not less than 1 hour. At the heavy degree of dumping syndrome patients need to eat slowly, desirably lying on left. Such position creates the best terms for evacuation of food from a stomach. Thus recommend also to repudiate from too hot and cold foods.

Medicinal treatment must include sedative, replaceable, antiserotonin, hormonal and vitamin therapy. The indications to operative treatment of patients with dumping syndrome are: heavy passing of disease, combination of dumping syndrome of middle degree with other postgastroectomy syndromes (with the syndrome of efferent loop, hypoglycemic syndrome and progressive exhaustion) and ineffective of conservative treatment of the dumping syndrome of middle degree. Most methods of operative treatment of dumping syndrome are directed on renewal of natural way of passing of food on a stomach and intestine, improvement of reservoir function of stomach and providing of proportioning receipt of food in a thin bowel.

Depending on reasons and mechanisms of development of dumping syndrome there are different methods of the repeated reconstructive operations. All of them can be divided into four basic groups: I. Operations which slow evacuation from stump of stomach. II. Redoudenization. III. Redoudenization with deceleration of evacuation from stump of stomach. IV. Operations on a thin bowel and its nerves.

Basic stages of reconstructive operations: 1) disconnection of adhesions in an abdominal cavity, releasing of gastrointestinal and interintestinal anastomosis and stump of duodenum; 2) cutting or resection of efferent and afferent loops; 3) renewal of continuity of upper part of digestive tract.

For correction of the accompany postgastroectomy pathology it is better to apply combined anti- (iso-) peristaltic gastrojejunoplasty. Thus transplant by length 20–22 cm, located between a stomach and duodenum, must consist of two parts: antiperistaltic (7–8 cm), connected with a stomach, and isoperistaltic, connected with a duodenum. An antiperistaltic segment brakes dumping of stomach stump, and isoperistaltic — hinders the reflux of duodenum content.

The attacks of weakness at a hypoglycemic syndrome arise up as a result of decline of content of sugar in a blood. It is accompanied by a acute muscular weakness, by headache, by falling of arterial pressure, by feeling of hunger and even by the loss of consciousness. It is needed to remember, that at this pathology, unlike dumping-syndrome, acceptance of food especially sweet facilitates the state of patient. However in some patients both syndromes unite and the attacks of weakness can arise up as directly after food intake, so in a few hours after it. In patients with such pathology the best results are got after antiperistaltic gastrojejunoplasty (Fink, 1976).

The postgastroectomy (agastric) asthenia arises up as a result of disturbance of digestive function of stomach, pancreas, liver and thin bowel.

In patients with such pathology stump of stomach almost fully loses ability to digest a food. It is related to the small capacity of stump and rapid evacuation of food from it, and also with the acute decline of production of hydrochloric acid and pepsin. In the mucous tunics of stump of stomach, duodenum and thin bowels as a result of fall of trophic role of gastrin and other hormones of digestive tract there are the progressive atrophy changes. Absence in gastric juice of free hydrochloric acid is the reason of acute diminishment of digestive ability of gastric juice and decline of it bactericidal. Such situation is assist in advancement to ascending direction of virulent flora, to development duodenitis, hepatitis, cholecystitis, dysbacteriosis, hypovitaminosis and decline of antitoxic function of liver. All it results in acute disturbance of evacuation from a stomach.

The clinical signs of postgastroectomy asthenia arise up after a some latent period which can last from a few months to some years. During this period patients often complain for a general weakness and bad appetite. The basic symptoms of postgastroectomy asthenia are: general weakness, edemata, acute weight loss, diarrhea, skin and endocrine abnormalities. The postgastroectomy asthenia more frequent meets at men at 40–50 years. In most cases diarrhea is the first symptom of disease, that can arise up in 2 months after operation. Diarrhea, usually, has permanent character and sometimes becomes profuse.

Weight loss appears too early, the deficit of mass of body achieves 20–30 kg. A patient quickly loses forces.

Conservative treatment is the blood, plasma and albumen transfusions. These preparations are prescribed 2–3 times per a week. Correction of disturbances of electrolyte exchange is conducted at the same time (transfusion of solutions to potassium, calcium and others like that). For the improvement of processes of albumen synthesis anabolic hormones are prescribed.

Operative treatment foresees the inclusion in the digestion process of duodenum, increase of capacity of stump of stomach and deceleration of evacuation of its content.

The afferent loop consists of part of duodenum, that stopped behind after a resection, area of empty bowel between a duodenojejunal fold and stump of stomach. The syndrome of afferent loop can arise up after the resection of stomach after the Billroth-II method. Violation of evacuation from an afferent loop and vomiting by a bile are its basic signs.

Acute and chronic obstruction of afferent loop are distinguished. The reason of acute obstruction is mechanical factors: postoperative commissure, volvulus, internal hernia, invagination, jamming behind mesentery of loop of bowel and stenosis of anastomosis.

Frequency of origin of sharp obstruction of afferent loop hesitates within the limits of 0,5–2 %. The disease can arise up in any time after operation: in a few days or a few years.

Chronic obstruction of afferent loop (actually syndrome of afferent loop), as well as acute, can arise up in any time after operation, however more often it develop after the resection of stomach with gastroenteroanastomosis on a long loop, especially when operation is performed without entero-enteroanastomosis by Brown.

The etiologic factors of syndrome of afferent loop are divided into two groups: 1) mechanical (postoperative commissure, invagination, disturbance of evacuation on a afferent loop, wrong location of afferent loop, very long afferent loop, fall of mucous tunic of afferent loop into a stomach); 2) functional (hypertensive dyskinesia of bilious ways and duodenum, damage and irritation of trunks of vagus nerves, hypotensive and spastic states of upper part of digestive tract, heightened secretion of bile and juice of pancreas under act of secretin and cholecystokinin).

For the clinical picture of acute obstruction typical is permanent, with a tendency to strengthening, pain in a epigastric area or in right hypochondrium, nausea and vomiting. At complete obstruction a bile in vomiting masses is absent. The general condition of patient progressively gets worse, the temperature of body rises, leukocytosis grows, tachycardia grows. At the objective examination painful and tension of muscles of abdominal wall is observed. In a epigastric area it is often possible to palpate tumular lump. Possible cases, when the increase of pressure in a bowel is passed on bilious ways and channels of pancreas. There can be pain and icterus in such patients. There are necrosis and perforation of duodenum with development of peritonitis during further progress of process. Acute obstruction of afferent loop in an early postoperative period can be the reason of insufficiency of stump of duodenum also.

During the roentgenologic examination of organs of abdominal cavity it is visible round form area of darkening and extended, filled by gas, bowels loop.

Patients, usually, complain for feeling of weight in a epigastric area and arching in right hypochondrium, that arises in 10–15 min. after acceptance of food and gradually grows. Together with that, appear nausea, bitter taste in a mouth, heartburn. Then there is increasing pain in a right to epigastric area. During this pain arises intensive, sometimes repeated vomiting by a bile, after which the all symptoms disappear. It could be after certain kind of food (milk, fats) or its big amount. Very rarely vomiting by bile unconnected with the feed. In heavy case patients lose up to 1 liter of bile with vomiting masses. During the objective examination observed subicteritiousness of the sclera, sign of dehydration of organism (decline of turgor of skin, dry tongue, oliguria, concentrated urine). Emptying is irregular, grey color, with considerable content of undigested fat and muscular fibres. Anaemia can develop at heavy passing of disease.

Distinguished easy, middle and heavy degrees of afferent loop syndrome. In patients with the easy degree of disease vomiting is 1–2 times per a month, and insignificant regurgitation arise up through 20 min – 2 hour after a food, more frequent after the use of milk or sweet food. At middle degree of afferent loop syndrome such attacks repeat 2–3 times per week, patients are disturbed by the considerably expressed pain syndrome, and with vomiting up to 200–300 ml of bile is lost. For a heavy degree the daily attacks of pain are typical, that is accompanied by vomiting by a bile (up to 500 ml and more).

A roentgenologic examination of the patients with the afferent loop syndrome is unspecific. Neither the passing of contrasting matter nor absence of filling of afferent loop can be considered as pathognomic signs of syndrome of afferent loop.

Treatment of acute obstruction of afferent loop is mainly operative. Essence of it is the removal of barriers of evacuation of content from an afferent loop. Adhesions are dissected, volvulus is straightened, invagination or internal hernia is liquidated. For the improvement of evacuation between afferent and efferent loops performs the entero-enteroanastomosis type “end-to-end” or after the Roux method.

Conservative treatment of syndrome of afferent loop is ineffective and, mainly, is mean the removal of hypoproteinemia and anaemia, spasmolytic preparations and vitamin are appointed. With this purpose a blood, plasma and glucose is poured with insulin, a novocaine lumbar blockade and blockade of neck-pectoral knot, washing of stomach is also done.

All operative methods of treatment of afferent loop syndrome can be divided into three groups:

I. Operations, that will liquidate the bends of afferent loop or shorten it.

II. Drainage operations.

III. Reconstructive operations.

The operations of the first group, directed on the removal of bends and invagination of afferent loop, can not be considered as radical. They need to be performed only at the grave general condition of patient.

The widest application in clinical practice at the syndrome of afferent loop has the operation offered by Roux (Pic. 3.2.17).

For the prophylaxis of afferent loop syndrome it is necessary to watch after correct imposition of anastomosis during the resection of stomach: to use for the gastroenteroanastomosis short loop of thin bowel (6–8 cm from the Treits ligament) for imposition, to sew afferent loop to small curvature for creation of spur, to fix reliably stump of stomach in peritoneum of transverse colon.

The origin of reflux after the distal resection of stomach is conditioned by some factors:

I. Traumatic factors: 1) traction of stomach during operation as reason of sprain of ligament of proximal part of stomach and mobilization of large curvature of stomach; 2) cutting of vessels of stomach and oblique muscles of it wall, in particular on small curvature; 3) vagotomy, that is accompanied by cutting of phrenico-esophageal and gastrophrenic ligaments; 4) imposition of gastrointestinal anastomosis, especially direct gastroduodenoanastomosis by Billroth-I, that results in smoothing of the Hisa corner; 5) frequent aspiration of gastric content in a postoperative period, that causes superficial esophagitis.

II. Trophic factors: 1) damage of vessels which are the reason of ischemia in the area of esophago-gastric connection, and thrombophlebitis of cardiac part of stomach; 2) disturbance of influencing of neurohumoral factors which take part in innervations of esophagus; 3) disturbance of trophism of diaphragm as a result of hypoproteinemia and weight loss; 4) ulcerous diathesis and megascopic volume of gastric secretion (especially nightly); 5) regurgitation of alkaline content of duodenum in stump of stomach which reduces tone of it muscular shell.

III. Mechanical factors: 1) gastric stasis; 2) diminishment of volume of gastric reservoir, that is accompanied by the increase of intragastric pressure.

The clinical picture of gastroesophageal reflux is conditioned by the mechanical and chemical irritations of esophagus by content of stomach or thin bowel. As a result, there is esophagitis, which can be catarrhal, erosive or ulcerous-necrotic. The symptoms of reflux are very various and can simulate different diseases of both pectoral and abdominal cavity organs.

The basic complaint of patients with this pathology is a smart behind a breastbone, especially in the area of the its lower part. It, usually, spreads upwards and can be accompanied by considerable salivation. Strengthening of pain at inclinations of trunk gave to the French authors an occasion to name this sign the “symptom of laces”. Unendurable heartburn is the second complaint, that arises up approximately in 1–2 hours after the food intake. Patients forced often to drink, somehow to decrease the unpleasant feelings, however this, certainly, does not bring them facilitation. Some of them, in addition, complain for bitter taste in a mouth.

Pain behind a breastbone often can remind the attack of stenocardia with typical irradiation. Sometimes such reflux is able to provoke real stenocardia.

Hypochromic anaemia is the frequent symptom of gastroesophageal reflux too.

The diagnosis of gastroesophageal reflux, mainly, is based on clinical information, results of roentgenologic examination, esophagoscopy.

The edema, hyperemia of mucous tunic of esophagus, easy bleeding and vulnerability it during examination, surplus of mucus and erosions covered by fibrin tape is considered the endoscopic signs of esophagitis. In doubtful case at the insignificantly expressed macroscopic changes the biopsy of mucous tunic helps to set a diagnosis.

Treatment of patients with gastroesophageal reflux is mainly conservative. Very important is diet, which avoid spicy, rough and hot food. Eating is needed often, by small portions. It is impossible also to lie down after the food intake, because the gastric content can flow in a esophagus. A supper must be not later than for 3–4 hours before sleep. Between the reception of food does not recommend to use a liquid. Next to that, it is necessary to remove factors which promote intraperitoneal pressure (carrying to the bracer, belt, constipation, flatulence). Sleeping is needed in position with a lift head and trunk. From medicinal preparations it is useful to recommend enveloping preparation.

Operative treatment of gastroesophageal reflux, that arose up after the distal resection of stomach, it is needed to recommend to the patients with the protracted passing and ineffective of conservative treatment. During operation, mainly, performed renewal of the broken Hisa angle. In addition, performed esophagoplasty, fundoplication by Nessen's and esophagofrenofundoplication.

The prophylaxis of this complication consists in the study of the state of cardiac part of stomach before and during every resection and fixing of bottom of stomach to the diaphragm and abdominal part of esophagus during leveling the Hisa angle.

Alkaline reflux-gastritis meets in 5–35 % operated patients after the resection of stomach, antrectomy, gastroenterostomy, vagotomy with pyloroplasty, and also cholecystectomy and papillosphincteroplasty.

The reason of this complication is influence of duodenum content for the mucous tunic of stomach (bilious acids, enzymes of pancreas and isolecithin). Last, forming from bile lecithin under act of phospholipase A, able to destroy the cells of superficial epithelium of mucous tunic of stomach by removing of lipid from their membranes. As a result the erosions and ulcers are formed in the patient organism. Bilious acids also has the expressed detergent's properties. As isolecithin and bilious acids, the very important bacterial flora which directly and through toxins can cause the damage of mucous tunic of stomach stump. Also, alkaline environment and disturbance of evacuation from the operated stomach influence favourably on microflora growth.

For the clinical picture of alkaline reflux-gastritis the permanent poured out pain in a epigastric area, belch and vomiting by a bile are typical. At some patients heartburn and pain is observed behind a breastbone also. In majority patients so proof loss of weight takes place, that even the protracted complex therapy and valuable feed does not provide addition to the deficit of mass of body. There are typical signs also – anaemia, hypo- or achlorhydria.

Reliable diagnostics of alkaline reflux-gastritis became possible after wide introduction in clinical practice of endoscopic examination. In such patients during gastroscopy hyperemia of mucous tunic of stomach is observed. It is often possible to observe reflux in the stomach of duodenum content. During histological examination of biopsy material a chronic inflammatory process, intestinal metaplasia, diminishment of mass of coating cells and area of hemorrhages are found. All it testifies the deep degenerative changes in the mucous tunic of stomach. The some authors underlines that the inflammatory changes, at least in the area of anastomosis, are observed in most persons which carried the resection of stomach. So, endoscopic examination can not be considered deciding in diagnostics. Even the diffuse inflammatory changes can take place in absent of clinical symptoms and, opposite, in case with expressed clinical symptoms the minimum changes of mucous tunic of stomach are sometimes observed.

Conservative treatment of reflux-gastritis (sparing diet, antacides, enveloping preparations), usually, is ineffective. Existing methods of surgical treatment, mainly, directed on the removal of reflux of duodenum content to the stomach. Most popular is operation by the Roux method. The some surgeons considers that distance from gastroenteroanastomosis to interintestinal anastomosis must be 45–50 cm.

Main reason of origin of peptic ulcer of anastomosis is leaving of the hyperacid state of stomach mucous, even after the performed operation. Such phenomenon can be consequence of many reasons: primary economy resection, wrong executed resection (when the mucous tunic of pyloric part is abandoned in stump of duodenum or stomach), heightened tone of vagus nerves and the Zollinger-Ellison syndrome.

Peptic ulcers, usually, arise up after operation during the first year. Typical signs are pain, vomiting, weight loss, bleeding, penetration and perforation.

Pain is the basic symptom of peptic ulcer. Often it has the same character and localization, as well as at peptic ulcer. However often observe it moving to the left or in the umbilical area. At first patients bind such feelings to the use of food, but then specify nightly and hungry pain. It at first is halted after a food, but in course of time is become permanent, unendurable, independent from food intake. It can increase during the flounces, the walk, can irradiate in the back, thorax or shoulder.

During the objective examination of patients is often possible to expose on a stomach hyperpigmentation from a hot-water bottle. During palpation to the left from epigastric area near a umbilicus the painful and moderate muscles tension of abdominal wall is observed. Sometimes is possible to palpate inflammatory infiltrate of different sizes. During the examination of patients with a peptic ulcer the important role has determination of gastric secretion against a background of histamine and insulin stimulation. There is a necessity also examination of basal secretion. These preoperative examinations in most patients enable to set the reason of hypersecretion which can be: 1) heightened tone of vagus nerves (positive Hollander test); 2) economy resection of stomach, often in combination with the heightened tone of vagus nerve (considerable increase of gastric secretion after histamine or pentagastrin stimulation in combination with the positive Hollander test); 3) abandoned part of mucous tunic of antral part of stomach (high basal secretion and small increase of secretion in reply to histamine and insulin stimulator); 4) the Zollinger-Ellison syndrome.

Roentgenologic diagnostics of peptic ulcer, usually, is difficult, especially at shallow, flat ulcers, bad mobility and insufficient function of anastomosis. A niche is the direct sign of a similar pathology, indirect are the expressed inflammatory changes of mucous tunic of stump of stomach and bowel, painful point in the projection of stump of stomach and anastomosis and bad function of anastomosis. The deciding value in diagnostics has endoscopic examination.

Conservative treatment of peptic ulcers, as a rule, is ineffective. So, operation must be the basic type of treatment. The choice of method of operative treatment depends on character of previous operation and from abdominal cavity pathology found during the revision. For today the most important parts of the repeated operations is vagotomy. There is obligatory also during the resection of stomach on the exception the revision of duodenum stump for liquidation of possibly abandoned mucous tunic of antral area.

Operative treatment at a peptic ulcer must consist of certain stages. Laparotomy and disconnection of adhesions through a considerable spike process (increasing of stomach, loops of intestine and liver to the postoperative scar) almost always causes large difficulties.

After the selection of anastomosis with afferent and efferent loops the last cut by the “UKL-60 appliance”, within the limits of healthy tissues with renewal of intestine continuity by “end-to-end” type anastomosis.

At patients with a peptic ulcer, that developed after gastroenterostomy, cut a duodenum and sutured its stump by one of the described methods. During it there can be the difficulties related to the presence in it active ulcer. When peptic ulcers do not cause rough deformation of stomach, apply degastroenterostomy, vagotomy and drainage operations.

In the case of the considerably expressed spike process it is possible to execute trunk subdiaphragmatic vagotomy, and in case of the insignificantly changed topography of this area — selective gastric vagotomy.

It is important to note, that stomach resected together with anastomosis, peptic ulcer and eliminated area of empty bowel by one block.

This pathology arises up as a result of perforated of peptic ulcer in a transverse colon with formation of connection between a stomach, small or large intestine.

Diagnostics of gastro-colon fistula at patients with expressed clinical signs of disease does not difficult. However, symptoms are often formed and is indicated up slowly, so such patients with different diagnoses long time treat oneself in the therapeutic or infectious parts.

The typical signs of this pathology is considered diminishment or disappearance of pain, that was before, and profuse, that does not respond to treatment, diarrhea. Patients has emptying up to 10–15 times per days and even more frequent. An excrement contains a plenty of undigested muscular fibres and fat acids (steatorrhea). In case of wide fistula an undigested food can be with an excrement.

Excrement smell from a mouth, usually, notice surrounding. The patients does not feel it. However appearance of excrement belch is indicate the hit into the stomach of excrement masses and gases, and could confirm this pathology.

The such patients very quickly lose weight (mass of body goes down on 50–60 %), their skin becomes pale with a grey tint. The protein-free edemata, ascites, hydrothorax, anasarca, signs of avitaminosis appear in non-treated case.

Through the severe losses of liquid and nonassimilable food there can be the increased appetite and unendurable thirst in such patients. However, they adopt a plenty of liquid and food but the state of them continues to get worse.

Headache, apathy and depression is observed, and at the objective examination is exhaustion (ochre colour of skin, dryness and decline of it turgor, edemata or slurred of swelling extremities, atrophy of muscles). A stomach often moderately pigmented from hot-water bottles, subinflated, with the visible peristalsis of intestine. During the changes of patient position it is possible to hear grumbling, splash and transfusion of liquid. The examination of blood can expose hypochromic anaemia.

Roentgenologic examination is a basic diagnostic method. There are three varieties of such examinations of gastro-colon fistula. During the examination with introduction of barium mixture through a mouth the hit of contrasting matter directly from a stomach into a colon is the typical roentgenologic symptom of such pathology. Irrigoscopy is more perfect and effective method. With suspicion on gastro-colon fistula it is better to perform irrigoscopy. Passing of contrasting matter to the stomach at this manipulation testifies the presence of fistula. The third method is insufflation of air in a rectum. With it help on the screen it is possible to observe the location and passing of fistula, and also, as a result, hit of air in a stomach, increase of it gas bubble. Thus there can be the belch with an excrement smell.

The important role played the tests with dyes: at peroral introduction of methylene-blue after the some time it found in excrement masses or, opposite, after an enema with methylene-blue dye appears in a stomach.

Treatment of gastro-colon fistula is exceptionally operative. It needs to be conducted after intensive preoperative preparation with correction of metabolism. All operations which can be applied at treatment of patients with gastro-colon fistula divide into palliative and radical (single-stage operation and multi-stage operation).

During the palliative operations the place of fistula of stomach, transverse colon and jejunum is disconnected and then sutured the created defects. Other variant is disconnection of stomach and transverse colon and leaving the gastroenteroanastomosis. It is necessary to remember, that during such operations the only fistula always removed and does not performed the resection of stomach. Clearly, that such situation also does not eliminate possibility of relapse of peptic ulcer and development of its complications. Taking into account it, palliative operations can be recommended in those case only, when the general condition of patient does not allow to perform radical operation.

Single-stage operation radical operations. The most widespread is degastroenterostomy with the resection of stomach. However, it is needed to remember that operation of disconnection of fistula, suturing of opening in the jejunum and transverse colon on the lines of fistula and resection of stomach applies only in case of absent of infiltrate and deformation and in the conditions of possibility to close a defect in bowels without narrowing of their lumen. This operation is the simplest, is enough easily carried by patients and it is enough radical.

Such complications appear through considerable time after operation (from 1 month to one year). Disturbances of function of gastrointestinal anastomosis can be caused by the reasons, related both to the technical mistakes during operation and with pathological processes which arose up in the area of anastomosis.

The clinical picture of disturbance of anastomosis function, mainly, depends from the degree of its closing. At complete it obstruction in patients arise up intensive vomiting, pain in a epigastric area, the symptoms of dehydration and other similar signs appear. In other words, the clinic of stenosis of the stomach output develops. Clearly, that during incomplete narrowing the clinical signs will be expressed less, and growth of them — more slow. Sometimes disturbance of evacuation can unite with the syndrome of afferent loop with a inherent clinical picture. At the roentgenologic examination of such patients expansion of stomach stump is exposed with the horizontal level of liquid and small gas bubble. Evacuation from it is absent or acutely slow.

Treatment of scar deformations and narrowing of anastomosis must be operative and directed for the disconnection of accretions and straightening of the deformed areas. In case of presence in patients large inflammatory infiltrate it does not need to perform disconnection. In such cases it is the best to apply roundabout anastomosis. If a resection by Finsterer was done in such patient, better to perform anterior gastroenteroanastomosis, and after a resection by Billroth-I — posterior. As a result of conducting of such operations the state of patient, as a rule, gets better, and often recovered the function of primary anastomosis.

Removing of all stomach and exception of duodenum from the process of digestion of food cause plural functional disturbances in an organism. Some of them meet already after the resection of stomach (dumping-syndrome, hypoglycemic syndrome), other more inherent for gastrectomy (anaemia, reflux- esophagitis and others like that).

Most patients, that carried gastrectomy, complain for a considerable physical weakness, heightened fatigueability, sometimes is complete weakness, loss of activity and acute decline of work capacity. Almost all of them notice bad sleep, worsening of memory and heightened irritates. The appearance of patients is typical. Their skin insignificantly hyperpigmented, dry, its turgor reduced, noticeable atrophy of muscles. Can be the signs of chronic coronal insufficiency in such patients, and in older-year persons is typical picture of stenocardia. Except for it, can be hypotension, bradycardia and decline of voltage on EKG; during auscultation deafness of tones is observed. From the side of the hormonal system the decline of function of sexual glands is typical: in men — declines of potency, in women — disturbances of menstrual cycle, early climax. Can be the signs of hypovitaminosis A, B, C and decline of resistibility of organism to chill, infectious diseases and tuberculosis.

The decline of mass of body is observed in 75 % patients, that carried gastrectomy. It is conditioned by the decline of power value of food as a result of disturbance of digestion, bad appetite and wrong diet. As a result of progressive hypoproteinemia there can be the protein-free edemata.

Patients with such pathology must be under the permanent clinical supervision and 1–2 times per year during a month to have the course of stationary prophylactic treatment which includes psycho-, diet-, vitaminotherapy, correcting and replaceable therapy, and also prophylaxis of anaemia.

Psychotherapy is especially indicated in the psychodepressive and asthenic states. It is performed in combination with medicinal treatment. Hypnotic preparation, bromide, tranquilizers are applied.

A food must be correctly prepared, without the protracted cooking. Patients need to feed on 6–10 times per days by small portions.

Next to dietotherapy, it is constantly necessary to apply replaceable therapy (Pancreatine, Pansinorm, Festal, Intestopan). In case of absent of esophagitis hydrochloric acid is appointed. For the improvement of albuminous exchange anabolic hormones are applied.

In case of reflux-esophagitis there are indicated feeds by small portions with predominance of liquid, ground, jelly-like foods, astringent, coating, anticholinergic preparations. Between the receptions of food does not recommend to use a liquid. In case of dysphagy appoints a sparing diet.

For the prophylaxis of iron-deficiency anaemia, that arises up in the first 2–3 years after gastrectomy, important the indication of iron preparations.

For warnings and treatments of pernicious anaemia applied cyanocobalamin for 200 mcg through a day and folic acid. Packed red blood cells is indicated in heavy case.

The relapse of ulcer is enough frequent complication of vagotomy. It meets in 8–12 % patients. The reasons of such relapses of ulcer can be: 1) inadequate decline of products of hydrochloric acid (incomplete vagotomy, reinnervation); 2) disturbance of emptying of stomach (ulcerous pylorostenosis after selective proximal vagotomy or after pyloroplasty); 3) local factors (duodenogastric reflux with development of chronic atrophy gastritis, disturbance of circulation of blood and decline of resistibility of mucous tunic); 4) exogenous factors (alcohol, smoking, medicinal preparations); 5) endocrine factors (hypergastrinaemia: hyperplasia of antral G-cells, the Zollinger-Ellison syndrome; hyperparathyroidism).

Three variants of clinical passing of relapse of ulcer are distinguished after vagotomy: 1) symptomless, when an ulcer is found during endoscopic examination; 2) recurrent with protracted lucid space; 3) persisting ulcer with typical periodicity and seasonality of exacerbation.

It is needed to underline that the clinical signs of this pathology during the relapse are less expressed, than before operation, and absence of pain does not eliminate the presence of ulcer. Sometimes bleeding can be first its sign. Complex examination, that includes roentgenologic, endoscopic examination, study of gastric secretion and determination of content of gastrin in the blood, allows not only to expose an ulcer but also, in most cases, to set its reason. The interpretation the results of gastric secretion examination in such patients are heavy. Taking into account it, it is needed to study both a basal secretion and secretion in reply to introduction of insulin and pentagastrin, and also level of pepsin.

Approximately in 35 % patients, mainly with the first two variants of clinical passing of disease, the relapses of ulcers, are treated by ordinary methods of conservative therapy. Yet in 30–40 % cicatrization of ulcers comes after application of preparations which stop a gastric secretion (cimetidine, ranitidine—150 mg for night). At other 10–20 % patients, mainly with the third variant of clinical passing, is necessary operative treatment.

The question of choice of the repeated operation in patients with the relapse of ulcer after vagotomy still does not decided. Some surgeons execute revagotomy, trunk vagotomy with drainage operation, revagotomy with antrectomy or resection of stomach. However much majority from them in case of relapse ulcer after vagotomy performed antrectomy in combination with trunk vagotomy.

Frequency of postvagotomy diarrhea hesitates from 2 to 30 %. The basic sign of complication in patient is present the liquid watery emptying about three times per days. The reasons of diarrhea are: gastric stasis and achlorhydria, denervation of pancreas, small intestine and liver, and also disturbance of motility of digestive tract. Discoordination of evacuations from a stomach, stagnation and hypochlorhydria assist to development in it different microorganisms, and it also can be the reason of diarrhea.

The clinical signs of postvagotomy diarrhea are specific. Acute beginning are typical –patient often does not have time to reach to the rest room. Such suddenness repressing operates on patients. As a result they are forced whole days to be at home, expecting the duty attack. An excrement changes colorings as a result of breeding of pigment and becomes more light.

Treatment of diarrhea must be complex. Above all things it is needed to recommend a diet with the exception of milk and other provoking products. For the removal of bacterial factor antibiotics are applied. Favourable action in case of the signs of stagnation in a stomach are had weak solutions of organic acids (lemon, apple and others like that).

Among other most distribution was got by the A.A. Kuragin and S.D. Hroismann (1971) suggestion to treat postvagotomy diarrhea by benzohexamethonium (for 1 ml 2,5 % solution 2–3 times per a day). Reported also about successful application of cholesteramine (for 4 g 3 times per a day with the subsequent decline of dose to 4 g per days).

At heavy passing of postvagotomy diarrhea, that does not respond to conservative treatment, it is needed to recommend operative treatment — degastroenterostomy with pyloroplasty. However, the type of drainage operation, as practice shows, does not influence on frequency of diarrhea origin. In this connection, some surgeons with success applied the inversion of the segment of thin bowel, located distal from the area of maximal absorption.

The cancer of stomach is a malignant formation, that develops from epithelium tissue of mucus stomach. Among the tumours of organs of digestion this pathology takes first place and is the most frequent, by the reason of death from malignant formations in many countries of world. Frequency of it at the last 30 years considerably diminished in the countries of Western Europe and North America, but yet remains high in Japan, China, countries of East Europe and South America.

Etiology of cancer of stomach is unknown. It is known that, as other diseases of gastrointestinal tract, a cancer damages a stomach. According to statistical information, it meets approximately in 40 % of all localizations of cancer.

The factors of external environment has the substantial influencing on frequency of this pathology. Above all things, feed, smoke food, salting, freezing of products and their contamination of aflatoxin. Consider that a “food factor” can be: a) by a carcinogen; b) by the solvent of carcinogens; c) to grow into a carcinogen in the process of digestion; d) to be instrumental in action of carcinogens; e) not enough to neutralize carcinogens.

In the USA and countries of Western Europe frequency of cancer of stomach in 2 times more large in the lower socio-economic groups of population. Some professional groups also can it (miners, farmers, works of rubber, woodworking and asbestine industry). High correlation communication is set between frequency of cancer of stomach and use of alcohol and smoking. The value of genetic factors (heredity, blood type) is not led to.

The cancer of stomach arises up mainly in age 60 years and above, more frequent men are ill.

Precancer. The precancer diseases of stomach are: a) chronic metaplastic disregenerator gastritis conditioned by helicobacter pylori; b) villous polypuses of stomach and chronic ulcers; c) nutritional anemia due to vitamin B12 deficiency (pernicious); d) resected stomach concerning an ulcer.

The presence of precancer changes of mucous tunic of stomach has substantial influence for frequency of stomach cancer. In those countries, where morbidity on the cancer of stomach is higher, considerably more frequent chronic gastritis are diagnosed. Lately in etiology of chronic gastritis take the important value helicobacter pylori. In Japan, where the cancer of stomach is in 40 % cases is the reason of death, chronic gastritis appears in 80 % cases of resected stomach, concerning a cancer.

Connection between polypuses, chronic gastric ulcers and possible it malignization comes into question in literature during many decades. Most authors consider that polypuses could be malignant differently. There are three histological types of polypuses: hyperplastic, villous and hamartoma. There are hyperplastic polypuses, but it not malignant.

Hamartoma is accumulation of cells of normal mucous tunic of stomach. They never becomes malignant.

Villous polypuses are potentially malignant in 40 % cases, but it happen in 10 times less, than hyperplastic. The possibility of malignization of chronic gastric ulcers is not proved. The American scientists support a hypothesis, that the cancer of stomach can be ulcerous often, but malignization of ulcers takes place rarely (no more than 3 %). From data of the Japanese scientists, on 50–70th there was higher correlation connection between chronic gastric ulcers and cancer of stomach. The frequent decline of this correlation is lately noticed (70 % on 50–70th and 10 % on 80th).

Frequency of cancer of stomach at patients with pernicious anaemia hesitates within the 5–10 %, that in 20 times higher, compare with control population. In patients with a resected stomach after peptic ulcers is multiplied the risk of origin of stomach cancer in 2–3 times (duration of latent period hesitates from 15 to 40 years). The reason of such dependence is not found out, but there is a version, that this is linked with a gastric epithelium metaplasia by an intestinal type.

From all malignant formations of the stomach in 95 % adenocarcinoma is observed. Epidermoid cancer, adeno-acanthoma and carcinoid tumours do not exceed 1 %. Frequency of leiomyosarcoma hesitates within the limits of 1–3 %. Lymphoma of gastrointestinal tract is localized in a stomach.

The prognosis of localization depends on the degree of invasion, histological variants of tumour.

The macroscopic forms of cancer of stomach in different times were described variously. More than 60 years ago the German pathologist Bermann described 5 macroscopic forms of cancer of stomach: 1) polypoid or mushroom-like; 2) saucer-shaped or with ulcerous and expressly salient edges; 3) with ulcerous and infiltration of walls of stomach; 4) diffuse -infiltrate; 5) unclassified.

American pathopsychologists is selected 4 forms. The tumours of stomach with ulcerous are the most frequent macroscopic form of cancer of stomach and arise up on soil of chronic ulcer. The signs suspicious on malignization are: the sizes of ulcer more than 2 cm in a diameter, appearance of the heightened edges.

The polypoid tumours of stomach observed only in 10 %. These tumours can achieve considerable sizes without an invasion and metastasis. Scirrhus carcinoma is the third macroscopic type. This category of tumours also does not exceed 10 %. The scirrhus carcinoma is the signs of infiltration by anaplastic cancer cells, diffusely developed connecting tissue which results in the bulge and rigidity of wall of stomach. So called “small cancers” belong to the fourth macroscopic type. It meet comparative rarely (no more than 5 %) and is characterized by superficial accumulation of cancer cells which substitute for normal mucus in such kind: a) superficial flat layer which does not rise above the level of mucus; b) salient (bursting) formation; c) erosions.

Mainly (more than 50 %) tumours arise up in a antral part or in distal (lower) third of stomach, rarer (to 15 %) — in a body and in cardia (to 25 %).

However, lately more often observed cardioesophageal cancers and diminishment of frequency of tumours of distal parts of stomach. In 2 % cases meet the multicentric focuses of growth, but from data of some authors, this percent could be multiplied in 10 times after carefully histological inspection of the resected stomachs. This assertion is based on the theory of the “tumour field” (D.I. Holovin, 1992). Especially this typically for patients which has pernicious anaemia or chronic metaplastic disregenerative gastritis.

Metastasis is carried out by lymphogenic, hematogenic and implantation ways mostly. Three (from data of some authors, four) pools of lymphogenic metastasis are selected: left gastric (knots on passing of small curvature of stomach in a gastro-subgastric ligament and pericardial); splenic (mainly, suprafrapancreatic knots); hepatic (knots in a hepato-duodenal ligament, right gastric omentum that lower pyloric groups, right gastric and suprapyloric groups, pancreatoduodenal group).

However, the such way of lymphogenic metastasis is conditional and incomplete, as at presence of block lymph flow passes retrograde metastasis, so called “jumping metastases” which predetermine the origin of remote lymphogenic metastases in left supraclavicular lymph nodes (Virhov metastasis) appear, in Lymph nodes of left axillar and inguinal areas, metastases in an umbilicus.

Direct distribution: small and large omentum, esophagus and duodenum; liver and diaphragm; pancreas, spleen, bile ducts.

Front wall of stomach: colon bowel and mesocolon; organs and tissues of retroperitoneal space.

Lymphogenic metastasis: regional lymph nodes, remote lymph nodes, left supraclavicular lymph node (Virhov), lymph node of axillar area (Irish); in a umbilicus (sisters Joseph).

Hematogenic metastasis: liver, lungs, bones, cerebrum.

Peritoneal metastasis: peritoneum, ovarium (the Krukenberg metastasis), Duglas space (the Shnieler metastasis).

All authors which are engaged in the study of problem of cancer of stomach underline absence or vagueness, no specificity of symptoms, especially on the early stages of disease. The displays of cancer of stomach are very various and depend on localization of tumour, character of its growth, morphological structure, distribution on contiguous organs and tissues. At localization of tumour in a cardiac part patient complains firstly, as a rule, for appearance of dysphagy.

At careful, purposeful collection of anamnesis it is not succeeded to expose some other, most early symptoms, which precedes to dysphagy and forces a patient to appeal to the doctor. The unpleasant feeling behind a breastbone and feeling of unpassing of hard food on a esophagus appear at the beginning of disease. After some time (as a rule, it is enough quickly, during a few weeks, sometimes even days) a hard food does not pass (it is to wash down by water or other liquid). This period can be during 1–3 months. Patients address a doctor exactly in this period. Other symptoms appear to this time: regurgitation, pain behind a breastbone, loss of mass of body, sometimes even exhaustion, the grey colouring of person, a skin is dry, quickly grows general weakness. Sometimes patients address a doctor, when already with large effort a spoon-meat passes only or complete stenosis came.

At localization of tumour in the antral part of stomach the first complaints, as a rule, are up to appearance of feeling of weight in epigastric region after the reception of food (even in a two-bit), “feeling of saturation” (after the reception of glass of water), belch (at first it is simple by air, and then with a smell). Feeling of weight grows for a day, patients forced to cause vomiting. In the morning there can be vomiting by mucus with the admixtures of “coffee-grounds” (so called “cancer” water). Patients loses weight (mass of body is lost), a weakness, anaemia grows.

Tumours localized in the body of stomach show up either a pain syndrome or syndrome of so called “small signs” (A.I. Savitsky, 1947), which is characterized by appearance of amotivational general weakness, decline of capacity, rapid fatigueability, depression (by the loss of interest to the environment), proof decline of appetite, gastric discomfort, making progress weight lost.

The carried chronic diseases of stomach, for which typical seasonality, can influence on the clinical sign of cancer of stomach. At appearance of “gastric” complaints out of season or in absent of effect from the got therapy concerning the exacerbation of “gastritis”, “ulcers” must guard a patient and doctor (symptom of “precipice” of gastric anamnesis).

In case of occurring of “gastric” symptoms first in persons in age 50 years and older it is foremost necessary to eliminate the cancer of stomach.

In parts of patients cancer of stomach shows up only the metastatic damage of other organs or complications. More than twenty so called “atypical” forms, which are characterized by “causeless” anaemia, ascites, icterus, fever, edemata, hormonal disturbances, changes of carbohydrate exchange, intestinal symptoms, are distinguished.

During the examination of patients with the cancer of stomach the pallor of skin covers (at anaemia) is observed, in neglected case is “frog” stomach (sign of ascites).

During palpation determined painful in a epigastric area, sometimes possible to palpate the tumour.

During auscultation of patients with pylorostenosis it is possible to define “noise of splash”.

Laboratory information: hypochromic anaemia, neutrophilic leukocytosis, megascopic ESR; during examination of gastric secretion: hypo- and acidity and achlorhydria.

Gastroduodenoscopy enables to diagnose a tumour even smaller 5 mm and conduct an aiming biopsy with histological examination of the taken material.

Roentgenoscopy and roentgenography examination of stomach. Basic signs: defect of filling, local absence of peristalsis, "malignant" relief of mucous tunic (Pic. 3.2.18).

Ultrasonic examination: presence of metastases in a liver, pancreas.

Computer tomography allows to estimate the basic parameters of tumour, germination in neighbouring organs and presence of metastases.

It is expedient to apply laparoscopy, mainly, for the decision of question about operable of tumour (diagnostics of metastatic defeat of organs of abdominal cavity).

At an early cancer complaints depend on the previous gastric diseases. Therefore, on the basis of clinical information, suspecting a tumour is possible only on occasion, when in patients next to clear pain symptoms an appetite goes down, appear anaemia, general weakness. In practice an early cancer is recognized at purposeful screening, and also in the process of endoscopic or roentgenologic examination of gastric patients.

A differential diagnosis is conducted with an peptic ulcer, gastritis, polyposis, other gastric and ungastric diseases. For a cancer there is typical firmness of symptoms, instead of their seasonality (typical syndrome of "precipice" of gastric anamnesis) or tendency to their gradual progress.

The row of diseases, with which the cancer of stomach is to differentiate to the doctor, depends from character of complaints of patients.

Five basic clinical syndromes are selected:

- 1) pain;
- 2) gastric discomfort;
- 3) anaemic;
- 4) dysphagic;
- 5) disturbance of evacuation from a stomach.

At patients, at what cancer of stomach shows up a pain syndrome and syndrome of gastric discomfort, a differential diagnosis is conducted with the peptic ulcer, gastritis, cancer of body of pancreas.

It is oriented on features dynamics of development of pain syndrome, ingravescence of the general condition, change of character of complaints.

A question about character of anaemia, source and nature of bleeding decides at an anaemic syndrome. In the process of examination attention is paid to the state of bottom of stomach, where bleeding malignant formations can be.

At a dysphagic syndrome a differential diagnosis is conducted with the cicatricial narrowing, achalasia of esophagus. For malignant formations testify short anamnesis, gradual progress of symptoms, signs of gastric discomfort, general weakness, weight lost.

At disturbance of evacuation from a stomach during stenosis of pyloric part, absence of ulcerous anamnesis, declining years of patients, relatively quick (weeks, months) growth of stenosis testify for tumor.

The presence of cancer of stomach is a indications for surgical treatment. However, counting on success is possible only at presence of the limited tumours (within the limits of the 0-II stages). At the III stage of disease implementation of the widespread combined operations in a radical volume is possible, however most patients die during 1–2 years. A distal or proximal subtotal resection (Pic. 3.2.19) and total gastrectomy (Pic. 3.2.20) is performed with removing of large and small omentumes and regional areas of metastasis with obligatory histological examination of stomach on the lines of resections.

During the combined operations organs which are pulled in to the pathological process are removed.

In case of IV stage of disease and satisfactory state of patient palliative operations which improve quality of life of patient are performed.

In case of presence of complications (mainly stenosis) and grave common condition of patient perform symptomatic operative treatments.

Symptomatic is operations which will liquidate one of symptoms of cancer of stomach. In this group of operations include: 1) roundabout gastrojejunostomosis (Pic. 3.2.21) and jejunostoma (in case of the stenosis tumours of stomach output); 2) gastrostoma (Pic. 3.2.22) in case of the cancer of cardiac part of stomach with disturbance of patency; 3) edging of bleeding vessels in case of complication of cancer by bleeding; 4) tamponade by omentum during the perforation of tumour.

The value of radial therapy and chemotherapy, as independent methods of treatment of cancer of stomach, is limited. Radial therapy is indicated for patients with cardiac cancer as preoperative course or as palliative treatment. Adjuvant mono- or polychemotherapy (mainly by 5-photouracil) is conducted in a postoperative period as combined therapy and in case of dissemination of the tumours.

Prognosis. The indexes of five-year survival of patients with the cancer of stomach hesitate within the limits of 5–30 %, but, from data of most authors, they do not exceed 10 %.

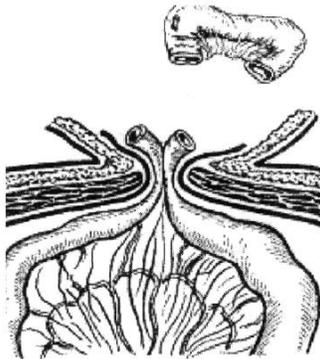

Tactics and choice of treatment method

The incarcerated hernia, regardless of time of its origin, localization and age of patient, must be operated on. However, if a patient is hospitalized already with the expressed symptoms of intestinal obstruction, than should be preoperative treatment. Such conservative therapy must be brief (1–1,5 hours), but always actively directed for correction of violations of metabolism and prophylaxis of possible pulmonary and cardiovascular complications. It is necessary also to conduct evacuation of the gastric contents and other preparatory procedures.

Patient with reduced hernia must be hospitalized and observed during 1–2 days. If a abdominal pain is contained or is growing, the signs of peritonitis and intoxication appear, than performed urgent laparotomy and necessary operation. If the symptoms of "acute" abdomen are not present, a patient examined and prepared for elective operation.

Operation at the incarcerated hernia is executed under the general anesthesia. A hernia sack is selected from surrounding tissue, cut it in the area of bottom and remove hernia water, defining its character and sending to bacterial inoculation. Retaining the damaged organs, a strangulated ring is cut. It is necessary to remember, that at the incarcerated femoral hernia ring cut up and some medially, because a femoral vein passes from a lateral side.

If a bowel is contents of hernia sack, we must estimate its viability. Remembering about possibility of the retrograde jamming, special attention must be paid to the state of strangulation furrow. About viability of the bowels testify: 1) renewal of its normal color; 2) presence or renewal of peristalsis; 3) renewal of pulsation of vessels of mesentery and bowel. If there are the certain doubting, a bowel is dipped on a holder in an abdominal cavity and in 15–20 minutes it is examined repeatedly. If one of the resulted signs of viability is absent even, it is necessary to conduct the resection of bowel. The resection is executed, receded from the strangulation furrow on a proximal loop 30–40 cm and distal — 15–20 cm. Anastomosis between proximal and distal loops it is better to impose "end-to-end". The plastic of hernia gate are conducted depending on indications after one of the surgical methods.

When the necrosis elements of omentum or fatty pendants of colon are contents of hernia sack, they must be removed within the limits of healthy tissue.

There can be necrosis of wall of colon or urinary bladder at sliding hernia. In such cases it is needed to be limited to the minimum surgical procedure: to dip a necrosis area by sutures inside the bowel or use it for forming of colostomy or epicycstostomy. These are the best to conclude operation.

In similar situations at the incarcerated parietal hernia in most patients it is possible to be limited to peritonization of displaced area of wall of bowel. If after the peritonization there is the threat of narrowing of bowel or necrosis goes outside of the strangulation furrow, it is needed to conduct the resection of bowel.

Because of insufficient blood flow of Meckel's diverticulum and, permanent threat of it necrosis, at patients with Littre's hernia it resection must be performed.

At the phlegmon of hernia sack operation is begun with hemiotomy. If the incarcerated organ is damaged by necrosis, and in a hernia sack present pus, than there is a necessity for surgeon to perform laparotomy. After that incarcerated organ resected within the limits of healthy tissue (in the generally accepted limits — 40 cm of proximal loop and 20 cm distal) and impose anastomosis. An abdominal cavity is sewn up. Incarcerated loops of bowel, together with it blind ends which located in an abdominal cavity, removed through a hernia sack, a peritoneum is sutured, the hernia sack is drained, the plastic of hernia gate are not performed. Skin is sewn up by widely spaced sutures.

ACUTE ILEUS. PATHOGENESIS. CLINIC. DIAGNOSTIC. TACTICS.

ACUTE DYNAMIC ILEUS.

ACUTE OBTURATIVE AND STRANGULATED INTESTINAL OBSTRUCTION.

Intestinal obstruction is a complete or partial violation of passing of maintenance by the intestinal tract.

Ileus is commonly defined simply as bowel obstruction. However, authoritative sources define it as decreased motor activity of the GI tract due to non-mechanical causes. In such sense, this does not include motility disorders that result from structural abnormalities, and, therefore, some mechanical obstructions are misnomers, such as gallstone ileus and meconium ileus, and are not true examples of ileus.

Types:

Decreased propulsive ability may be broadly classified as caused either by bowel obstruction or intestinal atony or paralysis. However, there are instances where there are symptoms and signs of a bowel obstruction, but with absence of a mechanical obstruction, mainly in *acute colonic pseudoobstruction*, also known as Ogilvie's syndrome.

Bowel obstruction. Bowel obstruction (or intestinal obstruction) is a mechanical or functional obstruction of the intestines, preventing the normal transit of the products of digestion. It can occur at any level distal to the duodenum of the small intestine and is a medical emergency. The condition is often treated conservatively over a period of 2–5 days with the patient's progress regularly monitored by an assigned physician. Surgical procedures are performed on occasion however in life-threatening cases, such as when the root cause is a fully lodged foreign object or malignant tumor.

Intestinal atony or paralysis. Paralysis of the intestine is often termed *paralytic ileus*. To be termed "paralytic ileus", the intestinal paralysis need not be complete, but it must be sufficient to prohibit the passage of food through the intestine and lead to intestinal blockage.

Paralytic ileus is a common side effect of some types of surgery, in these cases it is commonly called *postsurgical ileus*. It can also result from certain drugs and from

various injuries and illnesses, *i.e.* acute pancreatitis. Paralytic ileus causes constipation and bloating. On listening to the abdomen with a stethoscope, no bowel sounds are heard because the bowel is inactive.

A temporary paralysis of a portion of the intestines occurs typically after an abdominal surgery. Since the intestinal content of this portion is unable to move forward, food or drink should be avoided until peristaltic sound is heard from auscultation of the area where this portion lies.

Etiology and pathogenesis

The principal reasons of intestinal obstruction can be:

- 1) adhesions of abdominal cavity after traumas, wounds, previous operations and inflammatory diseases of organs of abdominal cavity and pelvis;
- 2) long mesentery of small intestine or colon, that predetermines considerable mobility of their loops;
- 3) tumours of abdominal cavity and retroperitoneal space.

Such principal reasons can cause violation of passing of intestinal maintenance, disorder of suction from the intestine and loss of plenty of electrolytes both from vomiting and in the intestine cavity as a result of disorders of bloodflow in its wall.

Most cases of ileus occur after intra-abdominal operations. Normal resumption of bowel activity after abdominal surgery follows a predictable pattern: the small bowel typically regains function within hours; the stomach regains activity in 1-2 days; and the colon regains activity in 3-5 days.

Serial abdominal radiographs mapping the distribution of radiopaque markers have shown that the colonic gradient for resolution of postoperative ileus is proximal to distal. The return of propulsive activity to the right colon occurs earlier than to the transverse or left colon.

Other causes of adynamic ileus are as follows:

- Sepsis
- Drugs (eg, opioids, antacids, warfarin, amitriptyline, chlorpromazine)
- Metabolic (eg, low potassium, magnesium, or sodium levels; anemia; hyposmolality)

- Myocardial infarction
- Pneumonia
- Trauma (eg, fractured ribs, fractured spine)
- Biliary colic and renal colic
- Head injury and neurosurgical procedures
- Intra-abdominal inflammation and peritonitis
- Retroperitoneal hematomas

Causes of Intestinal Obstruction

Causes of Intestinal Obstruction	
Location	Cause
Colon	Tumors (usually in left colon), diverticulitis (usually in sigmoid), volvulus of sigmoid or cecum, fecal impaction, Hirschsprung's disease, Crohn's disease
Duodenum	
Adults	Cancer of the duodenum or head of pancreas, ulcer disease
Neonates	Atresia, volvulus, bands, annular pancreas
Jejunum and ileum	
Adults	Hernias, adhesions (common), tumors, foreign body, Meckel's diverticulum, Crohn's disease (uncommon), Ascaris infestation, midgut volvulus, intussusception by tumor (rare)
Neonates	Meconium ileus, volvulus of a malrotated gut, atresia, intussusception

Pathophysiology. In simple mechanical obstruction, blockage occurs without vascular compromise. Ingested fluid and food, digestive secretions, and gas accumulate above the obstruction. The proximal bowel distends, and the distal segment collapses. The normal secretory and absorptive functions of the mucosa are depressed, and the bowel wall becomes edematous and congested. Severe intestinal distention is self-perpetuating and progressive, intensifying the peristaltic and secretory derangements and increasing the risks of dehydration and progression to strangulating obstruction.

According to some hypotheses, postoperative ileus is mediated via activation of inhibitory spinal reflex arcs. Anatomically, 3 distinct reflexes are involved: ultrashort reflexes confined to the bowel wall, short reflexes involving prevertebral ganglia, and long reflexes involving the spinal cord. The long reflexes are the most significant. Spinal anesthesia, abdominal sympathectomy, and nerve-cutting techniques have been demonstrated to either prevent or attenuate the development of ileus.

The surgical stress response leads to systemic generation of endocrine and inflammatory mediators that also promote the development of ileus. Rat models have shown that laparotomy, eventration, and bowel compression lead to increased numbers of macrophages, monocytes, dendritic cells, T cells, natural killer cells, and mast cells, as demonstrated by immunohistochemistry. Macrophages residing in the muscularis externa and mast cells are probably the key players in this inflammatory cascade. Calcitonin gene-related peptide, nitric oxide, vasoactive intestinal peptide, and substance P function as inhibitory neurotransmitters in the bowel nervous system. Nitric oxide and vasoactive intestinal peptide inhibitors and substance P receptor antagonists have been demonstrated to improve gastrointestinal function.

Strangulating obstruction is obstruction with compromised blood flow; it occurs in nearly 25% of patients with small-bowel obstruction. It is usually associated with hernia, volvulus, and intussusception. Strangulating obstruction can progress to infarction and gangrene in as little as 6 h. Venous obstruction occurs first, followed by arterial occlusion, resulting in rapid ischemia of the bowel wall. The ischemic bowel becomes edematous and infarcts, leading to gangrene and perforation. In large-bowel obstruction, strangulation is rare (except with volvulus).

Perforation may occur in an ischemic segment (typically small bowel) or when marked dilation occurs. The risk is high if the cecum is dilated to a diameter ≥ 13 cm. Perforation of a tumor or a diverticulum may also occur at the obstruction site.

Pathomorphology

The morphological signs of dynamic intestinal obstruction are: small thickening of wall (at considerable paresis is thinning), friability of tissue (the bowel breaks easily) and presence of liquid maintenance and gases in cavity of bowel. At mechanical obstruction it is always possible to expose the obstacle: strang, commissures, tumours, jammings of hernia, cicatricial strictures, wrong entered drainages, tampons and others like that. In place of compression strangulation is exposed. The bowel loop higher strangulation is extended, and distally — collapsed. In case of released invagination on small distance two strangulation furrows are observed, and distally from the second ring cylinder expansion of bowel lumen is observed.

Classification

(by D.P.Chuhrienko, 1958)

Acute intestinal obstruction is divided:

I. *According to morphofunctional signs.*

1. Dynamic intestinal obstruction:

a) paralytic;

б) spastic;

в) hemostatic (embolic, thrombophlebitic).

2. Mechanical intestinal obstruction(Fig.1):

a) strangulated, volvulus, jamming;(Fig. 2)

б) obturation (closing of bowel lumen, squeezing from outside);

в) mixed (invagination, spike intestinal obstruction).

II. *According to clinical passing.*

1. Acute.

2. Chronic.

III. *According to the level of obstruction.*

1. Small intestinal.
2. Large intestinal:
 - a) high;
 - б) low.

IV. *According to the passing of intestinal maintenance.*

1. Complete.
2. Partial.

V. *According to the origin.*

1. Innate.
2. Acquired.

VI. *According to development of pathological process.*

1. Stage of acute violation of intestinal passage.
2. Stage of hemodynamic disorders of bowel wall and its mesentery.
3. Stage of peritonitis.

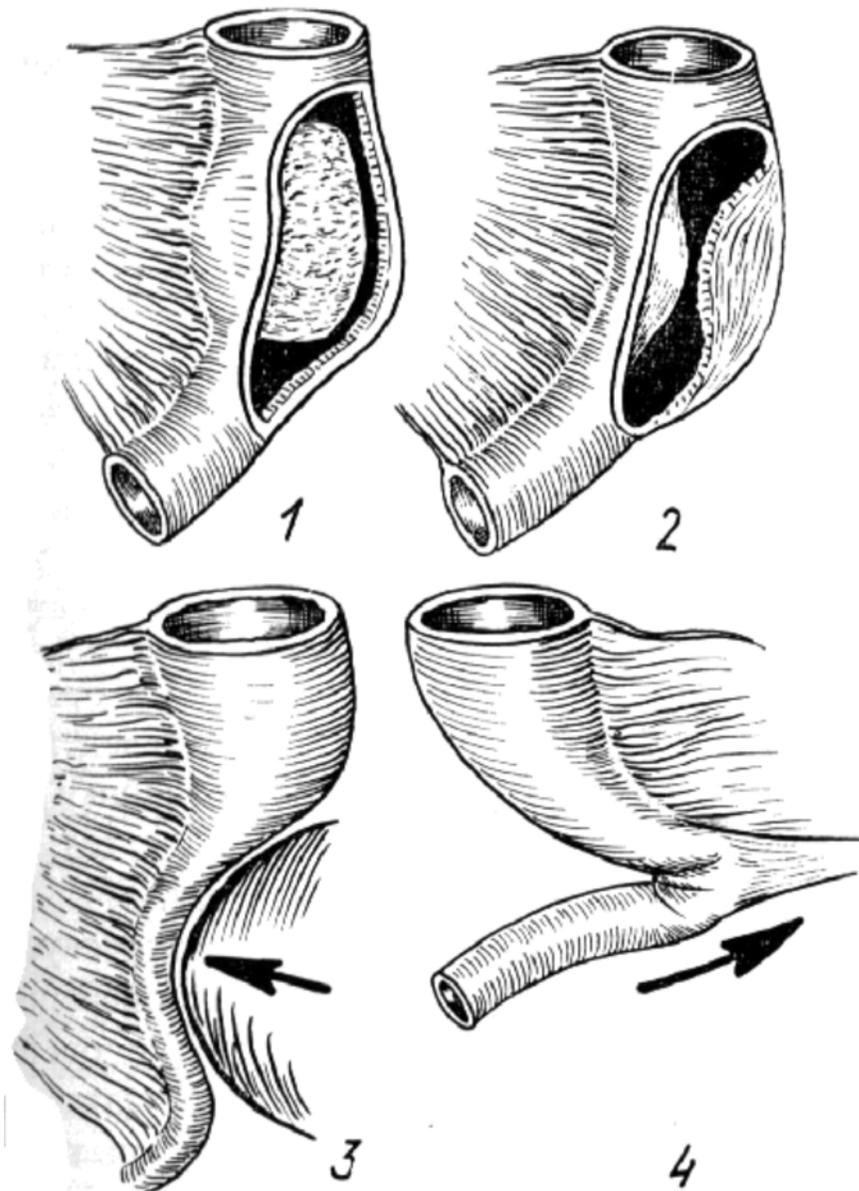

Fig.1. Types of mechanical intestinal obstruction. Obstacle reason of obturation: 1-Obturation; 2-Constriction; 3- Compression; 4- Angulation

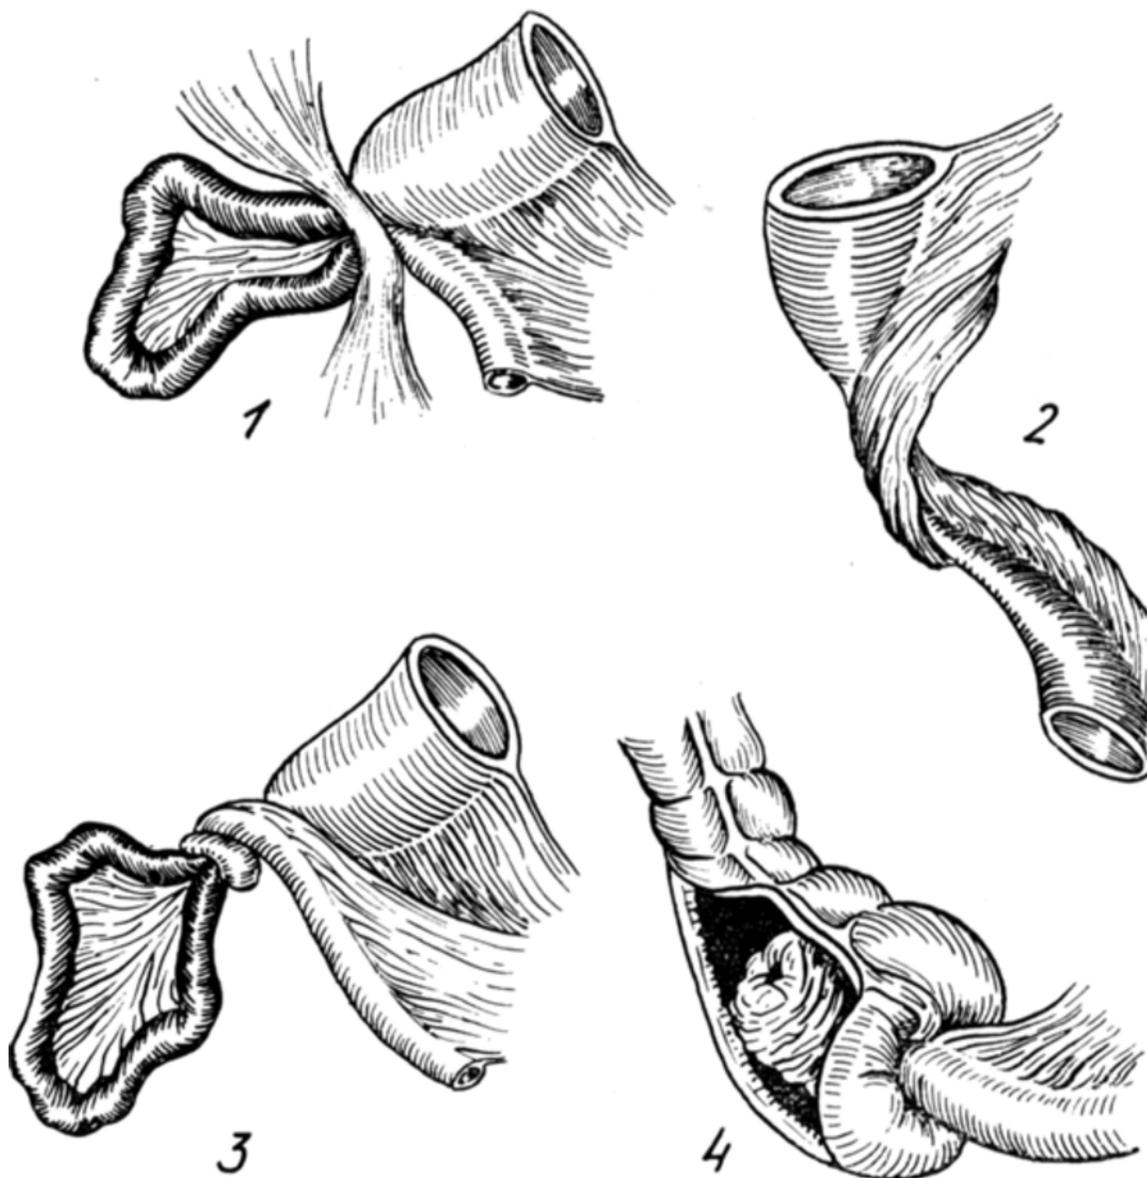

Fig.2. Mechanical intestinal obstruction. The disorders of blood circulation:
1-Strangulation; 2- Jamming; 3- Volvulus; 4- Invagination

Clinical management

Main symptoms:

- moderate, diffuse abdominal discomfort
- constipation
- abdominal distension
- nausea/vomiting, especially after meals
- lack of bowel movement and/or flatulence
- excessive belching

Beginning of clinical signs of intestinal obstruction is sudden — in 1–2 hours after taking the meal. The pain in the abdomen has the intermittent character and is met in all forms of mechanical intestinal obstruction. However, some types of strangulated intestinal obstruction (node formation, volvulus of thin and colons) can be accompanied by permanent pain. It is needed to mark that at spike intestinal obstruction, invagination and obturation cramp-like pain can be considered as pathognomic sign of disease. For paralytic intestinal obstruction more frequent is inherent permanent pain which is accompanied by the progressive swelling of abdomen. At spastic obstruction of intestine the pain is mainly acute, the abdomen is not blown away, sometimes pulled in.

Nausea and vomiting are met in 75–80 % patients with the heaviest forms of high level of intestinal obstruction (node formation, volvulus of small intestine, spike obstruction). At obturation obstruction and invagination they are observed not so often.

There is a characteristic thirst which can be considered as an early symptom. Besides, the higher intestinal obstruction, the greater the thirst.

Swelling of abdomen, the delay of emptying and gases are observed in 85–90% patients, mainly, with the high forms of obstruction (volvulus of small intestine, spike intestinal obstruction).

Together with that, for invagination emptying by liquid excrement with the admixtures of mucus and blood are more characteristic.

The abdomen may be distended and tympanic, depending on the degree of abdominal and bowel distention, and may be tender. A distinguishing feature is absent or hypoactive bowel sounds, in contrast to the high-pitched sound of obstruction. The silent abdomen of ileus reveals no discernible peristalsis or succussion splash.

In patients during palpation the soft abdomen is observed, sometimes — with easy resistance of front abdominal wall, and at percussion — high tympanitis. At auscultation at the beginning of disease increased peristaltic noises are present, then gradual fading of peristalsis is positive (the Mondor's symptom, “noise of beginning, quietness of end”).

There are other symptoms pathognomic for intestinal obstruction.

The Vala's symptom is the limited elastic sausage-shaped formation.

The Sklarov's symptom is the noise of intestinal splash.

The Kywul's symptom is the clang above the exaggerated bowel.

The Schlange's symptom is the peristalsis of bowel, that arises after palpation of abdomen.

The Spasokukotsky's symptom is "noise of falling drop".

The Hochenegg's symptom — incompletely closed anus in combination with balloon expansion of ampoule of rectum.

At survey roentgenoscopy or -graphy of the abdominal cavity in the loops of bowels liquids and gas are observed —the Klojber's bowl. (Fig.3; Fig.4)

Fig. 3. Intestinal obstruction.

X-ray examination of abdominal cavity – presence of the Klojber's bowels

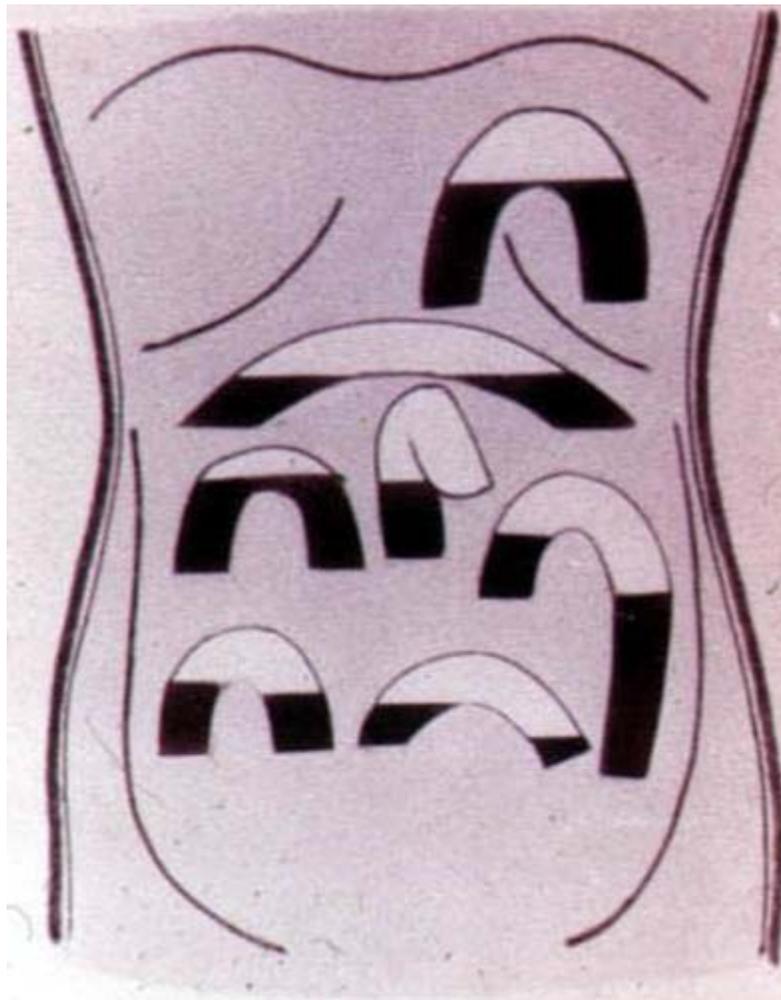

Fig. 4. Intestinal obstruction.

Mechanism of Klojbers bowels

Presence of liquid levels and air in the intestines

Variants of clinical passing and complications

Strangulated obstruction. The ischemic component is the characteristic feature of this form of intestinal obstruction, that is investigation of squeezing of mesentery vessels, which determines the dynamics of pathomorphologic changes and clinical signs of disease, and the basic place among them belongs to the pain syndrome. Consequently, sudden appearance of disease, acuteness of pain syndrome and ischemic disorders in the wall of bowel cause necrosis changes of area of bowel pulling in a process. It is accompanied by the making progress worsening of the patient

condition and origin of endotoxemia.

Obturation intestinal obstruction (Fig. 5), unlike strangulated, pass not so quickly.

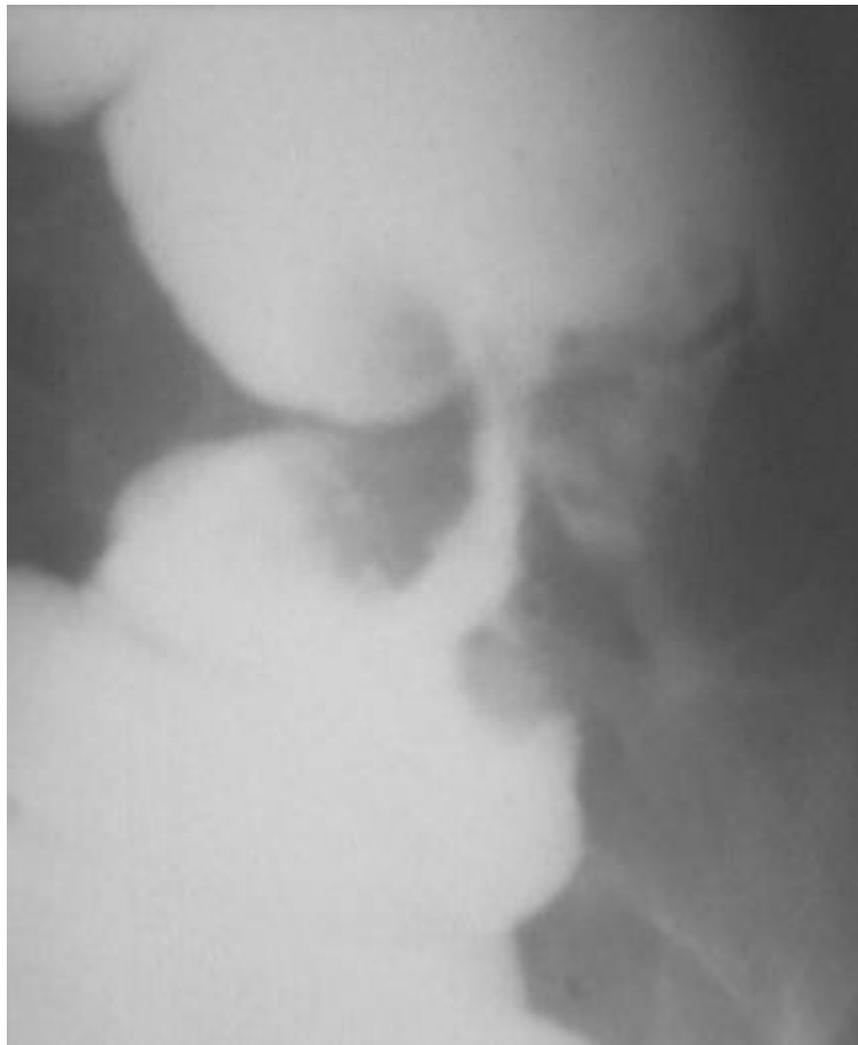

Fig. 5. Obturation mechanical obstruction by tumor.
Irrigogram

In its clinical picture on the first place there are the symptoms of violation of passage on the intestine (protracted intermittent pain, flatulence), instead of symptoms of bowel destruction and peritonitis.

For high, especially strangulated, intestinal obstruction progressive growth of clinical signs of disease and violation of secretory function of intestine is inherent. Thus the volume of circulatory blood diminishes, the level of haematocrit rises and leukocytosis grows. There are also deep violations of homeostasis (hypoproteinemia, hypokalemia, hyponatremia, hypoxia and others like that). In patients with low intestinal obstruction above-named signs are less expressed, and their growth is related

to more protracted passing of disease. Invagination of bowel which can be characterized by the triad of characteristic signs is the special type of intestinal obstruction with the signs of both obturation and strangulation: 1) periodicity of appearance of the intermittent attacks of pain in the abdomen; 2) presence of elastic, insignificantly painful, mobile formation in an abdominal cavity; 3) appearance of blood in the excrement or its tracks (at rectal examination).(Fig.6.)

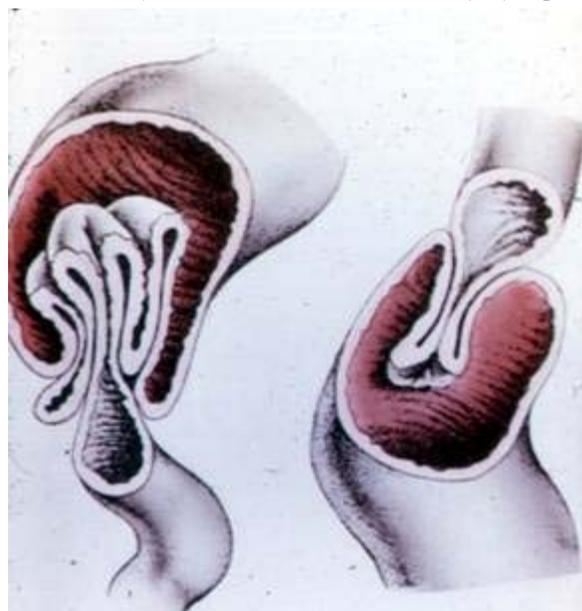

Fig. 6. Invagination of small intestine

The special forms of obturation intestinal obstruction is the obstruction caused by gall-stones. The last are got in the small intestine as a result of bed sore in the walls of gall-bladder and bowel, that adjoins to it. It is needed to mention that intestinal obstruction can be caused by concrement with considerably more small diameter than bowel lumen. The mechanism of such phenomenon is related to irritating action of bilious acids on the bowel wall. The last answers this action by a spasm with the dense wedging of stone in the bowel lumen.

Development of intestinal obstruction caused by gall-stones the attack of colic and clinic of acute cholecystitis precede always. Characteristically, that in the process of development of disease the pain caused by acute cholecystitis calms down, whereupon the new pain characteristic of other pathology — intestinal obstruction appears.

Dynamic intestinal obstruction is divided into paralytic and spastic(Fig.7).

Paralytic obstruction often arises after different abdominal operations, inflammatory diseases of organs of abdominal cavity, traumas and poisonings.

Fig.7. Spastic dynamic intestinal obstruction

The reason of spastic intestinal obstruction can be the lead poisonings, low-quality meal, neuroses, hysterias, helminthiasis and others like that. Clinic of dynamic intestinal obstruction is always variable in signs and depends on a reason, that caused it. Disease is characterized by pain in the abdomen, delay of gases and emptying. During palpation the abdomen is blown away, painful, however soft. To diagnose this form of intestinal obstruction is not difficult, especially, if its etiology is known.

Hemostatic intestinal obstruction (Fig.8) develops after embolism or thromboses of mesenteric arteries and thromboses of veins, there can be mixed forms. Embolism of mesenteric arteries arises in patients with heart diseases (mitral and aortic failings, heart attack of myocardium, warty endocarditis) and declared by damaging, mainly, upper mesentery arteries. Beginning of disease, certainly, is acute, with nausea, sometimes — vomiting. At first there is a picture of acute abdominal ischemic syndrome, that is often accompanied by shock (frequent pulse, decline of arterial and pulse pressure, death-damp, cyanosis of mucus membranes and acrocyanosis). Patients become excitative, uneasy, occupy the forced knee-elbow position or lie on the side with bound legs.

Fig.8. Hemostatic intestinal obstruction. Embolism of upper mesenteric arteries.
Necrosis of small intestines.

During the examination the abdomen keeps symmetry, abdominal wall is soft, the increased peristalsis is heard from the first minutes during 1–2 hours (hypoxic stimulation of peristalsis), which later goes out gradually (“grave quiet”). According to the phenomena of intoxication peritonitis grow quickly. At the beginning of disease the delay of gases and emptying is observed, later there is diarrhea with the admixtures of blood in an excrement. When the last is heavy to set macroscopically, it is needed to explore scourage of intestine.

Small-bowel obstruction (SBO). The most common cause of small-bowel obstruction (SBO) is postsurgical adhesions. Postoperative adhesions can be the cause of acute obstruction within 4 weeks of surgery or of chronic obstruction decades later. The incidence of SBO parallels the increasing number of laparotomies performed in developing countries. Another commonly identified cause of SBO is an incarcerated groin hernia. Other etiologies include malignant tumor (20%), hernia (10%),

inflammatory bowel disease (5%), volvulus (3%), and miscellaneous causes (2%). The causes of SBO in pediatric patients include congenital atresia, pyloric stenosis, and intussusception.

History. Obstruction can be characterized as either partial or complete versus simple or strangulated. No accurate clinical picture exists to detect early strangulation of obstruction.

Abdominal pain, often described as crampy and intermittent, is more prevalent in simple obstruction. Often, the presentation may provide clues to the approximate location and nature of the obstruction. Usually, pain that occurs for a shorter duration of time and is colicky and accompanied by bilious vomiting may be more proximal. Pain that lasts as long as several days, is progressive in nature, and is accompanied by abdominal distention may be typical of a more distal obstruction.

Changes in the character of the pain may indicate the development of a more serious complication (ie, constant pain of a strangulated or ischemic bowel).

Patients also report the following:

- Nausea
- Vomiting - Associated more with proximal obstructions
- Diarrhea - An early finding
- Constipation - A late finding, as evidenced by the absence of flatus or bowel movements
- Fever and tachycardia - Occur late and may be associated with strangulation
- Previous abdominal or pelvic surgery, previous radiation therapy, or both - May be part of the patient's medical history
- History of malignancy - Particularly ovarian and colonic malignancy

Physical Examination

Abdominal distention is present. The duodenal or proximal small bowel has less distention when obstructed than the distal bowel has when obstructed. Hyperactive bowel sounds occur early as GI contents attempt to overcome the obstruction; hypoactive bowel sounds occur late.

Exclude incarcerated hernias of the groin, femoral triangle, and obturator

foramina. Proper genitourinary and pelvic examinations are essential. Look for the following during rectal examination:

- Gross or occult blood, which suggests late strangulation or malignancy
- Masses, which suggest obturator hernia

Check for symptoms commonly believed to be more diagnostic of intestinal ischemia, including the following:

- Fever (temperature $>100^{\circ}\text{F}$)
- Tachycardia (>100 beats/min)
- Peritoneal signs

No reliable way exists to differentiate simple from early strangulated obstruction on physical examination. Serial abdominal examinations are important and may detect changes early.

Complications of SBO include the following:

- Sepsis
- Intra-abdominal abscess
- Wound dehiscence
- Aspiration
- Short-bowel syndrome (as a result of multiple surgeries)
- Death (secondary to delayed treatment)

Large-bowel obstruction (LBO) is an emergency condition that requires early identification and intervention. Approximately 60% of mechanical large-bowel obstructions (LBOs) are caused by malignancies, 20% are caused by diverticular disease, and 5% are the result of colonic volvulus. The most common causes of adult large-bowel obstruction are as follows:

- Neoplasm (benign or malignant)
- Stricture (diverticular or ischemic)
- Volvulus (eg, colonic, sigmoid, cecal)
- Incarcerated hernia
- Intussusception, usually with an identifiable anatomic abnormality in adults

but not in children

- Impaction or obstipation

Gallstone ileus

Neoplasms and diverticular disease

Obstructions caused by tumors tend to have a gradual onset and result from tumor growth narrowing the colonic lumen.

Diverticulitis is associated with muscular hypertrophy of the colonic wall. Repetitive episodes of inflammation cause the colonic wall to become fibrotic and thickened, leading to luminal narrowing.

Volvuli

A colonic volvulus results when the colon twists on its mesentery, which impairs the venous drainage and arterial inflow. Symptoms of this condition are usually abrupt.

A sigmoid volvulus typically occurs in older, debilitated individuals with a history of chronic constipation, or those living in an institutionalized setting.

A cecal volvulus is caused by a congenital defect in the peritoneum, which results in inadequate fixation of the cecum, and increased cecal mobility. Patients usually present with this disorder in the sixth decade of life.

Intussusception

Intussusception is primarily a pediatric disease; however, it is estimated that between 5% and 16% of all intussusceptions in the Western world occur in adults, of which approximately two thirds of adult intussusception cases are caused by tumors. Two main types of intussusception affect the large bowel: enterocolic and colocolic.

Enterocolic intussusceptions involve both the small bowel and the large bowel. These are composed of either ileocolic intussusceptions or ileocecal intussusceptions, depending on where the lead point is located.

Colocolic intussusceptions involve only the colon. They are classified as either colocolic or sigmoidorectal intussusceptions.

Acute colonic pseudo-obstruction/Ogilvie syndrome

Acute colonic pseudo-obstruction (ACPO), or Ogilvie syndrome, has many etiologies. This disorder is typically seen in elderly patients who are hospitalized with a

severe illness. In a retrospective review of more than 1400 cases of acute colonic pseudo-obstruction, the most common predisposing conditions were operative and nonoperative trauma (11%), infections (10%), and cardiac disease (10-18%).

History. Obtain the patient's history of bowel movements, flatus, obstipation (ie, no gas or bowel movement), and symptoms. Attempt to distinguish complete bowel obstruction from partial obstruction, which is associated with passage of some gas or stool, and from ileus. Also inquire about the patient's current and past history in an attempt to determine the most likely cause.

Major complaints in patients with large-bowel obstruction (LBO) include abdominal distention, nausea, vomiting, and crampy abdominal pain. An abrupt onset of symptoms makes an acute obstructive event (eg, cecal or sigmoid volvulus) a more likely diagnosis. A history of chronic constipation, long-term cathartic use, and straining at stools implies diverticulitis or carcinoma.

Changes in the patient's caliber of stools (eg, passage of melanotic bloody stools) strongly suggest carcinoma. When associated with weight loss, the likelihood of neoplastic obstruction increases.

A history of recurrent left lower quadrant abdominal pain over several years is more consistent with diverticulitis, a diverticular stricture, or similar problems.

A history of aortic surgery suggests the possibility of an ischemic stricture.

Diagnostic program

1. Anamnesis and physical methods of examination (auscultation of abdomen, percussion and others like that).
2. General analysis of blood, urines and biochemical blood test.
3. Survey sciagraphy of organs of abdominal cavity.
4. Coagulogramm.
5. Electrocardiography.
6. Irrigography.

Small-Bowel Obstruction Workup Approach Considerations

If the diagnosis is unclear, admission and observation are warranted to detect

early obstructions. Essential laboratory tests are needed; these include the following:

- Serum chemistries - Results are usually normal or mildly elevated
- Blood urea nitrogen (BUN) level - If the BUN level is increased, this may indicate decreased volume state (eg, dehydration)
- Creatinine level - Creatinine level elevations may indicate dehydration
- Complete blood count (CBC) - The white blood cell (WBC) count may be elevated with a left shift in simple or strangulated obstructions; increased hematocrit is an indicator of volume state (ie, dehydration)
- Lactate dehydrogenase tests
- Urinalysis
- Type and crossmatch - The patient may require surgical intervention
- Laboratory tests to exclude biliary or hepatic disease are also needed; they

include the following:

- Phosphate level
- Creatine kinase level
- Liver panels

Studies have been performed to evaluate the use of water-soluble oral contrast as a tool in the management of SBO and as a predictive tool for nonoperative resolution of adhesive SBO. It does not cause resolution of the SBO, but it may reduce the hospital stay in patients not requiring surgery.

Plain Radiography

Obtain plain radiographs first for patients in whom small-bowel obstruction (SBO) is suspected. At least 2 views, supine or flat and upright, are required. Plain radiographs are diagnostically more accurate in cases of simple obstruction. However, diagnostic failure rates of as much as 30% have been reported.

In one small study, the sensitivity of plain radiography was reported to be 75%, and specificity was reported to be 53%; similar findings were reported in a second study. In another study, plain films were more accurate in the detection of acute SBO and the accuracy was higher if interpreted by more-experienced radiologists.

Plain radiography is of little assistance in differentiating strangulation from simple obstruction. Some have used abdominal radiography to distinguish between

complete obstruction and partial or no SBO.

A study by Lappas et al proposed that 2 findings were more predictive of a higher grade or complete SBO: (1) the presence of an air-fluid differential height in the same small-bowel loop and (2) the presence of a mean level width greater than 25 mm. The study found that when the 2 findings are present, the obstruction is most likely high grade or complete. When both are absent, the authors proposed, a low-grade (partial) SBO is likely or nonexistent.

Dilated small-bowel loops with air-fluid levels indicate SBO, as does absent or minimal colonic gas. SBO is demonstrated in the radiographs below.

CT scanning

Computed tomography (CT) scanning is the study of choice if the patient has fever, tachycardia, localized abdominal pain, and/or leukocytosis.

CT scanning is useful in making an early diagnosis of strangulated obstruction and in delineating the myriad other causes of acute abdominal pain, particularly when clinical and radiographic findings are inconclusive. It also has proved useful in distinguishing the etiologies of small-bowel obstruction (SBO), that is, in distinguishing extrinsic causes (such as adhesions and hernia) from intrinsic causes (such as neoplasms and Crohn disease). In addition, CT scanning differentiates the above from intraluminal causes, such as bezoars. The modality may be less useful in the evaluation of small bowel ischemia associated with obstruction.

CT scanning is capable of revealing abscess, inflammatory process, extraluminal pathology resulting in obstruction, and mesenteric ischemia and enables the clinician to distinguish between ileus and mechanical small bowel obstruction in postoperative patients.

The modality does not require oral contrast for the diagnosis of SBO, because the retained intraluminal fluid serves as a natural contrast agent.

Obstruction is present if the small-bowel loop is greater than 2.5 cm in diameter dilated proximal to a distinct transition zone of collapsed bowel less than 1 cm in diameter. A smooth beak indicates simple obstruction without vascular compromise; a serrated beak may indicate strangulation. Bowel wall thickening, portal venous gas, or pneumatosis indicates early strangulation.

One small series reported a sensitivity of 93%, a specificity of 100%, and an accuracy of 94% for CT scanning in the detection of obstructions. Another series reported a sensitivity of 92% and specificity of 71% in the correct identification of partial or complete SBO.

Ultrasonography

Ultrasonography is less costly and invasive than CT scanning and may reliably exclude SBO in as many as 89% of patients; specificity is reportedly 100%.

In a small study by Jang et al in which the use of bedside ultrasonography by emergency physicians was compared with radiography for the detection of small-bowel obstruction (SBO), emergency physician-performed ultrasonography compared favorably with radiography. Dilated bowel on ultrasonography had a sensitivity of 91% and a specificity of 84% for SBO, while radiography had a sensitivity of 46% and a specificity of 66%.

Large-Bowel Obstruction Workup.

Approach Considerations

Laboratory studies are directed at evaluating the dehydration and electrolyte imbalance that may occur as a consequence of large-bowel obstruction (LBO) and at ruling out ileus as a diagnosis.

Routine complete blood cell count (CBC), serum chemistries, and urine specific gravity should be evaluated. A decreased hematocrit level, particularly with evidence of chronic iron-deficiency anemia, may suggest chronic lower gastrointestinal (GI) bleeding, particularly due to colon cancer. A stool guaiac test also should be performed, for similar reasons.

Obtain a prothrombin time (PT) as well as a type and crossmatch.

Although bowel obstruction, or even constipation, may mildly elevate the white blood cell (WBC) count, substantial leukocytosis should prompt reconsideration of the diagnosis. Ileus, secondary to an intra-abdominal or extra-abdominal infection or another process, is a possibility.

The suggestion of an abnormal anion gap (see the Anion Gap calculator) also should prompt an arterial blood gas (ABG) measurement and/or a serum lactate level measurement.

Plain Radiography

Obtain an upright chest radiograph to determine whether free air is present, which would suggest perforation of a hollow viscus and ileus rather than organic obstruction, as well as flat and upright abdominal radiographs, which may demonstrate dilatation of the small and/or large bowel and air-fluid levels.

Chest radiographs will demonstrate free air if perforation has occurred (see the first image below); abdominal radiographs may be diagnostic of sigmoid or cecal volvulus (ie, kidney bean appearance on the radiograph) (see the second and third images below, respectively). Intramural air is an ominous sign that suggests colonic ischemia. The absence of free air does not exclude perforation (this finding may be absent in half of all perforations).

Tracing colonic air around the colon, into the left gutter, and down into the rectum or demonstrating an abrupt cut-off in colonic air suggests the anatomic location of the obstruction.

A dilated colon without air in the rectum is more consistent with obstruction. The presence of air in the rectum is consistent with obstipation, ileus, or partial obstruction. However, this finding can be misleading, particularly if the patient has undergone rectal examinations or enemas.

Radiocontrast Radiography

Contrast studies include an enema with water-soluble contrast (ie, Gastrografin) (see the following images) or computed tomography (CT) scanning with intravenous (IV) and oral (PO) or rectal (PR) contrast. Contrast studies that reveal a column of contrast ending in a "bird's beak" are suggestive of colonic volvulus.

Indications for imaging with contrast

Radiopaque contrast material may be administered and imaging of the colon may be performed under the following circumstances:

- Perform it if the diagnosis of large bowel obstruction is suspected but not proven
- If differentiation between obstipation and obstruction is required
- If localization is required for surgical intervention

Water-soluble contrast vs barium

Water-soluble Gastrografin has important advantages over barium as a contrast agent and generally should be used first. Gastrografin usually does not cause chemical peritonitis if the patient has colonic perforation, and it has an osmotic laxative effect that may actually wash out an obstipated colon.

If large-bowel perforation is ruled out using a Gastrografin study but a more detailed anatomic definition is required (particularly of the right colon), a barium enema may be performed.

Computed Tomography Scanning

Although computed tomography (CT) scanning is useful to help rule out intra-abdominal abscess or other causes of ileus, this imaging modality is generally not used initially in patients with large-bowel obstruction (LBO), unless the diagnosis is still in question.

CT scanning, particularly with rectal contrast, may demonstrate a mass or evidence of metastatic disease. Generally, the findings do not alter management, because these patients will be explored and operatively decompressed, regardless of the CT scan findings.

CT colography may be useful in evaluating these patients, not only to delineate the source of the obstruction but also to rule out synchronous proximal lesions, which may occur in about 1% of patients and which might motivate a more extended resection if identified and if the patient's condition will tolerate the more extensive procedure.

Flexible Endoscopy

Flexible endoscopy preceded by rectal enema may be useful in evaluating left-sided colonic obstruction, including the anatomic location and pathology of the lesion. Because the cecum is not reached in such cases, the endoscopist must be alert to the possibility of incorrectly identifying anatomic landmarks and the location of the obstruction.

An abdominal radiograph with the tip of the endoscope at the site of the

obstruction may be extraordinarily helpful in identifying and documenting the location of the large-bowel obstruction (LBO).

Although flexible endoscopy is relatively comfortable for the patient and provides a better view than rigid sigmoidoscopy, rigid sigmoidoscopy may also be used, depending on the availability of resources and training of personnel.

Right-sided colonic obstruction is more difficult to evaluate without first administering an oral bowel preparation, which is contraindicated in the setting of bowel obstruction.

Differential diagnostics

- Abortion, Threatened
- Alcoholic Ketoacidosis
- Cholangitis
- Cholecystitis and Biliary Colic in Emergency Medicine
- Cholelithiasis
- Constipation
- Diverticular Disease
- Dysmenorrhea
- Endometriosis
- Inflammatory Bowel Disease
- Mesenteric Ischemia

Intestinal obstruction must be differentiated with the acute diseases of organs of abdominal cavity.

The perforation of gastroduodenal ulcer, as well as intestinal obstruction, passes acutely with inherent to it by sudden intensive pain and tension of muscles of abdomen. However, in patients with this pathology, unlike intestinal obstruction, the abdomen is not exaggerated, and pulled in with “wooden belly” tension of muscles of front abdominal wall. There is also characteristic ulcerous anamnesis. Roentgenologic and by percussion pneumoperitoneum is observed. Certain difficulties in conducting of differential diagnostics of intestinal obstruction can arise at atypical passing and in case of the covered perforations.

Acute pancreatitis almost always passes with the phenomena of dynamic

intestinal obstruction and symptoms of intoxication and repeated vomiting, with rapid growth. During the examination in such patients, unlike intestinal obstruction, rigidity of abdominal wall and painfulness is observed in the projections of pancreas and positive Korte's symptom and Mayo-Robson's. The examination of diastase of urine and amylase of blood have important value in establishment of diagnosis.

Acute cholecystitis. Unlike intestinal obstruction, patients with this pathology complain for pain in right hypochondrium, that irradiate in the right shoulder-blade, shoulder and right subclavian area. Difficulties can arise, when the symptoms of dynamic intestinal obstruction appear on the basis of peritonitis.

The clinic of kidney colic in the signs and character of passing are similar to intestinal obstruction, however, attacks of pain in the lumbar area with characteristic irradiation in genital parts, the thigh and dysuric disorders help to set the correct diagnosis. Certain difficulties in conducting of differential diagnostics also can arise in difficult patients, at frequent vomiting which sometimes can be observed in patients with kidney colic.

Table. Characteristics of Ileus, Pseudo-obstruction, and Mechanical Obstruction

	Ileus	Pseudo-obstruction	Mechanical Obstruction (Simple)
Symptoms	Mild abdominal pain, bloating, nausea, vomiting, obstipation, constipation	Crampy abdominal pain, constipation, obstipation, nausea, vomiting, anorexia	Crampy abdominal pain, constipation, obstipation, nausea, vomiting, anorexia
Physical Examination Findings	Silent abdomen, distention, tympanic	Borborygmi, tympanic, peristaltic waves, hypoactive or hyperactive bowel	Borborygmi, peristaltic waves, high-pitched bowel sounds, rushes,

		sounds, distention, localized tenderness	distention, localized tenderness
Plain Radiographs	Large and small bowel dilatation, diaphragm elevated	Isolated large bowel dilatation, diaphragm elevated	Bow-shaped loops in ladder pattern, paucity of colonic gas distal to lesion, diaphragm mildly elevated, air-fluid levels

Tactics and choice of treatment method

During the first 1,5–2 hours after hospitalization of patient complex conservative therapy which has the differential-diagnostic value and can be preoperative preparation is conducted.

Emergency Department Care (SBO)

Initial emergency department (ED) treatment consists of aggressive fluid resuscitation, bowel decompression, administration of analgesia and antiemetic as indicated clinically, early surgical consultation, and administration of antibiotics. (Antibiotics are used to cover against gram-negative and anaerobic organisms.)

Initial decompression can be performed by placement of a nasogastric (NG) tube for suctioning GI contents and preventing aspiration. Monitor airway, breathing, and circulation (ABCs).

Blood pressure monitoring, as well as cardiac monitoring in selected patients (especially elderly patients or those with comorbid conditions), is important.

Nonoperative inpatient care

Continued NG suction provides symptomatic relief, decreases the need for intraoperative decompression, and benefits all patients. No clinical advantage to using a long tube (nasointestinal) instead of a short tube (NG) has been observed.

A nonoperative trial of as many as 3 days is warranted for partial or simple

obstruction. Provide adequate fluid resuscitation and NG suctioning. Resolution of obstruction occurs in virtually all patients with these lesions within 72 hours. Good data regarding nonoperative management suggest it to be successful in 65-81% of partial small-bowel obstruction (SBO) cases without peritonitis. Nonoperative treatment for several types of SBO are as follows:

- Malignant tumor - Obstruction by tumor is usually caused by metastasis; initial treatment should be nonoperative (surgical resection is recommended when feasible)

- Inflammatory bowel disease - To reduce the inflammatory process, treatment generally is nonoperative in combination with high-dose steroids; consider parenteral treatment for prolonged periods of bowel rest, and undertake surgical treatment, bowel resection, and/or stricturoplasty if nonoperative treatment fails.

- Intra-abdominal abscess - CT scan- guided drainage is usually sufficient to relieve obstruction

- Radiation enteritis - If obstruction follows radiation therapy acutely, nonoperative treatment accompanied by steroids is usually sufficient; if the obstruction is a chronic sequela of radiation therapy, surgical treatment is indicated

- Incarcerated hernia - Initially use manual reduction and observation; advise elective hernia repair as soon as possible after reduction

- Acute postoperative obstruction - This is difficult to diagnose, because symptoms often are attributed to incisional pain and postoperative ileus; treatment should be nonoperative

- Adhesions - Decreasing intraoperative trauma to the peritoneal surfaces can prevent adhesion formation

Conservative Management (LBO)

Medical care of colonic obstruction is directed primarily at supporting the patient and treating any comorbid illnesses. This involves resuscitation, correction of fluid and electrolyte imbalances, and nasogastric decompression to temporarily treat the obstruction and to prevent vomiting and aspiration. Medications that slow colonic motility (eg, narcotics, anticholinergics) should be stopped, if possible.

Oral laxatives are contraindicated if large-bowel obstruction is suspected. If any evidence suggests simple constipation, patients should be managed with transrectal enemas. Tap water, isotonic sodium chloride solution, and a variety of other fluids may be used. In patients with renal insufficiency, the physician should be sensitive to the electrolyte content of the fluid.

If the patient's pain is sufficiently severe to merit use of significant analgesics, peritonitis, rather than large-bowel obstruction, should be considered as the first diagnosis.

For a small subset of patients, in whom the obstruction is not only malignant but also reflects substantially disseminated or even inoperable disease, consideration of completely nonoperative palliative therapy within the context of a palliative care or hospice approach may be appropriate. This might include somatostatin therapy and may or may not include nasogastric decompression.

For acute colonic pseudo-obstruction (ACPO), or Ogilvie syndrome, underlying precipitant factors must be identified and corrected. If no perforation is present, pseudo-obstruction is treated with conservative management for the first 24 hours. This includes bowel rest, hydration, and management of underlying disorders.

Pharmacologic treatment of acute colonic pseudo-obstruction with neostigmine or colonoscopic decompression may be effective in cases that do not resolve with conservative management. Colonoscopic decompression may be successful in as many as 80% of patients with acute colonic pseudo-obstruction.

Surgical intervention for acute colonic pseudo-obstruction is associated with a high mortality and morbidity. This treatment is reserved for refractory cases or cases complicated by perforation.

Cleansing enemas

Perform cleansing enemas if obstipation is suspected rather than true large-bowel obstruction. These can also be performed to prepare the distal colon for endoscopic evaluation.

Endoscopic reduction of volvulus

Endoscopic reduction is indicated for sigmoid volvulus when peritoneal signs are

absent, which would imply dead bowel or perforation. This procedure is also indicated when evidence of mucosal ischemia is not present upon endoscopy. An experienced person should perform the procedure.

Endoscopic reduction is not indicated for the less common cecal or transverse colon volvulus.

A rigid sigmoidoscope may be used if a flexible instrument is not available. The endoscopist must have sufficient experience with this technique.

Reduction of a volvulus does not imply cure. The sigmoid usually reinvaginates if definitive treatment is not carried out.

These patients are generally admitted to the hospital, subjected to mechanical bowel preparation, and managed surgically by sigmoid resection, unless contraindications are present.

Reduction of intussusception with barium enema

Barium enema for reduction of intussusception is useful and often successful in children in whom a pathologic leading point for the intussusception is unlikely. This procedure should be performed by an experienced radiologist, because the risk of perforation is significant.

In adults, typically a pathologic leading point for the intussusception is present. Success is far less likely, and patients still require surgery to deal with their pathology.

Endoscopic dilation and stenting of colonic obstruction

Endoscopic dilation and stenting of colonic obstruction is indicated for colonic near-total obstruction through which some small amount of lumen remains. The procedure may be palliative in a high-risk patient with an unresectable malignancy, accepting a risk of reobstruction of the stent, or preparatory to surgical resection.

In cases in which the stent is deployed before surgery, this procedure permits relief of the acute obstruction, resuscitation of the patient, and mechanical bowel preparation before a 1-stage colonic resection and reanastomosis, thus avoiding temporary or permanent colostomy.

Endoscopic dilation and stenting of colonic obstruction should be performed only by an endoscopist experienced in such procedures.

Surgical consultation and backup should be available, as the risk of perforation is increased during attempts at such procedures, with a potentially catastrophic result.

Although some experience with stenting has been positive, with some retrospective preference for the Ultraflex stent over the Wallstent because of ease of placement, a multicenter trial of endoscopic stenting using the Wallstent versus surgery for stage IV left-sided colorectal cancer was terminated early because of an unacceptably high incidence of perforation. Whether this finding reflects the technical aspects of the procedure in that study, the particular stent used, or a truly unacceptable incidence of this dangerous complication awaits further study.

Dietary considerations

Patients with complete large-bowel obstruction should receive nothing by mouth (NPO). Patients with a partial obstruction may tolerate minimal clear liquids, oral medications, and a gradual bowel preparation.

It is directed on warning of the complications related to pain shock, correction of homeostasis and, simultaneously, is the attempt of liquidation of intestinal obstruction by unoperative methods.

1. The measures directed for the fight against abdominal pain shock include conducting of neuroleptanalgesia, procaine paranephric block and introduction of spasmolytics. Patients with the expressed pain syndrome and spastic intestinal obstruction positive effect can be attained by epidural anaesthesia also.

2. Liquidation of hypovolemia with correction of electrolyte, carbohydrate and albuminous exchanges is achieved by introduction of salt blood substitutes, 5–10 % solution of glucose, gelatinol, albumen and plasma of blood. There are a few methods suitable for use in the urgent surgery of calculation of amount of liquid necessary for liquidation of hypovolemia. Most simple and accessible is a calculation by the values of hematocrit. If to consider 40 % for the high bound of hematocrit norm, on each 5 % above this size it is needed to pour 1000 ml of liquids.

3. Correction of hemodynamic indexes, microcirculation and disintoxication therapy is achieved by intravenous infusion of Reopolyhukine and Neohemodes.

4. Decompression of intestine tract is achieved by conducting of nasogastric

drainage and washing of stomach, and also conducting of siphon enema. It is needed to underline that technically the correct conducting of siphon enema has the important value for the attempt of liquidation of intestinal obstruction by conservative facilities, therefore this manipulation must be conducted in presence of a doctor. For such enema the special device is used with the rectal tip, by a PVC pipe by a diameter of 1,5–2,0 cm and watering-can of very thin material. A liquid into the colon is brought to appearance of the pain feeling, then drop the watering-can below the level of patient who lies. The passage of gases and excrement is looked after. As a rule, this manipulation is to repeat repeatedly with the use of plenty of warm water (to 15–20 and more litres).

Liquidating of the intestinal obstruction by such conservative facilities is succeeded in 50–60 % patients with mechanical intestinal obstruction.

Surgical Intervention

Surgical intervention is directed at relieving the obstruction.

A diverting transverse loop colostomy may be the least invasive procedure for a very ill patient with a left colonic obstruction. It permits relief of the obstruction and further resuscitation without compromising chances for a subsequent resection. A case report described the use of hand-assisted laparoscopy via the loop colostomy site for subsequent resection of the obstructing lesion.

A sigmoid colostomy without resection may be used in patients with a rectal obstruction that cannot be managed without a combined abdominoperineal approach. Cecostomy should not be performed, because the diversion is inadequate.

In younger patients without substantial comorbidity, some surgeons would consider primary anastomosis, rather than ileostomy, in the right colon, assuming no intraoperative hypotension, blood loss, or other complications are present.

If resection and proximal colostomy or ileostomy are performed, a mucous fistula is generally extracted from the distal end, unless the obstruction is rectosigmoid, in which case the distal end may be oversewn or stapled and left to drain transanally.

If the cause of the obstruction can be relieved nonsurgically, through procedures such as decompressing a volvulus, or if the obstruction is only partial, deferring surgery temporarily and supporting the patient while the large bowel is cleansed so that primary

anastomosis may be performed more safely is preferable.

A slow preoperative mechanical bowel preparation is indicated for patients who have incomplete obstruction, provided the patient can tolerate it. Some authors prefer polyethylene glycol solutions, such as GO-LYTELY, because they avoid issues of fluid and electrolyte imbalance. The fluid should be administered slowly (rather than given in the standard manner of 1 gal over 4 h), and the patient should be observed for abdominal cramping and intolerance.

Carcinoma

In most patients, the obstructing lesion is resected. Because the colon has not been cleansed, anastomosis is often risky. After resection, most surgeons perform a proximal colostomy if the obstruction is on the left side or ileostomy if it is on the right side.

In patients with substantial comorbidity and surgical risk or in the presence of an unresectable tumor, a diverting proximal colostomy or ileostomy may be performed without resection.

Left vs right colon carcinoma. Surgical treatment of left colon carcinoma includes resection without primary anastomosis or resection with primary anastomosis and intraoperative lavage. Endoscopically placed expandable metal stents can be used to relieve the large-bowel obstruction, thus allowing for a primary colorectal anastomosis.

Right colonic obstructions are treated with a right colectomy and a primary anastomosis between the ileum and the transverse colon. Patients with high-risk features for surgery (advanced age, complete obstruction, or severe comorbidities) may benefit from stent placement until patient can be optimized for a surgical procedure. Palliative colorectal stents are an option in patients who are poor surgical candidates or have advanced cancer.

Diverticulitis

Patients with persistent obstruction secondary to diverticular disease despite appropriate medical management are treated surgically. Surgical resection follows the same principles as the treatment of carcinomas. Elective colonic resection is offered to patients with recurrent disease.

Sigmoid vs cecal volvulus

Sigmoidoscopy with volvulus reduction is the procedure of choice for sigmoid volvuli. Second choice is sigmoid colectomy.

The primary treatment of cecal volvuli is also surgical. A cecopexy often needs to be performed to prevent recurrence. Second choice is colonoscopy, due to the high risk of colonic perforation.

Intussusception

Adult colonic intussusception is treated with primary colon resection without prior reduction.

Patients with dynamic paralytic intestinal obstruction are expedient to stimulation of peristalsis of intestine to be conducted, besides, necessarily after infusion therapy and correction of hypovolemia. A lot of kinds of stimulation of intestine peristalsis are offered. Most common of them are:

1) hypodermic introduction of 1,0 ml of 0,05 % solution of proserin; 2) through 10 min — 60 ml intravenously stream of 10 % solution of chlorous sodium; 3) hypertensive enema.

Surgical treatment of intestinal obstruction must include such important moments:

1. According to middle laparotomy executed the novocaine blockade of mesentery of small and large intestine and operative exploration of abdominal cavity organs during which the reason of intestinal obstruction and expose viability of intestine is set.(Fig.9)

Fig.9. Intestinal obstruction.

Overblowing of small intestine

The revision at small intestine obstruction begins from the Treitz' ligament to iliocecal corner. At large intestine obstruction the hepatic, splenic and rectosigmoid parts are observed intently. Absence of pathological processes after revision needs the examination of places of cavity and jamming of internal hernia: internal inguinal and femoral rings, obturator openings, pockets of the Treitz' ligament, Winslow's opening, diaphragm and periesophageal opening.

2. Liquidation of reasons of obstruction (scission of connection, that squeezes a bowel, violence of volvulus and node formation of loops, desinvagination, deleting of obturative tumours and others like that).

It is needed to mark that the unique method of liquidation of acute intestinal obstruction does not exist. At the lack of viability of bowel the resection of nonviable area is executed with 30–40 cm of afferent and 15–20 cm of efferent part with imposition of “side-to-side”(Fig. 10; Fig. 11) anastomosis or “end-to-end”(Fig.12).

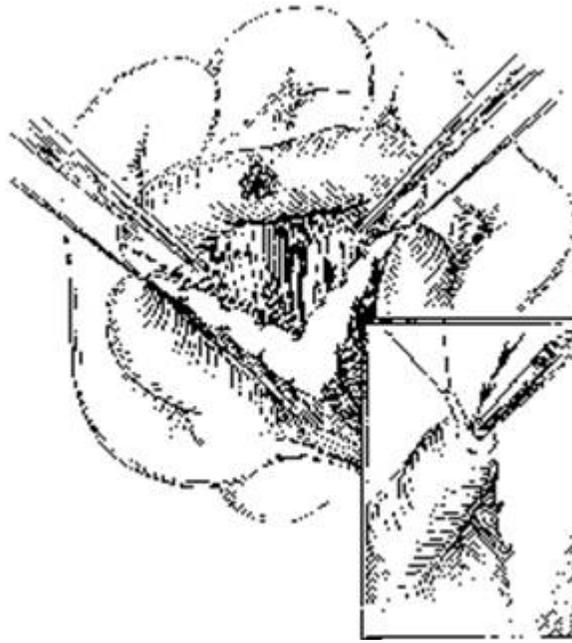

Fig 10. The resection of the small intestine with imposition of anastomosis "side – to side"

- mobilization of segment of the small intestine
- peritonization of the stump of bowel

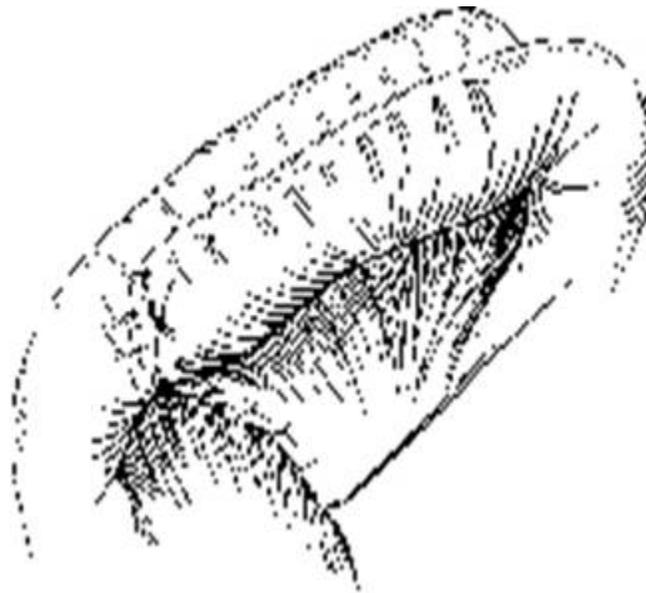

Fig 11. Enteroenteroanastomosis "side-to-side" is formed.

Fig 12. The resection of the small intestine with imposition of “end-to-end” anastomosis

A- mobilization and removing of the changed loop of the bowel

B- formation of the back lip of anastomosis

C- Final view of enteroenteronastomosis

3. Intubation. (Fig.13) Decompression of intestine foresees conducting in the small intestine of elastic probe by thickness of 8–9 mm and length of 3–3,5 m with the plural openings by a diameter 2–2,5 mm along all probe, except for part, that will be in the oesophagus, pharynx and outwardly. A few methods of conducting of probe are offered in a bowel (nasogastric, through gastrostomy, ceco- or appendicostoma). Taking it into account, such procedure needs to be executed individually and according to indications.

Fig. 13. Nasogastrintestinal probe

Each of them has the advantages and failings. In connection with the threat of origin of pneumonia, entering an intubation probe to the patients of old ages is better by means of gastrostomy. Most surgeons avoid the method of introduction of probe through ceco-appendicostoma because of technical difficulties of passing in a small intestine through a Bauhin's valve.(Fig.14)

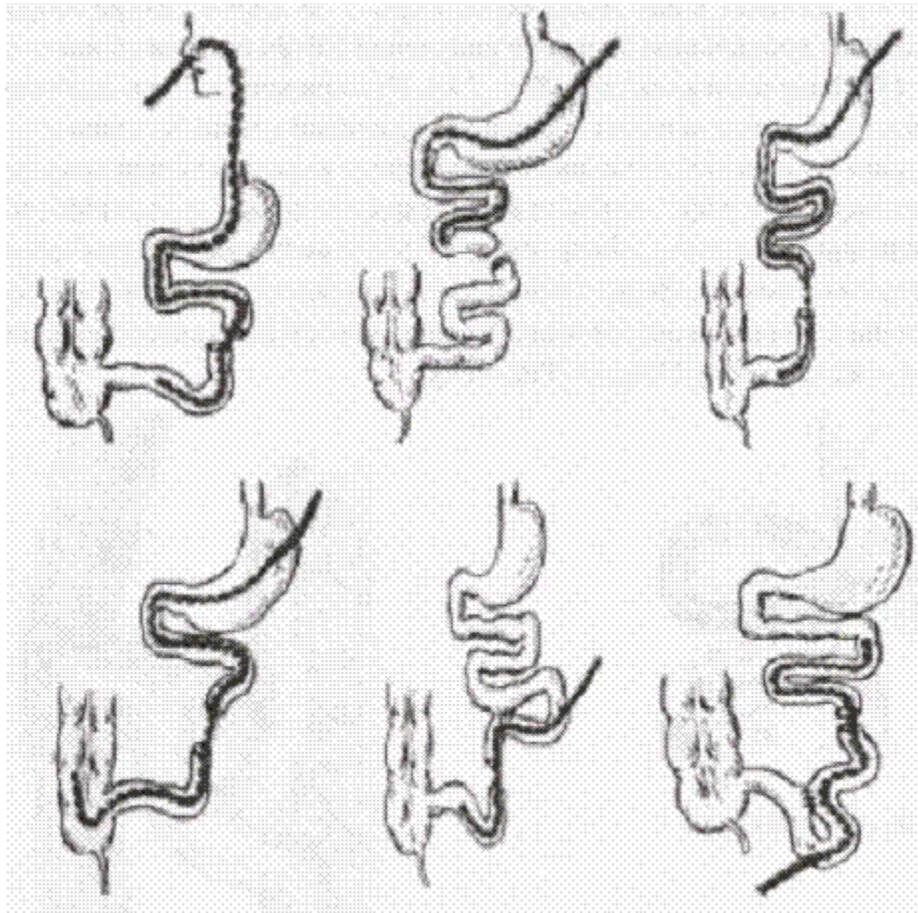

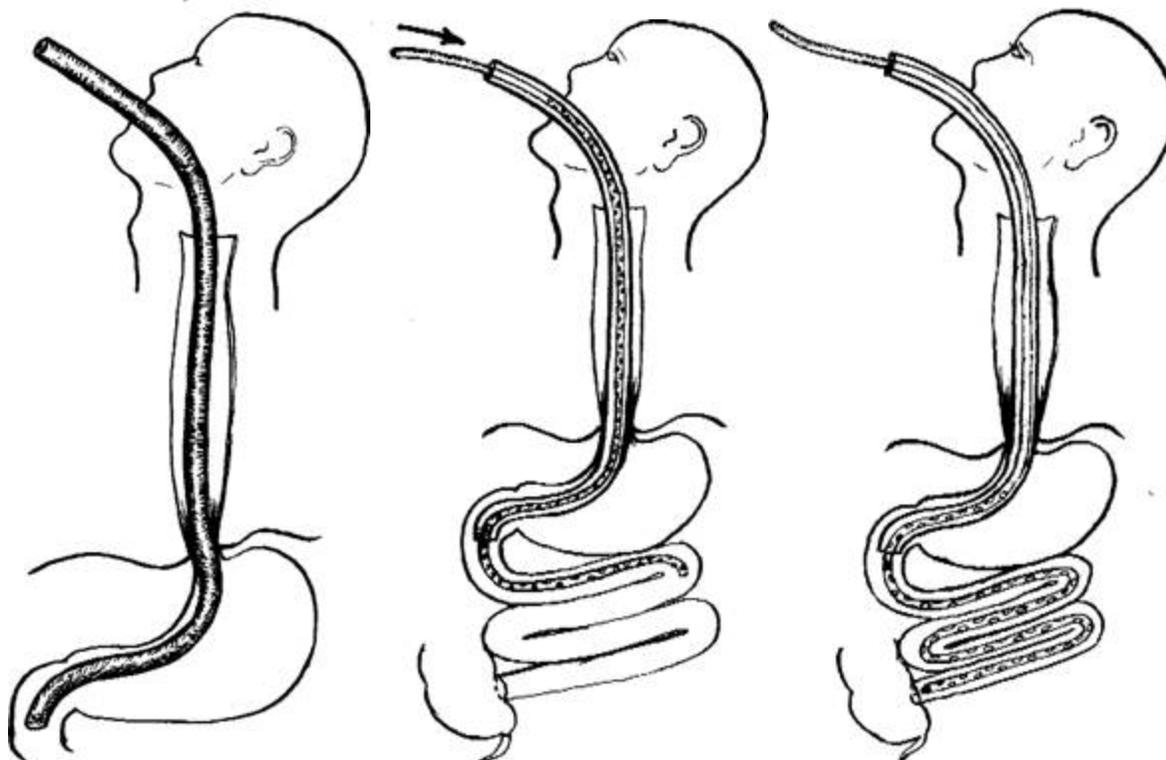

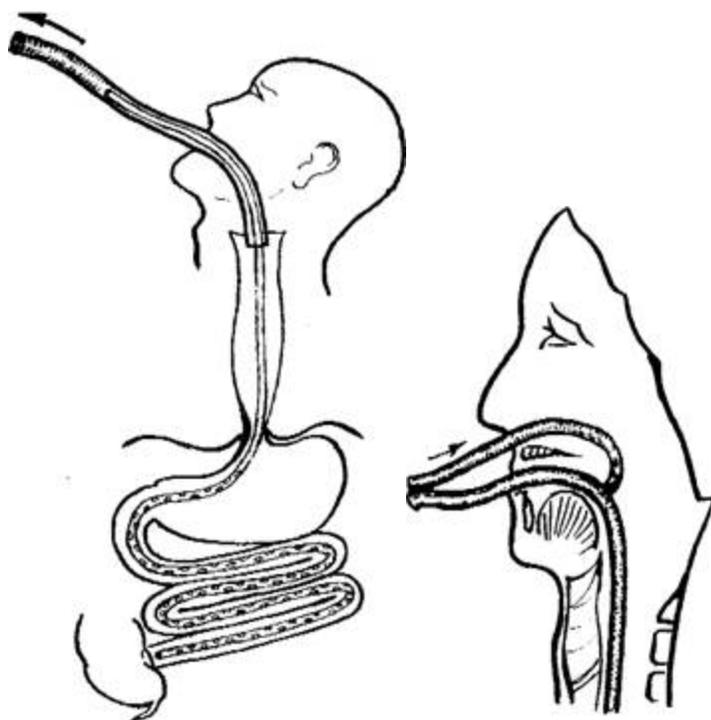

Fig.14. Types of decompression of digestive tract

Today the most wide clinical application has intubation of intestine extracted by the nasogastric method with the use of other thick probe as explorer of the first (by L.J. Kovalchuk, 1981)(Fig.15). Such method not only simplifies procedure of intubation but also facilitates penetration through the piloric sphincter and duodenojejunal bend, and also warns passing of intestinal maintenance in a mouth cavity and trachea. Thus probe is tried to be conducted in the small intestine as possible farther and deleted the next day after appearance of peristalsis and passage of gases, however not later than on 7th days, because more protracted sign of probe carries the real threat of formation of bedsores in the wall of bowel.

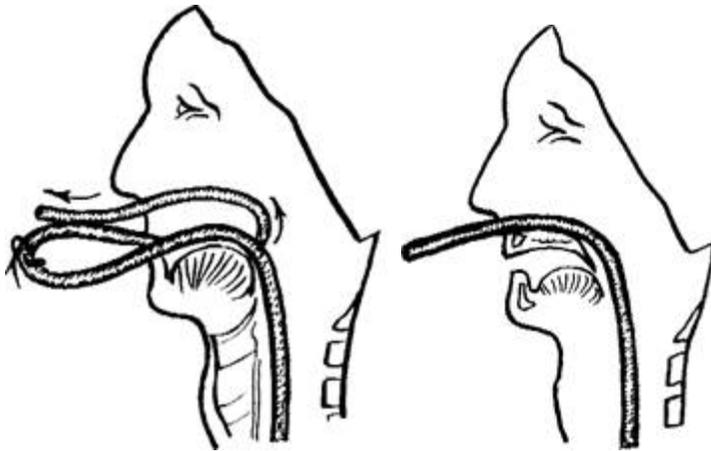

1. Gastric probe-guide is placed distally to pylorus per os
 2. Beginning of intubation
 3. Intubation till caecum

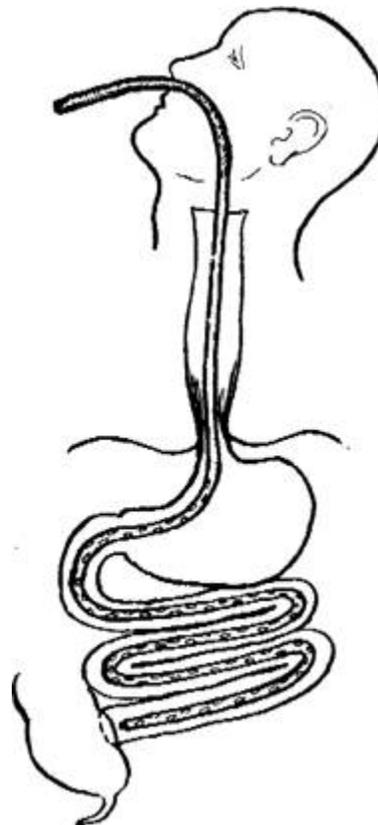

4. Removing of gastric probe
 5. Fixation of proximal part

of intestinal probe to the nasal catheter

6. Removing of proximal part of intestinal
7. Proximal part is removed through the nose probe from the oral cavity through the nose

8. Final view of nasogastric intubation

Fig. 15. Principles of nasogastric intubation

4. Sanation and draining of abdominal cavity is executed by the generally accepted methods of washing of antiseptic. Draining of the abdominal cavity it is needed from four places: in both iliac areas and both hypochondrium, better by the coupled synthetic drain pipes.

GASTRIC ULCER

[Video](#)

The gastric ulcer is the chronic disease with polycyclic passing. The main typical of peptic ulcer is the presence of ulcerous defect in a mucous tunic. One of basic places belongs among the gastroenterology diseases to this pathology. Such phenomenon

explained by not only considerable distribution of disease but also those dangerous complications which always accompany gastric ulcers.

Pic. The presence of ulcerous defect in a mucous tunic.

Etiology and pathogenesis

Frequency of morbidity on the peptic ulcer among the adult population is about 4 %. More frequent age in patients with gastric ulcers is 50–60 years.

To development mechanism of disease is still not enough studied. From a plenty of different theories in relation to genesis of peptic ulcer no one able to explain the disease. So, each of such factors as neurogenic, mechanical, inflammatory, vascular is present in the mechanism of development of peptic ulcer. Consider for today, that disturbance between the factors of aggression and defense of mucous tunic arose peptic ulcer. To the first factors belong: hydrochloric acid, pepsin, reverse diffusion of ions of hydrogen, products of lipid hyperoxidizing. To the second: mucus and alkaline components of gastric juice, property of epithelium of mucous tunic to permanent renewal, local blood flow of mucous tunic and submucous membrane.

In the terminal stage of mechanism of origin of gastric ulcers important role has the peptic factor and disturbance of trophism of gastric wall as a result of local ischemia. It confirmed by decreasing of blood flow in the wall of stomach at patients with ulcers on

30–35 % compared to the norm. It is proved, that a local and functional ischemia more frequent arises up on small curvature of stomach in the areas of ectopy of the antral mucous tunic in acid-forming. Exactly there ulcers appear.

Important part in ulcerogenesis is acted by duodenogastric reflux and gastritis. Also, gastrostasis can provoke hypergastrinaemia and hypersecretion and formed gastric ulcers.

Numeral scientific developments of the last years testify to the important infectious factor in the mechanism of origin of peptic ulcer conditioned, mainly, by helicobacter pylori.

Pathomorphology

Such stages of disease are distinguished: erosion, acute and chronic ulcers.

Erosions, mainly, are plural. Their bottom as a result of formation of muriatic haematine is black, edges — infiltrated by leucocytes. A defect usually does not penetrate outside muscular tissue of the mucous tunic. If necrosis gets to more deep layers of wall of stomach, a acute ulcer develops. It has a funnel-shaped form. Bottom is also black, edges is swelled. Chronic ulcers are mainly single, sometimes arrive to the serous layer. A bottom is smooth, sometimes hilly, edges is like elevation, dense.

Classification

For today the most known classification of gastric ulcers by Johnson (1965). There are three types of gastric ulcers are distinguished: I – ulcers of small curvature (for 3 cm higher from a goalkeeper); II– double localization of ulcers simultaneously in a stomach and duodenum; III – ulcers of goalkeeper part of stomach (not farther as 3 cm from a goalkeeper). In the area of small curvature of body of stomach is localized 70,9 % ulcers, on a back wall, nearer to small curvature — 4,8 %, in the area of cardial part – 12,9 %, in a goalkeeper part — 11,4 %. The ulcers of large curvature of stomach are casuistry and meet infrequently.

Clinical management

The complaints of patients with the gastric ulcer always give valuable information about the disease. The detailed analysis of their anamnesis allows to pay attention to the possible reasons of origin of ulcer, time of the first complaints, to the changes of symptoms.

Pain. A pain symptom in the peptic ulcer disease is very important. There are typical passing for this disease: hunger – pain – food intake – facilitation – again hunger – pain – food intake – facilitation (so during all days). Night pain for the gastric ulcer is not typical. The such patients rarely wake up in order to take a food. For diagnostics of ulcer localization it is important to know the time of appearance of pain. Between acceptance of food and appearance of pain it is the shorter, than the higher placed gastric ulcer. Thus, at patients with a cardial ulcer pain arises at once after the food intake, with the ulcers of small curvature — in 50–60 minutes, at pyloric localization — approximately in two hours. However this feature it is enough relative and some patients in general do not mark dependence between food intake and pain. In other patients the pain attack is accompanied by the salivation.

A epigastric region near the xiphoid process is typical localization of pain. The irradiation of pain is not usual for gastric ulcers. Irradiation occur in patients with penetration and depended from organ, in which an ulcer penetrates.

At the examination of ulcerous patient it is expedient to determine the special pain points: *Boas* (pain at pressure on the left of the X–XII pectoral vertebrae), *Mendel* (pain at percussion on the left to epigastric region).

Vomiting, the sign of disturbance of motility function of stomach, is the second typical symptom of gastric ulcer. More frequent gastrostasis arises as a result of failure of stomach muscular, it atony which can be effect of organ ischemia. Vomiting could arises both on empty stomach and after food intake.

Heartburn is one of early symptoms of gastric ulcer, however at the prolonged passing of disease it can be hidden or quite disappear. Often it precedes of pain arising (initial heartburn) or accompanies a pain symptom. Mostly heartburn arises after the food intake, but can appear independently. it is observed not only at hypersecretion of the

hydrochloric acid, but at normal secretion, even reduced acidity of gastric juice.

The belching at gastric ulcers is examined rarely, more frequent in patients with cardial and subcardial ulcers. It is necessary to bind to disturbance of function of cardial valve.

The general condition of patients with the uncomplicated gastric ulcer usually satisfactory, and in a period between the attacks — even good. However for most patients lost of the body weight and pallor are typical. In a epigastric region hyperpigmental spots are examined after the prolonged application of hot-water bottle. At palpation of stomach in this area sometimes appears local painful. It is needed also to check up “noise of splash”, the presence of which can be the sign of possible gastrostasis.

At the examination of mouth cavity a tongue has whiter-yellow incrustation. In patients with penetration ulcers and disturbances evacuations from a stomach examined dryness of tongue.

Stomach, as a rule, regular rounded shape, however during the pain attack is pulled in. There is antiperistalsis arises during the pylorostenosis.

The increased secretion of hydrochloric acid in patients with gastric ulcers observed rarely and, mainly, at prepyloric ulcer localizations. Mostly secretion is normal, and in some patients is even reduced.

X-Ray examination. The direct signs of ulcer at X-Ray examinations are: symptom of “Haudek's niche” (Pic. 3.2.1), ulcerous billow and convergence of folds of mucous tunic. Indirect signs: symptom of “forefinger” (circular spasm of muscles), segmental hyperperistalsis, pylorospasm, delay of evacuation from a stomach, duodenogastric reflux, disturbance of function of cardial part (gastroesophageal reflux).

Gastroscopy can give important information about localization, sizes, kind of ulcer, dynamics of its cicatrization, and also allow to perform biopsy with subsequent histological examination.

Clinical variants and complication

The gastric ulcer passing can be acute and chronic. Acute ulcers arise as answer for the stress situations, related to the nervous overstrain, trauma, loss of blood, some

infectious and somatic diseases. By a diameter ulcers has from a few millimeters to centimeter, a round or oval form with even edges. Thus in most cases clinically observed clear ulcerous clinical signs. If complications is absent (bleeding, perforation) such ulcers treated and mostly heal over.

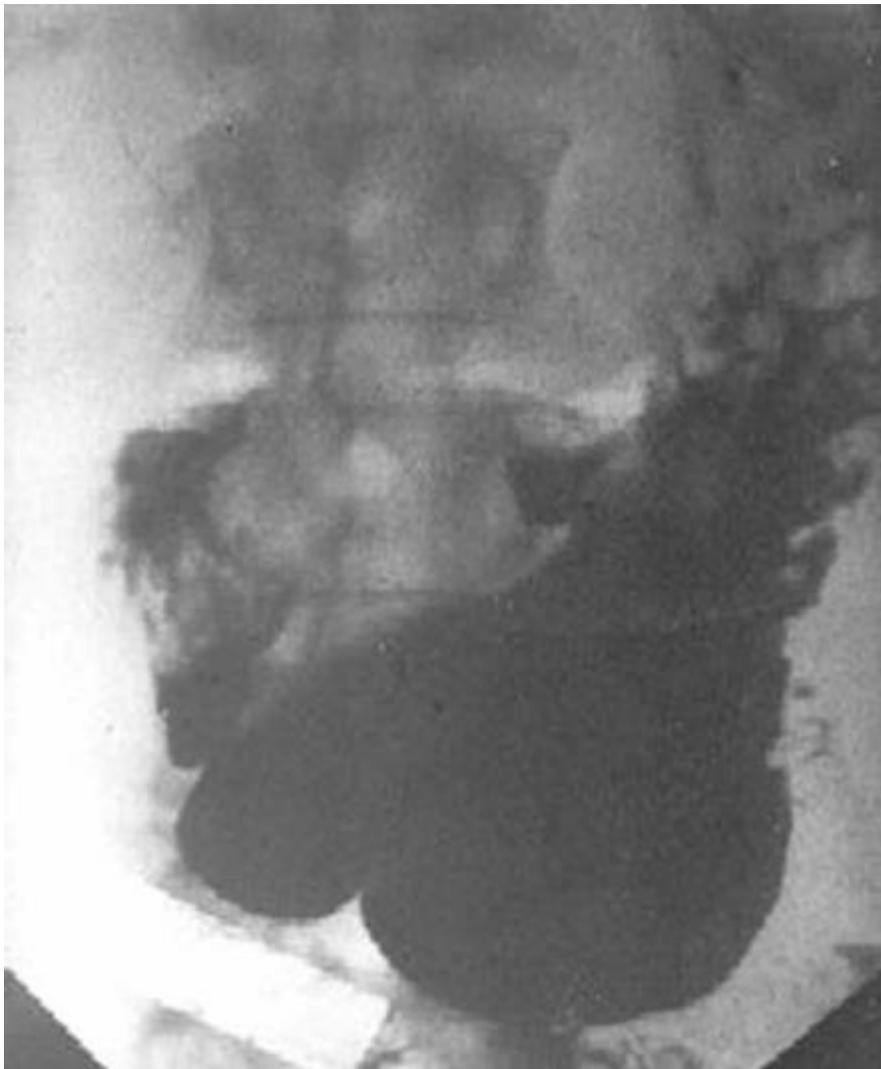

G.J. Burchynskyy (1965) such variants of clinical flow distinguished:

1. Chronic ulcer which does not heal over long time.
2. Chronic ulcer which after the conservative therapy heals over relatively easily, however inclined to the relapses after the periods of remission of a different duration.
3. Ulcers, which localization are had migrant character. Observed in people with acute ulcerous process of stomach.
4. Special form of gastric ulcer passing after the already carried disease. Passed with the expressed pain syndrome. Characterized by the presence in place of ulcerous defect of scars or deformations and absence of symptom of “niche”.

There are such complications can develop in patients with gastric ulcer: penetration, stenosis, perforation, bleeding and malignization.

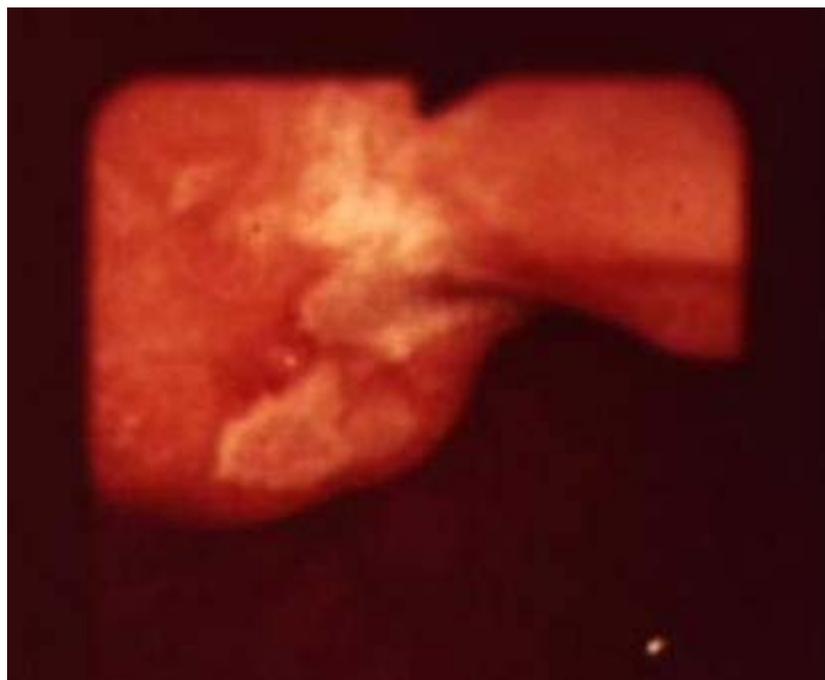

Diagnosis program

1. Anamnesis and physical examination.
2. Endoscopy.
3. X-Ray examination of stomach.
4. Examination of gastric secretion by the method of aspiration of gastric contents.
5. Gastric pH metry.
6. Multiposition biopsy of edges of ulcer and mucous tunic of stomach.
7. Gastric Dopplerography.
8. Sonography of abdominal cavity organs.
9. General and biochemical blood analysis.
10. Coagulogram.

Pic. Symptom of "Haudek's niche"

Pic. Peptic ulcer of the stomach (endoscopy)

Differential diagnostics

Chronic gastritis, as well as at an gastric ulcer, characterized by the pain

syndrome, that arises after the food intake. In such patients it is possible to observe nausea and vomiting by gastric content, heartburn and belch. However, unlike an gastric ulcer, for gastritis typical symptom of “quick satiation by a food”. Unsteady emptying, diarrhea also more inherent to gastritises. At gastric ulcer more frequent the delays are observed, constipation for 4–5 days.

The *cancer of stomach*, it is comparative with an gastric ulcer, has considerably more short anamnesis. The most typical clinical signs of this pathology are: absence of appetite, weight loss, rapid fatigability, depression, unsociability, apathy. In such patients X-Ray examination expose the “defect of filling”, related to exophytic tumor and deformation of walls of organ. A final diagnosis is set after the results of multiposition biopsy of shady areas of mucous tunic of stomach.

Differential diagnostics also needs to be conducted with the so called precancerous states: gastritis with the achlorhydria; chronic, continuously recurrence ulcers, poliposis and Addison-Biermer anemia.

Tactic and choice of treatment method

Conservative treatment of gastric ulcer always must be complex, individually differentiated, according to the etiology, pathogeny, localization of ulcer and character of clinical signs (disturbance of functions of gastroduodenal organs, complication, accompanying diseases).

Conservative therapy must include:

- Omeprazole 20 mg 2 time per day or H₂- blocker histamine receptor (ranitidine) — 150 mg in the evening, famotidine — 40 mg at night, roxatidine — 150 mg in the evening
- antacid drugs — in accordance with the results of pH-metry;
- reparative drugs (dalargin, solcoseryl, actovegin) — for 2 ml 1–2 times per days
- antimicrobial drugs (clarytromicine 500 mg twice daily, de-nol, metronidazole)

Treatment of patient with a gastric ulcer must continue not less than 6–8 weeks.

Surgical treatment must be performed in cases:

- a) at the relapse of ulcer after the course of conservative therapy;
- б) in the cases when the relapses arise during supporting antiulcer therapy;
- в) when an ulcer does not heal over during 1,5–2 months of intensive treatment, especially in families with “ulcerous anamnesis”.
- г) at the relapse of ulcer in patients with complications (perforation or bleeding);
- д) at suspicion on malignization ulcers, in case of negative cytological analysis.

The choice of method of surgical treatment of gastric ulcer depended from localization and sizes of ulcer, presence of gastro- and duodenostasis, accompanying gastritis, complications of peptic ulcer (penetration, stenosis, perforation, bleeding, malignization), age of patient, general condition and accompanying diseases. In patients with cardial localization of ulcer the operation of choice is the proximal resection of stomach, which, from one side, allows to remove an ulcer, and from other — to save considerable part of organ, providing it functional ability (Pic. 3.2.2). In case with large cardial ulcers, when the vagus nerves pulled in the inflammatory infiltrate and it is impossible to save integrity even one of them, operation needs to be complemented by pyloroplasty. It will give possibility to warn pylorospasm and gastrostasis, which in an early postoperative period can be the reason of anastomosis insufficiency and other complications.

At the choice of method of surgical treatment of gastric ulcers with *subcardial localization* on small curvature without duodenostasis it is better to apply the methods of stomach resection with saving of passage through a duodenum.

For this purpose we have developed the method of segmental resection of stomach with addition selective proximal vagotomy. The redistribution of gastric blood flow between the functional parts of stomach as reply to medicinal vagotomy (intravenous introduction 1,0 ml 0,1 % solution of atropine of sulfate) is studied. Hyperemia of acid-forming part of stomach comes after introduction of preparation. The functional scopes of stomach parts are determined. The border between acid-forming and antral parts are the most frequent localization of gastric ulcers.

During this operation middle laparotomy is performed, intravenously entered 1,0 ml 0,1 % solution of atropine, then the scopes of functional stomach parts are identified and by stitches-holders is marked a intermedial segment. Selective proximal vagotomy is performed. After mobilization of large curvature of stomach within the limits of intermedial segment it resection is performed. After that gastro-gastro anastomosis “end-to-end” is formed (Pic. 3.2.3).

The analysis of supervisions of the patients operated by such method in postoperative period has good results. It allows to recommend this operation for clinical practice, in case of gastric ulcers of subcardial localizations, without duodenostasis, penetration, malignization or nerves Latarjet damaging.

The operation of choice in patients with subcardial ulcers and duodenostasis is gastric resection by Billroth II.

At the choice of method of surgical treatment of ulcers which are localized in upper and middle third of stomach, it is necessary to consider such factors, as absence of penetration in a small omentum and absence of the duodenostasis. In such patients is performed segmental resection of stomach with ulcer removing with selective proximal vagotomy. In case of penetration ulcer in a small omentum with involvement in infiltrate Latarjet nerves, such operation is impossible because of future spasm of pylorus and gastrostasis. If duodenostasis is absence than better to apply pylorus-saving resection by Maki-Shalimov. In patients with duodenostasis better to apply gastric resection by Billroth II.

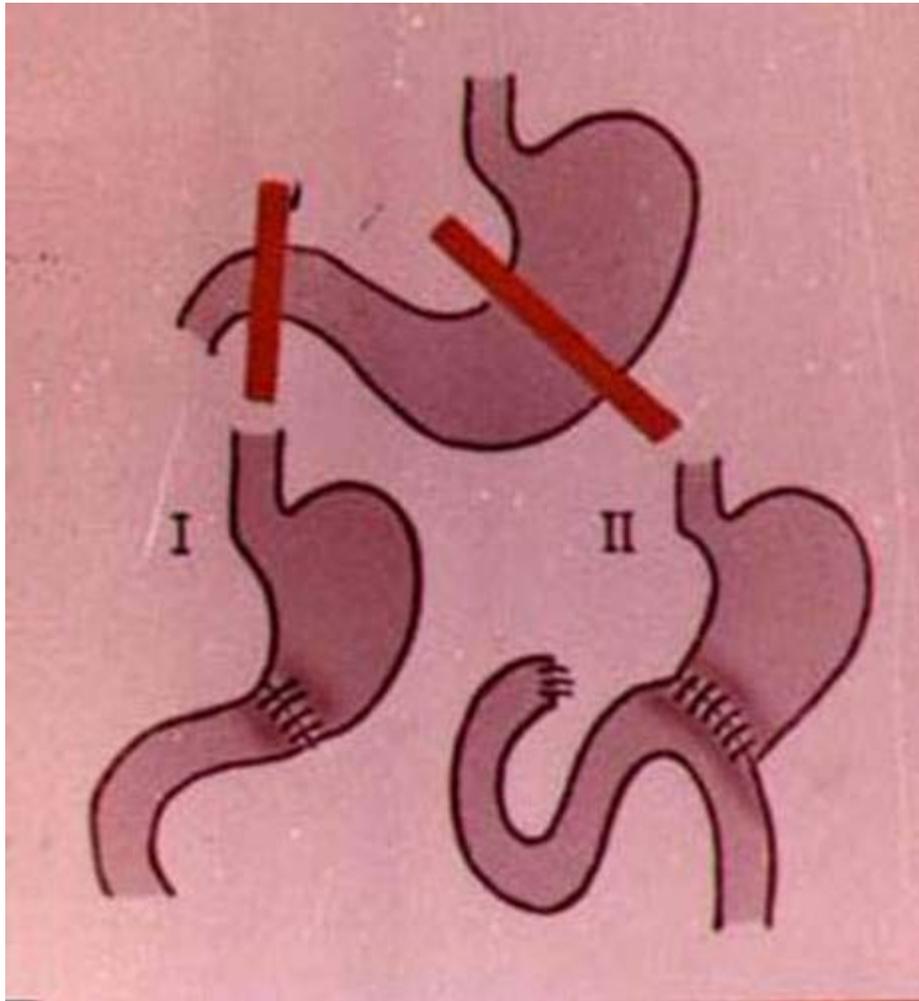

At the border of gastric resection near pyloric sphincter can be spasm and gastrostasis in a postoperative period . Avoiding such complication is possible, if this border of gastric resection passes no more than 1,5 cm from a pyloric sphincter (M.M. Risaev, 1986). So, at a resection, that passes higher than 2,0 cm from a pylorus, integrity of both loops is kept.

Patients with antral ulcers without the duodenostasis performed the gastric resection by Billroth I (Pic. 3.2.6), and on presence of duodenostasis – Billroth II.

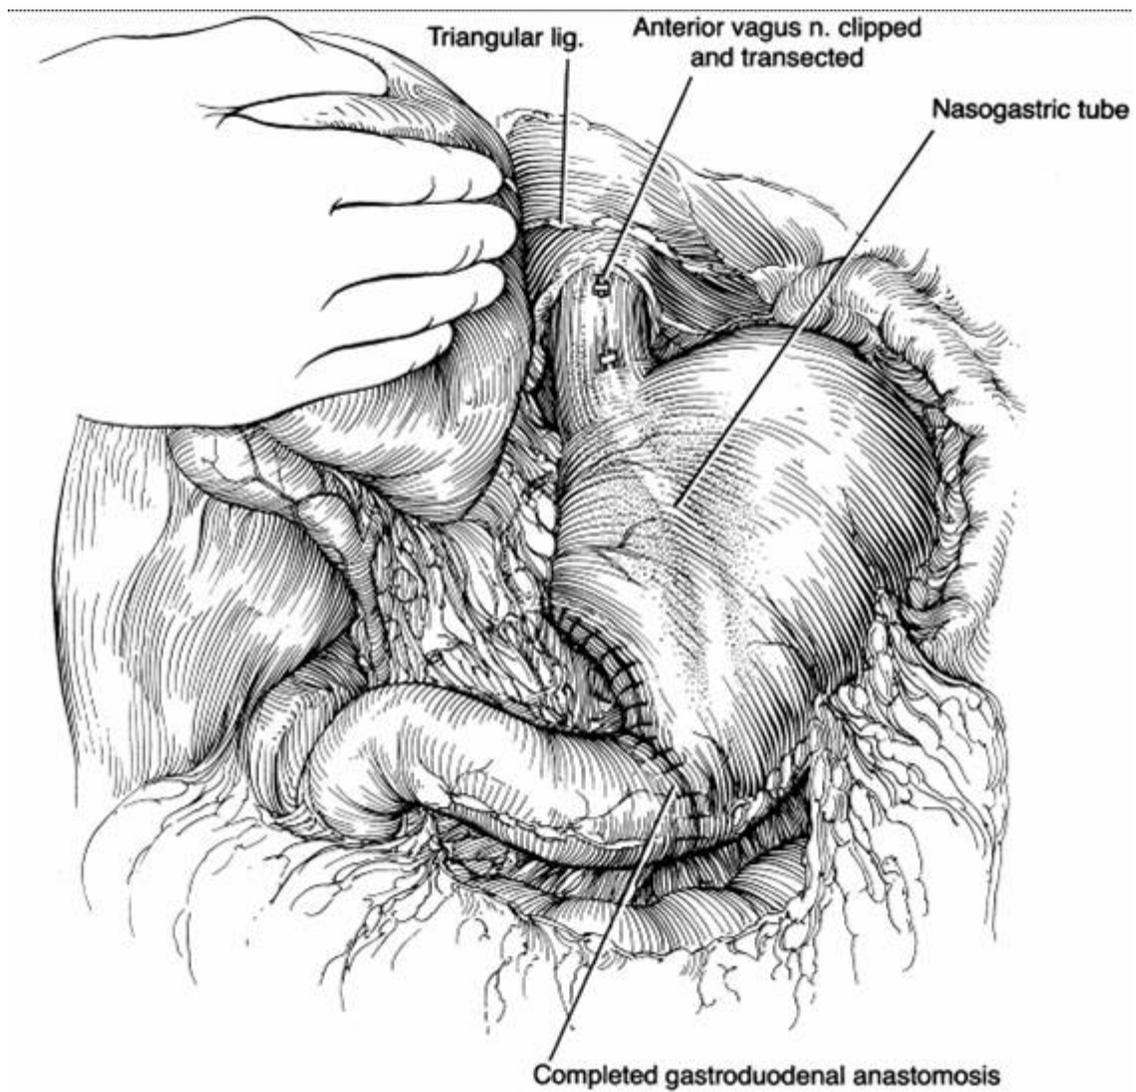

Prepyloric ulcers is similar to the ulcers of duodenum. Such localization of gastric ulcers without malignization allow to perform selective proximal vagotomy. However, at

large prepyloric ulcers with penetration without duodenostasis is better to perform the gastric resection by Billroth I and on presence of duodenostasis – by Billroth II.

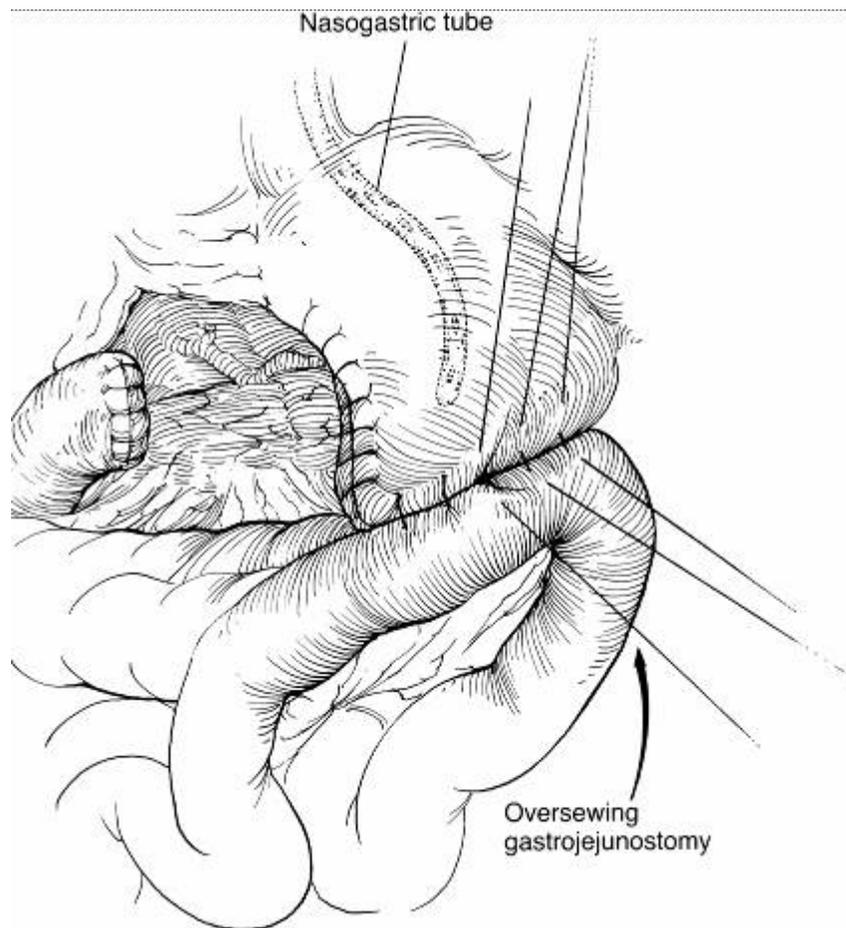

By contra-indication to operations with saving of food passing through the duodenum are also decompensated pylorostenosis , functional gastrostasis and duodenostasis. In such patients it is better to perform gastric resection by Billroth II.

Pic. Billroth II reconstruction

DUODENAL ULCER

The duodenal ulcer is the chronic recurrent disease which characterized by ulcerous defect on a mucous tunic of duodenum. Pathology often makes progress with complications development.

Etiology and pathogenesis

There are some etiologic factors of the duodenal ulcer: *Helicobacter pylori*, emotion tension and neuropsychic stress overstrain, heredity and genetic inclination, presence of chronic gastroduodenitis, disturbance of diet and harmful habits (alcohol,

smoking). In pathogenesis of peptic ulcer a leading role is played disturbance of equilibrium between aggressive and projective properties of secret of stomach and its mucous tunic. The aggressive factors are vagus hyperfunctioning and hypergastrinemia; hyperproduction of hydrochloric acid and pepsin, and also reverse diffusion of the ions H^+ , action of biliary acids and isoleucine, toxins and enzymes of helicobacter pylori (HP). There are factors which contribute to ulcerogenic action: disturbance of motility of stomach and duodenum, ischemia of duodenum, and metaplasia of the epithelium.

Pathomorphology

Morphogenesis of duodenal ulcer fundamentally does not differ from ulcer in a stomach. Chronic ulcers are mainly single, is localized on the front or back wall of bulb (bulbar ulcer) and only in 7–8 % cases – below it (postbulbar ulcer). The plural ulcers of duodenum are met in 25 % cases.

Classification

(by A.L.Hrebenev, A.O.Sheptulin, 1989)

The duodenal ulcer is divided:

I. *By etiology:*

- A. True duodenal ulcer.
- B. Symptomatic ulcers.

II. *By passing of disease:*

- 1. Acute (first exposed ulcer).
- 2. Chronic:
 - a) with the rare exacerbation;
 - b) with the annual exacerbation;

- c) with the frequent exacerbation (2 times per a year and more frequent).

III. *By the stages of disease:*

1. Exacerbation.
2. Scarring:
 - a) stage of “red” scar;
 - b) stage of “white” scar.
3. Remission.

IV. *By localization:*

1. Ulcers of bulb of duodenum.
2. Low postbulbar ulcers.
3. Combined ulcers of duodenum and stomach.

V. *By sizes:*

1. Small ulcers up to 0,5 cm.
2. Middle — up 1,5 cm.
3. Large — up to 3 cm;
4. Giant ulcers over 3 cm.

VI. *By the presence of complications:*

1. Bleeding.
2. Perforation.
3. Penetration.
4. Organic stenosis.
5. Periduodenitis.
6. Malignization.

Clinical management

Pain in the epigastric region is the most expressed symptom of duodenal ulcer, often with displacement to the right in the projection area of bulb of duodenum and gall-bladder. Also for this pathology is typical the pain, that arises in 1,5–2 hours after food intake, “hungry” and nightly pain. As a rule, it is acute, sometimes unendurable, and is halted only after the use of food or water. Such patients complains for the seasonal exacerbation, more frequent in spring and in autumn. However exacerbation can be also in winter or in summer. In the acute period of disease heartburn often increases. However heartburn is the frequent symptom of cardial insufficiency and gastroesophageal reflux. For an duodenal ulcer the acute burning feeling of acid in a esophagus, pharynx and even in the cavity of mouth is especially typical. Often are belch by air or sour content, excessive salivation. Vomiting is not a typical symptom for duodenal ulcer. More typical sign is nausea. Sometimes for facilitation patients wilfully cause vomiting. These symptoms, arises in the late periods of passing of duodenal ulcer.

Intensity of pain and dyspepsia syndromes depends both on the depth of penetration and from distribution of ulcerous and periulcerous processes. Superficial ulceration within the mucous tunic, as a rule, does not cause the pain because it does not have sensible receptors. However, more deep layers of wall (muscular and especially serous) have plural sensible vegetative receptors. Therefore, on deepening and distribution of process arises visceral pain. At evident periulcerous processes and penetration of ulcers to neighboring organs and tissues, usually, a parietal peritoneum, that has spinal innervation, is pulled in. Pain becomes viscerosomatic, more intensive. A such pain syndrome (with an irradiation in the back) is typical for low postbulbar ulcers and bulbous ulcers of back wall, which penetrates in a pancreas and hepato-duodenal ligament. Usually such patients has good appetite. Some of them limit themselves in acceptance of ordinary food, go into to the dietary feed by small portions, and some — even hold back from a food, being afraid to provoke pain, and as a result of it weight is lost. Some of patients feeds more intensive and often.

The psychical status of patients often are changed as a asthenoneurotic syndrome: irritates, decline of working capacity, indisposition, hypochondria, abusiveness.

An inspection, as a rule, gives insignificant information. In many cases on the abdominal skin it is possible to notice hyperpigmentation after application of hot-water bottle. During the pain attack patients often occupy the forced position. At superficial palpation on the abdominal wall determined hyperesthesia in ulcer projection. In the

epigastric region, during deep palpation, it is possible to define pain and muscular tension, mostly moderate intensity. There is important symptom of local percussion painful (Mendel's symptom): percussion by fingers in the symmetric epigastric areas provoke pain in the ulcer, which is increased after the deep breath. The roentgenologic and endoscopic are main diagnostic methods. The symptom of ulcerous "niche" is a classic roentgenologic sign. It is depot of contrast agent, which is corresponded to ulcerous defect, with clear contours and light bank to which converged fold mucus. Cicatricial deformation of bulb of duodenum as a shamrock, butterfly, narrowing, tube, diverticulum and other forms is the important sign of chronic ulcerous process. A roentgenologic method is especially important for determination of configuration and sizes of stomach and duodenum, and also for estimation of motility functions. X-Ray examination is the main method at the peptic ulcer complicated by stenosis, with disturbance of evacuation, duodenostasis, duodenal-gastric reflux, gastroesophageal reflux, diverticulum. But by X-Ray examination is difficult to diagnose small superficial ulcers, acute ulcers, erosions, gastritises and duodenitises. The most informing method in such cases it endoscopy.

During endoscopy examination it is possible to define localization, form, sizes and depth of ulcer. During bleeding grumes, trickle or pulsating of blood are observed. By irrigation by styptic solutions, by cryocoagulation, by laser coagulation endoscopy allows to secure hemostasis. Endoscopy allows to perform the biopsy of ulcer tissues for determination of possible malignization.

Clinical variants and complication

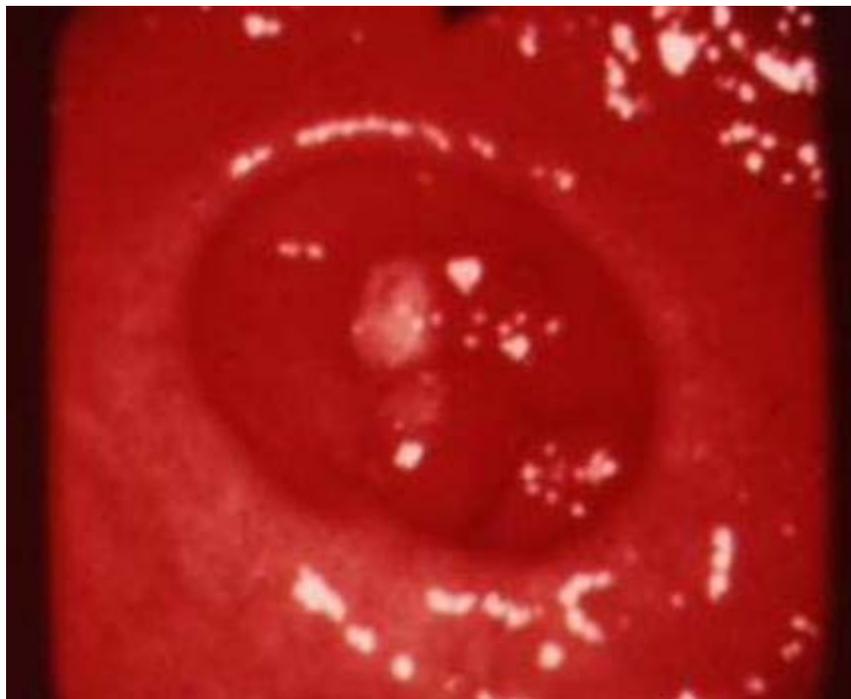

In patients with low postbulbar ulcers the clinical signs are more expressed. It characterized by late (in 2–3 hours after food intake) and intensive "hungry" and nightly pain, that often irradiate to the back and to the right hypochondrium. The postbulbar ulcers are inclined to more frequent exacerbation, and also to more frequent complications, such, as penetration, stenosis and bleeding.

The are more frequent ulcerous bleeding (the bulbous happen in 20–25 % cases, postbulbar — in 50–75 %), perforations (10–15 % cases). Penetration, stenosis and malignization in patients with duodenal ulcers are observed rarely.

Penetration is frequent complication of “low” and postbulbar ulcers of duodenum, which are placed on posterior, posterior superior and posterior inferior walls. Penetrates, usually, deep chronic ulcers, by passing through all layers of duodenum in neighboring organs and tissues (head of pancreas, hepato-duodenal ligament, small and large omentum, gall-bladder, liver). Such penetration is accompanied by development of inflammatory process in the neighboring organs and surrounding tissues and forming of cicatrical adhesions. A pain syndrome becomes more intensive, permanent and often pain irradiated in the back. Sometimes in the area of penetration it is possible to palpate painfully infiltrate.

Diagnostic program

1. Anamnesis and physical examination.
2. Endoscopy.
3. X-Ray examination of stomach and duodenum.
4. General and biochemical blood analysis.
5. Coagulogram.

Pic. Duodenoscopy

Differential diagnostics

The duodenal ulcer must be differentiated from acute and chronic cholecystitis, pancreatitis, gastroduodenitis. Endoscopy is help to diagnose duodenal ulcer.

Tactic and choice of treatment method

Conservative treatment. In most patients after conservative treatment an ulcer heals over in 4–6 weeks. Warning of relapses can be carried out by only supporting therapy during many years.

The best therapy of duodenal ulcer is associated with a helicobacter infection, there is the use of antagonists of H₂- receptors of histamine (renitidine— 300 mg in the evening or 150 mg twice for days; famotidine— 40 mg in the evening or 20 mg twice for days; nisatidine — 300 mg in the evening or 150 mg twice for days; roxatidine — 150 mg in the evening) in combination with sucralfate (venter) — for 1 г three times for days and antacid (almagel, maalox or gaviscon —1 dessert-spoon in a 1 hour after food intake). To this complex it is needed to add antibacterial preparations (De-nol – 1 tabl. 4 times per a day during 4–6 weeks + oxacylline for 0,5 g 4 times per a day — 10 days + Tryhopol (metronidazole) for 0,5 g 4 times per a day — 15 days).

In treatment of duodenal ulcer used chinolitics and miolitics (atropine, methacin, platyphyllin), and also mesoprostol (200 mg 4 times per days) and omeprasole (20 or 40 mg on days).

Such treatment of patients with the duodenal ulcer must be 4–6 weeks. If complications absents there is no necessity in the special diet.

Because of appearance of new pharmaceutical preparations and modern therapeutic treatment, indication to the operative methods narrowed. But the number of acute complications of duodenal ulcer does not go down, especially bleeding and perforations which require the urgent surgery.

Indications to the elective operation:

1. Passing of duodenal ulcer with the frequent relapses which could not be treated conservatively.
2. Repeated ulcerous bleeding.
3. Stenosis of the outlet part of the stomach.
4. Chronic penetrating ulcers with the pain syndrome.
5. Suspicion of malignization of ulcers.

Methods of surgical treatment.

At patients with the duodenal ulcer three types of operations are distinguished:

- organ-saving operations;
- organ-sparing operations;
- resection.

From them the better are: organ-saving operations with vagotomy, excision of the ulcer and drainage operation.

Types of vagotomy: trunk (TrV) (Pic. 3.2.7), selective (SV) (Pic. 3.2.8), selective proximal (SPV) (Pic. 3.2.9). Selective proximal vagotomy is optimal in the elective surgery of duodenal ulcer. However in urgent surgery a trunk, selective or selective proximal is often used in combination with drainage operations.

Drainage of the stomach operations are: Heineke-Mikulicz pyloroplasty, Finney pyloroplasty, submucous pyloroplasty by Diver-Barden-Shalimov, gastroduodenostomy by Jaboulay, gastroenteroanastomosis.

It is necessary to mark that “clean isolated” SPV, performed in patients with duodenal ulcer, often (in 15–20 % cases) results in relapses. The considerably less number of relapses (8–10 %) is observed after SPV in combination with drainage operations. Especially dangerous are the relapses of the ulcers placed in the projection of the large duodenal papilla, after gastroduodenostomy by Jaboulay.

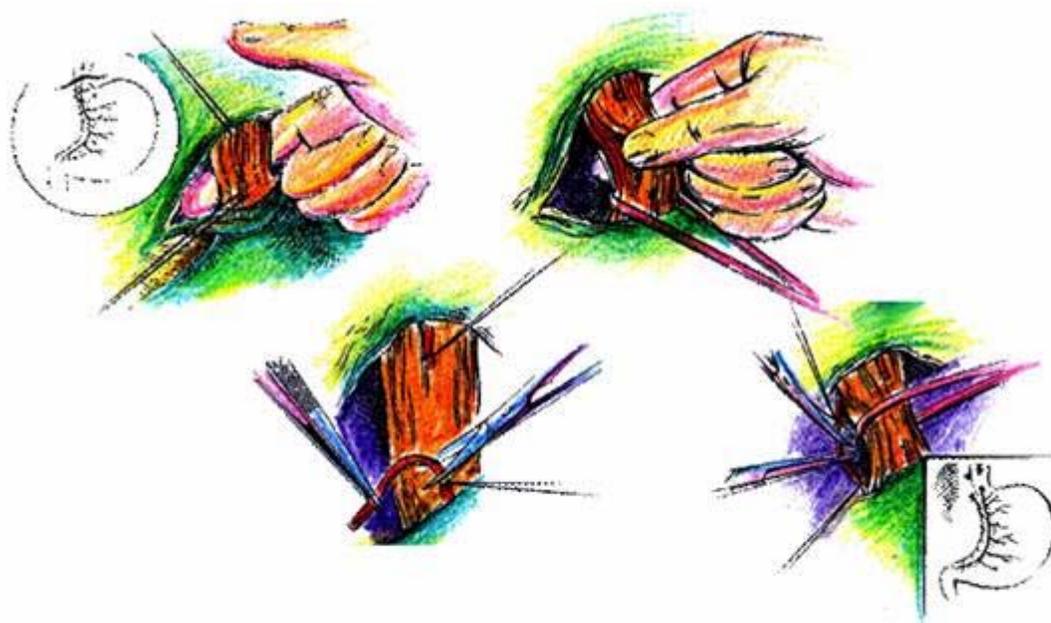

The least number of relapses of duodenal ulcer is observed after organ-saving operations, that combine SPV and ulcer excision.

If the ulcer is localized on the anterior surface of the duodenal bulb it can be performed by

the method Jade (Pic. 3.2.13) with subsequent to the pyloroplasty by Heineke-Mikulich.

At patients with decompensate stenosis and expressed dilatation and by the atony of stomach it is needed to apply the classic resection of stomach depending on possible damping-syndrome by Billroth -I or Billroth -II.

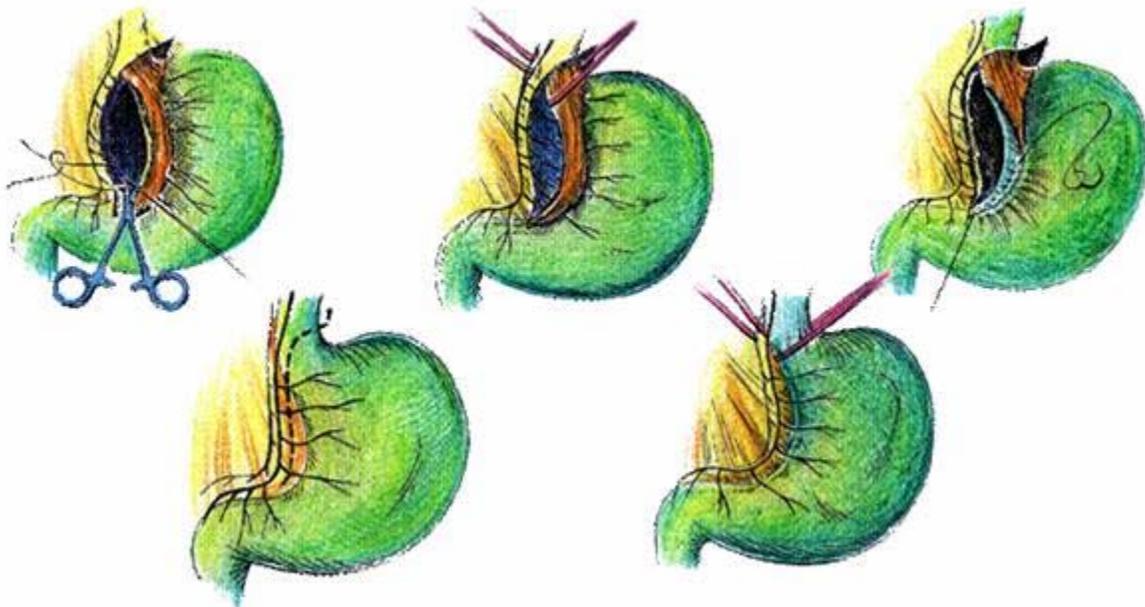

The choice of subtotal resection of stomach needs to be done at suspicion for malignization or at histological confirmed malignization ulcers. In a duodenum this process happens very rarely.

ULCEROUS STENOSIS

Ulcerous stenosis is complication of Peptic ulcer or duodenum, which characterized by narrowing.

Pic. Ulcer stenosis.

Etiology and pathogenesis

Stenosis of outgoing part of stomach and duodenum of ulcerous origin arises as a result of scarring and common morphological changes around an ulcer. Narrowing, disturbance of the coordinated motility of gastric peristalsis come as a result of it and creates

the obstacle to the even moving of stomach content to the duodenum.

Pathomorphology

Such pathology in the compensation stage arises hypertrophy of the stomach walls. The pyloric ring has a 0,5–0,7 cm in diameter. The mucous tunic of pyloric part of stomach is thickened, with rough folds. Muscular fibers are hypertrophied and solid. Histological hyperplasia of pyloric glands is observed.

During decompensation the muscular layer of stomach higher stenosis becomes thinner, tone of him goes down, and a pyloric ring narrows to a few millimetres. Microscopically present atrophy of mucous tunic and muscular fibers, vessels sclerosis. A stomach collects the form of the stretched sack which goes down to the level of small pelvis.

Classification

(by O.O. Shalimov and V.F.Saenko, 1987)

Three clinical stages of stenosis are distinguished:

- I — compensated;
- II — subcompensated;
- III — decompensated.

The morphological changes in the initial part of stomach and duodenum are represented by the classification offered by M.I. Kusin (1985). On the basis of clinical, roentgenologic, endoscopic, electrogastrographical and intraoperative methods the examinations distinguished three stages of stenosis:

- I — inflammatory;
- II — cicatricial-ulcerous;
- III — cicatricial.

In accordance with localization, by V.F.Saenko (1988) distinguished three types of

stenosis:

- I — stenosis of goalkeeper;
- II — stenosis of bulb of duodenum;
- III — postbulbar duodenal stenosis.

First two types of stenosis are similar by functional and the organic changes. It united them by one name — pyloroduodenal, or high duodenal stenosis. The second group is postbulbar duodenal stenosis. Feature of them is that a goalkeeper does not take participation in the cicatricial- ulcerous process and its function is not broken.

Clinical management

The first signs of stenosis can be exposed already in eight-ten years from the beginning of the peptic ulcer disease. Mainly, this is narrowing and rigidity and disturbance of retractive activity of goalkeeper, which create a barrier for transition of stomach content to the duodenum.

In the stage of the *compensated stenosis* hypertrophy of wall of stomach develops and tone of muscular shell rises. Hereupon gastric content, slowly, but passes through the narrowed area of stomach output. In this stage patients, usually, complained about feeling of plenitude in an epigastric area after food intake, periodic vomitings by sour gastric content. On empty stomach by a stomach pump 200–300 ml gastric content is removed.

In the *subcompensated stage* muscular layer of stomach becomes thinner. Tone of it goes down, peristalsis relaxes, and it looks like the stretched sack. Evacuation disorders is increased. Fermentation and rotting developed in stagnant gastric content. On this stage of disease development patients, usually, complain for the permanent feeling of weight in epigastric region and regurgitation with an unpleasant “rotten” smell of sulphuretted hydrogen.

Vomiting becomes systematic (once or twice on a day) up to half of liter per day. On empty stomach it is possible to aspirate from it more 500 ml of content with the food used the day before.

In the *decompensation stage* of the clinical signs make progress quickly. There are

heavy disturbances of the general condition of patient, considerable loss of weight (to 30–40 %), acutely expressed dehydration of organism, hypoproteinemia, hypokalemia, azotemia and alkalosis. In case of the protracted neglected disease, as a result of progress of disturbances of metabolism, there can be a convulsive syndrome (gastric tetany). Vomiting in this stage not always can be considered by a typical sign, in fact patients often renounce to adopt a food, and a stomach acquires considerable sizes, overdistension form, its tone is violated and atrophy of wall comes. In such patients in an epigastric area it is possible to define the contours of the stretched stomach, with a slow peristalsis. In the distance it is possible to hear the splash. By a probe from a stomach to 1.5–2 litres of food with a putrid smell are removed. There can be gastric tetany at considerable disturbances of electrolyte metabolism.

A diagnosis is set according to a typical syndrome, results of sounding of stomach, roentgenoscopy, at which by contrasting of a barium expose stenosis of initial part of stomach or duodenum, determines its origin and estimates a degree.

Roentgenologically in the compensation stage stomach is in normal sizes, its peristalsis deep, increased, evacuation of content proceeds no more than 6 hours. In the stage of subcompensation a stomach is megascopic, its peristalsis is loosened, evacuation stays too long to 24 hours. During decompensation a stomach is considerably extended as a sack, deformed, the waves of antiperistalsis can take place, a contrast stays too long more than 24–48 hours. The method of the double contrasting by a barium and air considerably facilitates diagnostics.

Determination of stomach motility has not only diagnostic but also prognostic value for the choice of method of operation.

In the stage of compensation motility of stomach is well-kept, often even increased. With the increasing degree of stenosis the motility disturbance increased, up to gastroplegia.

In the biochemical blood test is marked the decline of content of albumen to 54–48 g/l; potassium — to 2,9–2,5 mmol/l; chlorides — to 85–87 mmol/l. The changes of such indexes are most expressed at patients with gastrogenous tetany.

The study of secretory function of stomach allows to define the degree of compensation of stenosis and is important at the choice of adequate method of operation.

Gastroscopy with a biopsy is the enough informing method of examination of such

patients. By this method is possible to determine a reason and degree of stenosis, and also state of mucous tunic of stomach.

Diagnosis program

1. Complaints of patient and anamnesis of disease.
3. Sounding of stomach and examination of gastric content.
4. Fibergastroduodenoscopy, biopsy.
5. Intragastric pH-metry.
6. Study of motility of stomach.
7. Roentgenologic examination of stomach and duodenum (structural features, passage).
8. Sonography.

Pic. X-Ray examination. Ulcer stenosis.

Differential diagnostics

Stenosis of the output part of stomach and duodenum of ulcerous origin it is needed to differentiate with functional gastrostasis and narrowing of tumour and chemical genesis.

Functional gastrostasis more frequent meets at women. Basic, that distinguishes it from other pathologies, there is absence of some organic changes in the area of pyloric part of stomach or in a duodenum, that can be exposed during fibergastroscopy.

Differential diagnostics of stenosis of *tumour genesis*, as a rule, also does not cause the special difficulties. A diagnosis is finally confirmed by histological

examinations of the biopsy material taken during endoscopy.

Postburn stenosis of piloroantral area of stomach observed, from data of statistics, more than in 25 % cases of patients with the burn of esophagus. In anamnesis in each of such patients takes place by mistake or the intentionally taken an a swig at acid, alkali or other chemical matter. Some diagnostic difficulties can arise up at the isolated postburn stenosis of pyloric part of stomach. The however attentively collected anamnesis and professionally conducted endoscopic examination enable to set a correct diagnosis.

Tactic and choice of treatment method

Treatment of ulcerous stenosis of piloroantral part of stomach and duodenum must be exceptionally operative. A method depend on many factors: degree of stenosis, these secretory and motility functions of stomach, age of patient, presence of accompanying diseases and others like that. In the compensated and subcompensated stages of stenosis and at enough well-kept functions of stomach it is possible to perform of organ-saving operations (vagotomy with drainage stomach operations, economy resection of stomach). At growth of the signs of stenosis and disturbance of basic functions of stomach, the volume of operation must be increased up resection by the Bilioth's second method.

At the patients and older age persons with heavy accompanying pathology is performed minimum surgery —gastroenteroanastomosis.

Preoperative preparation must be strictly individual.

At patients with insignificant disturbances of gastric motor activity (stage of compensation, subcompensations) and with good level of metabolism indexes it is better to shorten preoperative preparation in time. Such patients, usually, operated on 3–4 day. Preparation before operation at patients with decompensated pilorostenosis must be directed for the correction of metabolism disturbances. Such patients must receive transfusion of liquid up to 2,5–3 l per day with content of the ions K^+ , Na^+ , Ca^{++} , amino acid and glucose; plasma, albumen. Twice on days performed decompression and washing of stomach and anti-ulcerous therapy. Effective preoperative preparation in such patients requires 5–7 days, sometimes more.

PERFORATED GASTRODUODENAL ULCERS

The typical perforation of gastric or duodenum ulcer is strengthening of necrosis process in the area of ulcerous crater with subsequent disturbance of integrity of wall, that result to the permanent effluence of gastroduodenal content and air in a free abdominal cavity.

Etiology and pathogenesis

In 50,7 % cases perforates the ulcers of duodenum, in 42,8 % are ulcers of pyloric part of stomach, in 4,8 % are ulcers of small curvature of body of stomach and in 0,7 % are cardial ulcers.

Ulcers, which lie on the front wall of stomach and duodenum more frequent give the perforation with general peritonitis, while ulcers on a back wall — perforation with adhesive inflammation.

The reasons of ulcers perforation are: exacerbation of peptic ulcer, harmful habits, stresses, professional, athletic overexertion, faults in the feed and abuses by strong waters.

Pathomorphology

In pathogeny of acute perforation important: progressive necrosis processes in the area of ulcerous crater with activating of virulent infection; hyperergic type of local vaculo-stromal reaction with the thrombosis of veins of stomach and duodenum; local manifestation of autoimmune conflict with accumulation of sour mucopolysaccharides on periphery of ulcer and high coefficient of plasmatization of mucous tunic (K.I. Mishkin, A.A. Frankfurt, 1971).

Classification

(by V.S. Savelev, 1986)

Perforated gastroduodenal ulcers are divided:

1. *After etiology:*

- ulcerous;
- un ulcerous.

2. *After localization:*

- gastric (small curvature, cardial, antral, prepyloric, pyloric) ulcer, front and back walls;
- ulcers of duodenum (front and back walls).

3. *After passing:*

- perforated in an abdominal cavity;
- covered perforations;
- atypical perforations.

Clinical management

The clinical picture of perforation is very typical and depends on distribution of inflammatory process and infection of abdominal cavity. In clinical passing of the perforations distinguish three phases: shock, “imaginary prosperity” and peritonitis (Mondor, 1939).

For the phase of shock (to 6 hours last) typical very acute pain in epigastric region (Delafua compares it to pain from the stab with a dagger) with an irradiation in a right shoulder and collar-bone, a face is pale, with expression of strong fear, lines become (facies abdominalis) acute, a death-damp irrigates skin covers. A pulse is at first slow (vagus pulse), later becomes frequent and less filling. Sometime observed the reflex

vomiting and delay of gases. Arterial pressure is reduced. On examination stomach is pulled in, does not take part in the act of breathing. At palpation is “wooden belly stomach”, especially in an upper part, where, usually, there is most pain. Positive Blumberg's sign. At percussion is disappearance of hepatic dullness (the Spizharnyy symptom). At rectal examination expose painful in the area of rectouterine or rectovesical pouch (the Kulenkampff's symptom).

The phase of shock changes by the phase of “imaginary prosperity”, when the reflex signs go down: the general condition of patient gets better, a pulse becomes normal, arterial pressure rises, a stomach-ache diminishes partly. However observed tension of muscles of front abdominal wall, positive Blumberg's sign.

The phase of “imaginary prosperity” in 6–12 hours from the moment of perforation changes by the phase of peritonitis: a pulse is frequent, a stomach is swollen through growing flatulence, intestinal noises are not listened, a face acquires the specific kind — facies Hippocratica — the eyes fall back, lips turn blue, a nose becomes sharp, a tongue becomes dry and furred, breathing superficial and frequent, a temperature rises.

Variants of clinical passing and complication

Covered perforation (A.M. Shnicler, 1912). At this pathology the perforative hole after a perforation is closed by a fibrin, by a omentum, by the fate of liver, sometimes — piece of food. After that some amount of stomach content and air gets in an abdominal cavity. After the protection a stomach-ache diminishes, but proof tension of muscles of front abdominal wall, especially overhead quadrant of stomach is kept. At percussion hepatic dullness is doubtful. During x-Ray examination it is not always possible to mark gas in right hypochondrium (Pic. 3.2.14).

Consequences of passing of the covered perforation: the repeated perforation with development of classic clinical signs can come; at separation of process from a free abdominal cavity a subdiaphragmatic or subhepatic abscess is formed; complete closing of defect by surrounding tissue with gradual convalescence of patient.

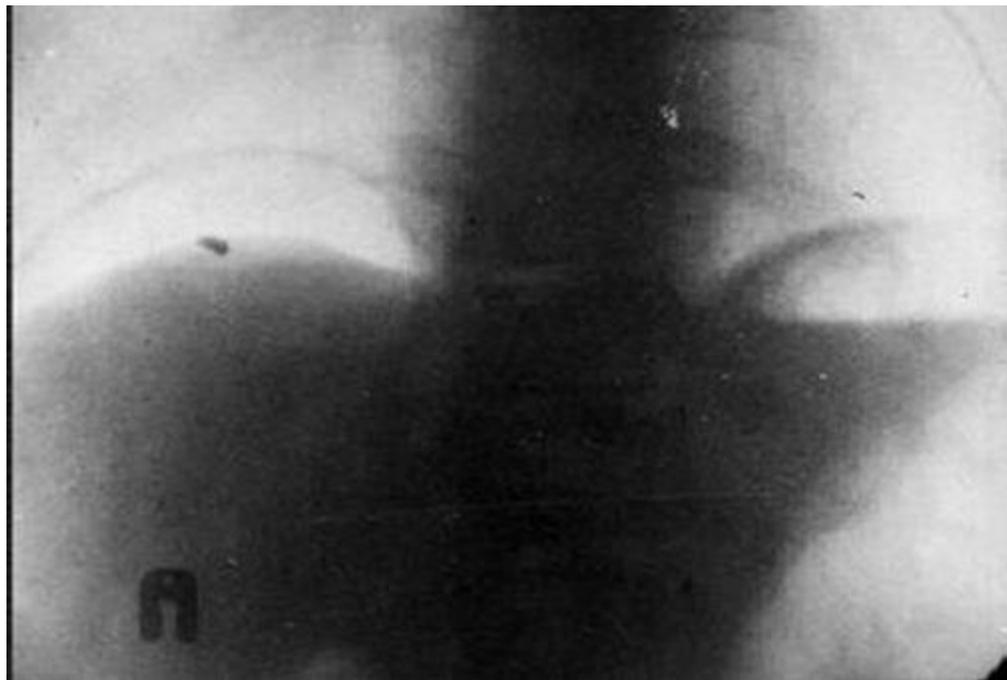

The atypical perforation is the perforation, at which gastric or intestinal content gets not to the abdominal cavity, but in retroperitoneal space (ulcers of back wall of duodenum), large or small omentum (ulcers of small curvature of stomach), hepato-

duodenal ligament.

In such patients during a perforation pain is not acutely expressed. During palpation observed insignificant rigidity of muscles of front abdominal wall. On occasion, especially on the late stages of disease, there can be hypodermic emphysema and crepitation.

Diagnosis program

1. Anamnesis and physical examination.
2. Global analysis of blood and urine, biochemical blood test, coagulogram.
3. X-Ray examination of abdominal cavity organs for presence of free gas (pneumoperitoneum).
4. Pneumogastrography, contrasting pneumogastrography.
5. Fiber-gastroduodenoscopy.
6. Sonography of abdominal cavity organs.
7. Laparocentesis with the Neymark diagnostic test (to the 2–3 ml of abdominal cavity exudate adds 4–5 drops of the 10 % solution of iodine. If the admixtures of gastric content appear in exudate, then under action of iodine gastric content gets a dirtily-dark blue color).
8. Laparoscopy.

Pic. X-Ray examination of abdominal cavity organs. Presence of free gas (pneumoperitoneum).

Tactic and choice of treatment method

The diagnosed perforated gastric and duodenum ulcer is an absolute indications to

operation. Preoperative preparation must include: in I phase are antishock action; in the II and III phases — reanimation preparations, introductions of antibiotics for 2–3 hours before operation, liquidation of hypovolemia by salt blood substitutes (solution of chlorous sodium), solutions of dextran (polyhlukine, reopolihlukine, hemodes). Amount of liquid necessary for correction of hypovolemia, calculate after hematokrit by central vein pressure. Taking for the norm of hematokrit 40 %, on each 5 % higher norms need to be poured 1000,0 ml liquids.

Conservative treatment (method of Tejlor, 1946) can be justified at the refusal of patient from operation or in default of conditions for its implementation.

It must include:

- permanent nasogastral aspiration of gastric content;
- introduction of preparations which brake a gastric secretion (atropine, H₂-blockers and others like that);
- introduction of antibiotics;
- correction of metabolism;
- laparocentesis with drainage and closed lavage of the abdominal cavity.

In the decision of question about the choice of method of operative treatment of perforated gastroduodenal ulcers the important value has the following factors: localization of ulcer, clinico-morphological description of ulcer (perforation of acute or chronic ulcer), connected with the perforation such complications of ulcer, as bleeding, cicatricial-ulcerous stenosis, penetration, degree of risk of operation and feature of clinical situation.

Operative treatments at a perforated ulcer divide into palliative and radical.

Palliative operations

Palliative operations are: closure of the perforative hole of ulcer, tamponade of the perforative hole by a omentum on a leg by B.A. Opperl - P.N.Polikarpov - M.A.Pidhorbunsky (1896, 1927, 1948) (Pic. 3.2.15). Indications and terms for their implementation are:

- perforation of acute duodenal ulcer in youth and young age without anamnesis;
- perforation of acute ulcer in the II–III phases of passing;
- perforation of callous gastric ulcer in the II–III phases of passing;
- expressed and high degrees of risk of operation.

Radical operations

The radical operations at perforated ulcers are: resection of stomach and excision of the perforative hole of ulcer in combination with pyloroplasty and StV, SV or SPV.

Indications and terms for implementation of resection of stomach are:

- perforation of callous gastric ulcer in I phase of clinical passing;
- repeated perforation of ulcer;
- perforation of ulcer in I phase of clinical passing in combination with stenosis and bleeding of ulcer;
- perforation of duodenal ulcer in I phase of passing in combination with a gastric ulcer;
- unexpressed and moderate degree of risk of operation;
- sufficient qualification of surgeon and material resources of operating-anaesthetic brigade.

Indications for implementation of operation of excision of the perforative hole of ulcer with pyloroplasty, StV, SV and SPV are: perforation of ulcer of front wall of duodenum or pyloric part of stomach in the I–II phases of passing;

- perforation of ulcer of front wall of duodenum in the I–II phases of passing in combination with the bleeding ulcer of back wall;
- perforation of duodenal ulcer in the I–II phases of passing in combination with the compensated stenosis of outgoing part of stomach;
- increased gastric secretion;
- insignificant and moderate degree of risk of operation;

— sufficient qualification and technical preparedness of surgeon.

[video](#)

BLEEDING GASTRODUODENAL ULCERS

Bleeding gastroduodenal ulcers are outpouring of blood in the gastrointestinal tract cavity as a result of strengthening and distribution of necrosis process in the ulcer area to vessels with the subsequent melting of their walls.

Complication of peptic or duodenal ulcer by bleeding is critical situation which threatens to life of patient and requires from the surgeon of immediate and decisive actions for clarification of reasons of bleeding and choice of tactic of treatment. The ulcerous bleeding has 60 % of the acute bleeding from the upper parts of gastrointestinal tract.

Etiology and pathogenesis

The origin of the gastrointestinal bleeding at patients with a gastric or duodenal ulcer almost is always related to exacerbation of ulcerous process. The reason of bleeding is a erosive vessel, that is on the bottom of ulcer. The expressed inflammatory and sclerotic processes round the damaged vessel embarrassed its contraction, that diminishes chances on the spontaneous stop of bleeding.

Gastric ulcers, compare with the ulcers of duodenum, complicated by bleeding more frequent. Bleeding at gastric ulcers are more expressed, profuse, with heavy passing.

At the duodenal ulcer bleeding more frequent complicate the ulcers of back wall, which penetrates in the head of pancreas.

At the men ulcer is complicated by bleeding twice more frequent, than at women. It costs to mark that 80 % patients which carried bleeding from an ulcer and treated oneself by conservative preparations, are under the permanent threat of the recurrent bleeding.

Pathomorphology

Strengthening of necrosis process are leading factors in the origin of the ulcerous bleeding in the area of ulcerous crater with distribution of this process to a vessel and subsequent melting of vascular wall; activation of fibrinolysis in tissues of stomach and duodenum; ischemia of tissues of wall of stomach.

Classification

Bleeding gastroduodenal ulcers after the degree of weight of loss of blood (by O.O. Shalimov and V.F.Saenko, 1987) are divided:

I degree is *easy* — observed at the loss to 20 % volume of circulatory blood (at a patient with weight of body 70 kg it is up to 1000 ml);

II degree — *middle weight* is loss from 20 to 30 % volume of circulatory blood (1000–1500 ml);

The III degree is *heavy* — is observed at loss of blood more than 30 % volume of circulatory blood (1500–2500 ml).

Clinical management

At patients with an peptic ulcer disease, bleeding pops up, mainly at night. Vomiting can be the first sign of it, mostly, at gastric localization of ulcers. Vomiting masses, as a rule, looks like “coffee-grounds”. Sometimes they are as a fresh red blood or its grume.

The black tar-like emptying are the permanent symptom of the ulcerous bleeding, with an unpleasant smell (“melena”), that can take place to a few times per days.

Bloody vomiting and emptying as “melena” is accompanied by worsening of the general condition of patient. A acute weakness, dizziness, noise in a head and darkening

in eyes, sometimes — loss of consciousness. A collapse with the signs of hemorrhagic shock can also develop. Exactly with a such clinical picture the such patients get to the hospital. It is needed to remember, that for diagnostics anamnesis is very important. Find out often, that at a patient an peptic ulcer was already diagnosed once. It appears sometimes, that bleeding is repeated or surgery concerning a perforated ulcer took place in the past. At some patients a gastric or duodenum ulcer is was not diagnosed before, the however attentively collected anamnesis exposed, that at a patient had a stomach-ache. Thus it communication with acceptance of food and seasonality is typical (more frequent appears in spring and in autumn). Patients tell, that pain in overhead part of abdomen which disturbed a few days prior to bleeding suddenly disappeared after first its displays (*the Bergmann's symptom*).

At patients with the ulcerous bleeding there are the typical changes of hemodynamic indexes: a pulse is frequent, weak filling and tension, arterial pressure is mostly reduced. These indexes need to be observed in a dynamics, as they can change during the short interval of time.

There is the pallor of skin and visible mucous tunics at a examination. A stomach sometimes is moderately exaggerated, but more frequent is pulled in, soft at palpation. In overhead part it is possible to notice hyperpigmental spots — tracks from the protracted application of hot-water bottle. Painful at deep palpation in the area of right hypochondrium (duodenal ulcer) or in a epigastric area (gastric ulcer) it is possible to observe at penetrated ulcers. Important symptom of Mendel also — painful at percussion in the projection of piloroduodenal area.

At the examination of patients with the gastrointestinal bleeding finger examination of rectum is obligatory. It needs to be performed at the first examination, because information about the presence of black excrement (“melena”) more frequent get according to a patient anamnesis, that can result in erroneous conclusions. Finger examination of rectum allows to expose tracks of black excrement or blood. In addition, it is sometimes possible to expose the tumour of rectum or haemorrhoidal knots which also are the source of bleeding.

The deciding value in establishment of diagnosis has the endoscopic examination. Fiber-gastroduodenoscopy enables not only to deny or confirm the presence of bleeding but also, that it is especially important, to set its reason and source. Often embarrassed the examination of stomach and duodenum present in it blood and content. In such cases

it is necessary to remove blood or content, by gastric lavage, and to repeat endoscopic examination. During the examination often exposed the bleeding with fresh blood from the bottom of ulcer or ulcerous defect with one or a few erosive and thrombosed vessels (stopped bleeding). The bottom of ulcer can be covered by the package of blood.

Important information about such pathology is given by haematological indexes also. Diminishment of number of red corpuscles and haemoglobin of blood, decline of haematocritis is observed in such patients. However always needed to remember, that at first time after bleeding haematological indexes can change insignificantly. Conducting of global analysis of blood in a dynamics in every a few hours is more informing.

Variants of clinical passing and complication

It is necessary always to remember that complication of peptic ulcer by bleeding happens considerably more frequent, than is diagnosed. Usually, to 50–55 % moderate bleeding (microbleeding) have the hidden passing. The massive bleeding meet considerably rarer, however almost always run across with the brightly expressed clinical signs which often carries dramatic character. In fact profuse bleeding with the loss 50–60 % to the volume of circulatory blood could stop the heart and cause the death of patient.

The clinical signs and passing of disease depend on the degree of lost of blood (O.O. Shalimov and V.F.Saenko, 1987).

For lost of blood I degree typical there is a frequent pulse to 90–100, decline of arterial pressure of to 90/60 mm Hg. The excitability of patient changes by lethargy, however clear consciousness is, breathing some frequent. After the stop of bleeding and in absent of hemorrhage compensation the expressed disturbances of circulation of blood does not observe.

At patients with the II degree of hemorrhage the general condition needs to be estimated as average. Expressed pallor of skin, sticky sweat, lethargy. Pulse — 120–130 per min., weak filling and tension, arterial pressure — 90–80/50 mm Hg. At first hours the spasm of vessels (centralization of circulation of blood) comes after bleeding, that predetermines normal or increased, arterial pressure. However, as a result of the protracted bleeding compensate mechanisms of arterial pressure are exhausted and can acutely go down at any point. Without the proper compensation of hemorrhage the such patients can survive, however almost always there are considerable disturbances of blood

circulation with disturbance of functions of liver and kidneys.

The III degree of hemorrhage characterizes heavy clinical passing. There is a pulse in such patients — 130–140 per min., and arterial pressure — from 60 to 0 mm Hg. Consciousness is almost always darkened, acutely expressed adynamy. Central vein pressure is low. Oliguria is observed, that can change by anuria. Without active and directed correction of hemorrhage a patient can die.

But, not always weight of bleeding which is conditioned by the degree of hemorrhage correspond the general condition of patient. On occasion the considerable loss of blood during the set time is accompanied by the relatively satisfactory condition of patient. And vice versa, moderate hemorrhage can bring to the considerable worsening of general condition. It can depend both on compensate possibilities of organism and from the presence of accompanying pathology.

It is needed to remember, that the ulcerous bleeding can accompanying with the perforation of ulcer. During perforation ulcers are often accompanied by bleeding. Correct diagnostics of these two complications has the important value in tactical approach and in the choice of method of surgical treatment. In fact simple suturing of perforated and bleeding ulcer can complicated in postoperative period by the profuse bleeding and cause the necessity of the repeated operation.

Diagnosis program

1. Anamnesis and physical examination.
2. Finger examination of rectum.
3. Gastroduodenoscopy.
4. Global analysis of blood.
5. Coagulogram.
6. 7. Biochemical blood test.
7. X-Ray examination of gastrointestinal tract.
8. Electrocardiography.

Pic. Endoscopy - stopped bleeding.

Differential diagnostics

At wide introduction of gastroduodenoscopy of question of differential diagnostics of bleeding lost the actuality. However much a problem arises up at impossibility to execute this examination through the heavy general condition of patient or taking into account other reasons. Differential diagnostics is conducted with bleeding of un ulcerous origin, which arise up in different parts of digestive tract.

For bleeding from the *varicose extended veins of esophagus* during portal hypertension at patients with the cirrhosis of liver the acute beginning without pain is characteristic, like during exacerbation of ulcerous disease. These bleeding differ by the special massiveness and considerable hemorrhage. Vomiting by fresh blood, expressed

tachycardia, falling of arterial pressure are observed. In such patients it is possible to find the signs of cirrhosis of liver and portal hypertension (“head of jelly-fish”, hypersplenism, ascites, often is icterus).

Sliding hernia of the esophagus opening of diaphragm can be accompanied by formation of ulcers in the place of clench of the stomach by the legs of diaphragm and bleeding from them. However for this pathology are more typical microbleeding, that is hidden. In such patients often the present protracted anaemia which can achieve the critical values. Sometimes in them observe more expressed bleeding with “classic” vomiting “coffee-grounds” and melena. During the roentgenologic examination with barium is possible to expose the signs of sliding hernia of the esophagus opening: the obtuse cardial angle, absence or diminishment of gas bubble of stomach or “ringing symptom”.

The cancer tumour of stomach in the destruction stage can be also complicated by bleeding. However, such bleeding are massive, and chronic character is carried mostly with gradual growth of anaemia. For this pathology there are the inherent worsenings of the general condition of patient, loss of weight of body, decline of appetite and waiver of meat food. At the roentgenologic examination the “defect of filling” is exposed in a stomach.

The gastric bleeding can be related to the diseases of the cardio-vascular system (atherosclerosis, hypertensive disease), however such happens mainly in the older years people. Clearly, that in such patients during the endoscopic examination the source of bleeding exposing is not succeeded.

Among other diseases, with which it is necessary to differentiate the ulcerous bleeding, it is needed to remember the Mallory-Weiss syndrome, benign tumours of stomach and duodenum (more frequent leiomyoma), hemorrhagic gastritis, acute (stress) erosive defeats of stomach, arteriovenous fistula of mucous tunic.

Often differential diagnostics performed according to the level of localization of source of bleeding in different parts of gastrointestinal tract. For the upper parts of digestive tract (esophagus and stomach) typical there is vomiting by grume or “coffee-grounds” content and emptying by “melena”. The farther aboral placed source of bleeding, the bloody emptying changes the more so. During the bleeding from a thin bowel excrement looks as “melena”. In case of such pathology of colon (polypuses,

tumours, unspecific ulcerous colitis) emptying have the appearance of fresh red blood, mostly as packages.

Tactic and choice of treatment method

The conservative therapy indicated to patients with the stopped bleeding of I degree and bleeding of the II–III degrees at patients which have heavy accompanying pathology, because of operative risk.

Conservative therapy must include:

— prescription of hemostatic preparations (intravenously the aminocapronic acid 5 % — 200–400 ml, chlorous calcium 10 % — 10,0 ml, vicasol 1 % — 3,0 ml);

— addition to the volume of circulatory blood (gelatin, poliglukine, salt blood substitutes);

— preparations of blood (fibrinogen — 2–3 r, cryoprecipitate);

— blood substitutes therapy (red corpuscles mass, washed red corpuscles, plasma of blood);

— antiulcerous preparations — blocker of H₂- receptor (ranitidine, roxatidine, nasatidine— for 150 mg 1–2 times per days);

— antacid and adsorbents (almagel, phosphalugel, maalox— for 1–2 dessertspoons through 1 hour after food intake).

It is expedient to apply washing of stomach by water with ice and the use 5 % solution of aminocapronic acid inward for to a 1 soup spoon in every 20–30 minutes.

The endoscopic methods of stop of bleeding are used also. Among them most effective is a laser and electro-coagulation.

Absolute indications to surgical treatment are: 1) lasting bleeding I degree; 2) recurrent bleeding after hemorrhage I degree; 3) bleeding of the II–III degrees; 4) stopped bleeding with hemorrhage of the II–III degrees at the endoscopically exposed ulcerous defect with a presence on the ulcer bottom thrombosed vessels or erosive vessels covered by the package of blood.

The *choice of method of surgical treatment* always needs to be decided

individually. On today the best tactic which gives advantage to organ-saving and organosparing methods of operations. The removing ulcer as sources of bleeding must be an obligatory condition. The methods of sewing of bleeding vessels or edging of ulcer and bandaging of vessels which feed a stomach and duodenum did not justify itself through the real threat of relapse of bleeding already in an early postoperative period (9–12 days).

Palliative operations (cutting of ulcer, forming of roundabout anastomosis) can be justified only taking into account the general condition of patient and on a necessity as possible quick and least traumatically to make off operation.

At the bleeding ulcers of duodenum it is better to apply excision of ulcer or it exteritirization after methods, developed by V.Zajtsev and Velihotsky. Operation complemented by one of types of vagotomy, it is better by a selective proximal with piliroplastic. The resection of stomach on the second or first method of Bilioth can be realized only in the stable general condition of patient. During the resection of stomach in case of low bleeding duodenal ulcers it is better to execute mobilization of duodenum and suturing of its stump on transcholedochus drainage which formed as transcholedochus duodenotomy (Laqey, 1942). This method warns the possible intraoperative damages of choledoch, that are the possible at low duodenal ulcers. Transcholedochus duodenotomy by performing the decompression of stump of duodenum, warns insufficiency of its stitches, that can arise up in an early postoperative period.

In case of bleeding gastric ulcers, the resection methods of operations are also usable. Only on occasion, when patients has the grave general condition, it is possible to assume the wedge cutting of ulcer.

[video](#)

MALIGNIZATION

CANCER OF STOMACH

The cancer of stomach is a malignant formation, that develops from epithelium tissue of mucus stomach. Among the tumours of organs of digestion this pathology takes

first place and is the most frequent, by the reason of death from malignant formations in many countries of world. Frequency of it at the last 30 years considerably diminished in the countries of Western Europe and North America, but yet remains high in Japan, China, countries of East Europe and South America.

Etiology and pathogenesis

Etiology of cancer of stomach is unknown. It is known that, as other diseases of gastrointestinal tract, a cancer damages a stomach. According to statistical information, it meets approximately in 40 % of all localizations of cancer.

The factors of external environment has the substantial influencing on frequency of this pathology. Above all things, feed, smoke food, salting, freezing of products and their contamination of aflatoxin. Consider that a “food factor” can be: a) by a carcinogen; b) by the solvent of carcinogens; c) to grow into a carcinogen in the process of digestion; d) to be instrumental in action of carcinogens; e) not enough to neutralize carcinogens.

In the USA and countries of Western Europe frequency of cancer of stomach in 2 times more large in the lower socio-economic groups of population. Some professional groups also can it (miners, farmers, works of rubber, woodworking and asbestine industry). High correlation communication is set between frequency of cancer of stomach and use of alcohol and smoking. The value of genetic factors (heredity, blood type) is not led to.

The cancer of stomach arises up mainly in age 60 years and above, more frequent men are ill.

Precancer. The precancer diseases of stomach are: a) chronic metaplastic disregenerator gastritis conditioned by helicobacter pylori; b) villous polypuses of stomach and chronic ulcers; c) nutritional anemia due to vitamin B12 deficiency (pernicious); d) resected stomach concerning an ulcer.

The presence of precancer changes of mucous tunic of stomach has substantial influence for frequency of stomach cancer. In those countries, where morbidity on the cancer of stomach is higher, considerably more frequent chronic gastritises are diagnosed. Lately in etiology of chronic gastritises take the important value helicobacter pylori. In Japan, where the cancer of stomach is in 40 % cases is the reason of death, chronic gastritis appears in 80 % cases of resected stomach, concerning a cancer.

Connection between polypuses, chronic gastric ulcers and possible its malignization comes into question in literature during many decades. Most authors consider that polypuses could be malignant differently. There are three histological types of polypuses: hyperplastic, villous and hamartoma. There are hyperplastic polypuses, but it is not malignant.

Hamartoma is accumulation of cells of normal mucous tunic of stomach. They never become malignant.

Villous polypuses are potentially malignant in 40 % cases, but it happens in 10 times less, than hyperplastic. The possibility of malignization of chronic gastric ulcers is not proved. The American scientists support a hypothesis, that the cancer of stomach can be ulcerous often, but malignization of ulcers takes place rarely (no more than 3 %). From data of the Japanese scientists, on 50–70th there was higher correlation connection between chronic gastric ulcers and cancer of stomach. The frequent decline of this correlation is lately noticed (70 % on 50–70th and 10 % on 80th).

Frequency of cancer of stomach at patients with pernicious anaemia hesitates within the 5–10 %, that is 20 times higher, compare with control population. In patients with a resected stomach after peptic ulcers is multiplied the risk of origin of stomach cancer in 2–3 times (duration of latent period hesitates from 15 to 40 years). The reason of such dependence is not found out, but there is a version, that this is linked with a gastric epithelium metaplasia by an intestinal type.

Pathomorphology

From all malignant formations of the stomach in 95 % adenocarcinoma is observed. Epidermoid cancer, adeno-acanthoma and carcinoid tumours do not exceed 1 %. Frequency of leiomyosarcoma hesitates within the limits of 1–3 %. Lymphoma of gastrointestinal tract is localized in a stomach.

The prognosis of localization depends on the degree of invasion, histological variants of tumour.

The macroscopic forms of cancer of stomach in different times were described variously. More than 60 years ago the German pathologist Bermann described 5

macroscopic forms of cancer of stomach: 1) polypoid or mushroom-like; 2) saucer-shaped or with ulcerous and expressly salient edges; 3) with ulcerous and infiltration of walls of stomach; 4) diffuse -infiltrate; 5) unclassified.

American pathopsychologists is selected 4 forms. The tumours of stomach with ulcerous are the most frequent macroscopic form of cancer of stomach and arise up on soil of chronic ulcer. The signs suspicious on malignization are: the sizes of ulcer more than 2 cm in a diameter, appearance of the heightened edges.

The polypoid tumours of stomach observed only in 10 %. These tumours can achieve considerable sizes without an invasion and metastasis. Scirrhus carcinoma is the third macroscopic type. This category of tumours also does not exceed 10 %. The scirrhus carcinoma is the signs of infiltration by anaplastic cancer cells, diffusely developed connecting tissue which results in the bulge and rigidity of wall of stomach. So called “small cancers” belong to the fourth macroscopic type. It meet comparative rarely (no more than 5 %) and is characterized by superficial accumulation of cancer cells which substitute for normal mucus in such kind: a) superficial flat layer which does not rise above the level of mucus; b) salient (bursting) formation; c) erosions.

Mainly (more than 50 %) tumours arise up in a antral part or in distal (lower) third of stomach, rarer (to 15 %) — in a body and in cardia (to 25 %).

However, lately more often observed cardioesophageal cancers and diminishment of frequency of tumours of distal parts of stomach. In 2 % cases meet the multicentric focuses of growth, but from data of some authors, this percent could be multiplied in 10 times after carefully histological inspection of the resected stomachs. This assertion is based on the theory of the “tumour field” (D.I. Holovin, 1992). Especially this typically for patients which has pernicious anaemia or chronic metaplastic disregenerative gastritis.

Metastasis is carried out by lymphogenic, hematogenic and implantation ways mostly. Three (from data of some authors, four) pools of lymphogenic metastasis are selected: left gastric (knots on passing of small curvature of stomach in a gastro-subgastric ligament and pericardial); splenic (mainly, suprainfrapancreatic knots); hepatic (knots in a hepato-duodenal ligament, right gastric omentum that lower pyloric groups, right gastric and suprapyloric groups, pancreatoduodenal group).

However, the such way of lymphogenic metastasis is conditional and incomplete,

as at presence of block lymph flow passes retrograde metastasis, so called “jumping metastases” which predetermine the origin of remote lymphogenic metastases in left supraclavicular lymph nodes (Virhov metastasis) appear, in Lymph nodes of left axillar and inguinal areas, metastases in a umbilicus.

Direct distribution: small and large omentum, esophagus and duodenum; liver and diaphragm; pancreas, spleen, bile ducts.

Front wall of stomach: colon bowel and mesocolon; organs and tissues of retroperitoneal space.

Lymphogenic metastasis: regional lymph nodes, remote lymph nodes, left supraclavicular lymph node (Virhov), lymph node of axillar area (Irish); in a umbilicus (sisters Joseph).

Hematogenic metastasis: liver, lungs, bones, cerebrum.

Peritoneal metastasis: peritoneum, ovarium (the Krukenberg metastasis), Duglas space (the Shnicler metastasis).

Classification (by system of TNM)

T— primary tumour.

T0 is a primary tumour is not determined.

Tx — not enough data for estimation of primary tumour.

Tis is invasive carcinoma: intraepithelial tumour without the invasion of own shell mucus (Carcinoma in situ).

T1 is a tumour infiltrate the wall of stomach to the submucous layer.

T2 is a tumour damages mucus, submucous and muscular layers.

T3 is a tumour germinates in a serous shell.

T4 is a tumour passes to the neighbouring structures.

N are regional lymphatic nodes.

Nx — not enough information for the damage assessment of lymphatic nodes.

No — metastases in regional lymph nodes are not present.

N1 are damaged perigastral lymph nodes in the distance no more than 3 cm from a primary tumour along small or large curvature of stomach.

N2 are damaged perigastral lymph nodes in the distance more than 3 cm from a primary tumour, which can be removed during operation, including lymph nodes placed along left gastric, splenic, abdominal and general hepatic arteries.

M is remote metastases.

Mx — not enough information for estimation of remote metastases.

Mo — remote metastases are not present.

M1 is presence of remote metastases.

Groupment by stages

Stage 0 T No Mo.

Stage I T1-2 No Mo.

Stage II T2-3 No Mo.

Stage III T1-4 N1-2 Mo.

Stage IV any T, any N M1.

Except for clinical classification (TNM or cTNM), for the most detailed study *pathological classification (postsurgical, posthistological) which is signed pTNM.*

G — histopathological differentiation:

G1 is the well differentiated tumour;

G2 is the moderately differentiated tumour;

G3-4 — it is badly or undifferentiated tumour.

Clinical management

All authors which are engaged in the study of problem of cancer of stomach underline absence or vagueness, no specificity of symptoms, especially on the early stages of disease. The displays of cancer of stomach are very various and depend on localization of tumour, character of its growth, morphological structure, distribution on contiguous organs and tissues. At localization of tumour in a cardial part patient complains firstly, as a rule, for appearance of dysphagy.

At careful, purposeful collection of anamnesis it is not succeeded to expose some other, most early symptoms, which precedes to dysphagy and forces a patient to appeal to the doctor. The unpleasant feeling behind a breastbone and feeling of unpassing of hard food on a esophagus appear at the beginning of disease. After some time (as a rule, it is enough quickly, during a few weeks, sometimes even days) a hard food does not pass (it is to wash down by water or other liquid). This period can be during 1–3 months. Patients address a doctor exactly in this period. Other symptoms appear to this time: regurgitation, pain behind a breastbone, loss of mass of body, sometimes even exhaustion, the grey colouring of person, a skin is dry, quickly grows general weakness. Sometimes patients address a doctor, when already with large effort a spoon-meat passes only or complete stenosis came.

At localization of tumour in the antral part of stomach the first complaints, as a rule, are up to appearance of feeling of weight in epigastric region after the reception of food (even in a two-bit), “feeling of saturation” (after the reception of glass of water), belch (at first it is simple by air, and then with a smell). Feeling of weight grows for a day, patients forced to cause vomiting. In the morning there can be vomiting by mucus with the admixtures of “coffee-grounds” (so called “cancer” water). Patients loses weight (mass of body is lost), a weakness, anaemia grows.

Tumours localized in the body of stomach show up either a pain syndrome or syndrome of so called “small signs” (A.I. Savitskyy, 1947), which is characterized by appearance of amotivational general weakness, decline of capacity, rapid fatigueability, depression (by the loss of interest to the environment), proof decline of appetite, gastric discomfort, making progress weight lost.

The carried chronic diseases of stomach, for which typical seasonality, can influence on the clinical sign of cancer of stomach. At appearance of “gastric” complaints out of season or in absent of effect from the got therapy concerning the exacerbation of “gastritis”, “ulcers” must guard a patient and doctor (symptom of “precipice” of gastric

anamnesis).

In case of occurring of “gastric” symptoms first in persons in age 50 years and older it is foremost necessary to eliminate the cancer of stomach.

In parts of patients cancer of stomach shows up only the metastatic damage of other organs or complications. More than twenty so called “atypical” forms, which are characterized by “causeless” anaemia, ascites, icterus, fever, edemata, hormonal disturbances, changes of carbohydrate exchange, intestinal symptoms, are distinguished.

During the examination of patients with the cancer of stomach the pallor of skin covers (at anaemia) is observed, in neglected case is “frog” stomach (sign of ascites).

During palpation determined painful in a epigastric area, sometimes possible to palpate the tumour.

During auscultation of patients with pylorostenosis it is possible to define “noise of splash”.

Laboratory information: hypochromic anaemia, neutrophilic leukocytosis, megascopic ESR; during examination of gastric secretion: hypo- and anacidity and achlorhydria.

Gastroduodenoscopy enables to diagnose a tumour even smaller 5 mm and conduct an aiming biopsy with histological examination of the taken material.

Roentgenoscopy and roentgenography examination of stomach. Basic signs: defect of filling, local absence of peristalsis, “malignant” relief of mucous tunic (Pic. 3.2.18).

Ultrasonic examination: presence of metastases in a liver, pancreas.

Computer tomography allows to estimate the basic parameters of tumour, germination in neighbouring organs and presence of metastases.

It is expedient to apply laparoscopy, mainly, for the decision of question about operable of tumour (diagnostics of metastatic defeat of organs of abdominal cavity).

Diagnosis program

1. Anamnesis and physical methods of examination.

2. Roentgenologic examination of stomach.
3. Endoscopic examination with a biopsy (if necessary from a few places and even repeatedly), cytologic and histological examination.
4. Sonography, computer tomography.
5. Laboratory, radioisotope methods of examination.
6. Laparoscopy.
7. Diagnostic (therapeutic) laparotomy.

Differential diagnostics

At an early cancer complaints depend on the previous gastric diseases. Therefore, on the basis of clinical information, suspecting a tumour is possible only on occasion, when in patients next to clear pain symptoms an appetite goes down, appear anaemia, general weakness. In practice an early cancer is recognized at purposeful screening, and also in the process of endoscopic or roentgenologic examination of gastric patients.

A differential diagnosis is conducted with an peptic ulcer, gastritis, polyposis, other gastric and ungastric diseases. For a cancer there is typical firmness of symptoms, instead of their seasonality (typical syndrome of “precipice” of gastric anamnesis) or tendency to their gradual progress.

The row of diseases, with which the cancer of stomach is to differentiate to the doctor, depends from character of complaints of patients.

Five basic clinical syndromes are selected:

- 1) pain;
- 2) gastric discomfort;
- 3) anaemic;
- 4) dysphagic;
- 5) disturbance of evacuation from a stomach.

At patients, at what cancer of stomach shows up a pain syndrome and syndrome of gastric discomfort, a differential diagnosis is conducted with the peptic ulcer, gastritis,

cancer of body of pancreas.

It is oriented on features dynamics of development of pain syndrome, ingravescence of the general condition, change of character of complaints.

A question about character of anaemia, source and nature of bleeding decides at an anaemic syndrome. In the process of examination attention is paid to the state of bottom of stomach, where bleeding malignant formations can be.

At a dysphagic syndrome a differential diagnosis is conducted with the cicatricial narrowing, achalasia of esophagus. For malignant formations testify short anamnesis, gradual progress of symptoms, signs of gastric discomfort, general weakness, weight lost.

At disturbance of evacuation from a stomach during stenosis of pyloric part, absence of ulcerous anamnesis, declining years of patients, relatively quick (weeks, months) growth of stenosis testify for tumor.

Tactic and choice of method of surgical treatment

The presence of cancer of stomach is a indications for surgical treatment. However, counting on success is possible only at presence of the limited tumours (within the limits of the 0–II stages). At the III stage of disease implementation of the widespread combined operations in a radical volume is possible, however most patients die during 1–2 years. A distal or proximal subtotal resection (Pic. 3.2.19) and total gastrectomy (Pic. 3.2.20) is performed with removing of large and small omentumes and regional areas of metastasis with obligatory histological examination of stomach on the lines of resections.

During the combined operations organs which are pulled in to the pathological process are removed.

In case of IV stage of disease and satisfactory state of patient palliative operations which improve quality of life of patient are performed.

In case of presence of complications (mainly stenosis) and grave common condition of patient perform symptomatic operative treatments.

Symptomatic is operations which will liquidate one of symptoms of cancer of stomach. In this group of operations include: 1) roundabout gastrojejunoanastomosis

(Pic. 3.2.21) and jejunostoma (in case of the stenosis tumours of stomach output); 2) gastrostoma (Pic. 3.2.22) in case of the cancer of cardial part of stomach with disturbance of patency; 3) edging of bleedingx vessels in case of complication of cancer by bleeding; 4) tamponade by omentum during the perforation of tumour.

The value of radial therapy and chemotherapy, as independent methods of treatment of cancer of stomach, is limited. Radial therapy is indicated for patients with cardial cancer as preoperative course or as palliative treatment. Adjuvant mono- or polychemotherapy (mainly by 5-phtoruracil) is conducted in a postoperative period as combined therapy and in case of dissemination of the tumours.

Prognosis. The indexes of five-year survival of patients with the cancer of stomach hesitate within the limits of 5–30 %, but, from data of most authors, they do not exceed 10 %.

METHODICAL INSTRUCTIONS FOR 4th YEAR STUDENTSMETHODOLOGICAL INSTRUCTION TO LESSON №4
" ULCERATIVE DISEASE OF THE STOMACH (UDS) AND THE DUODENUM (UDD), COMPLICATED ULCER"

The aim. To master clinics, diagnostics, differential diagnostics of various clinical forms of UDS and UDD. To learn the treatment tactics, indications and contraindications for operative intervention, operative intervention type at various clinical forms of UDS and UDD, principles of postoperative period course, expertise of the working ability after operations for UDS and UDD.

Professional orientation of students. UDS and UDD is one of the most frequent surgical illnesses of organs of gastric-intestinal tract. Morbidity reaches the level of 10-15%. Major complications of UDS and UDD are perforation, bleeding, ulcerative stenosis, malignization. They are vitally dangerous and require urgent or pressing surgical interventions. Postoperative lethality after urgent operations because of UDS and UDD complications sometimes reaches 15-20%.

Methodology of Practical Class 9.00-12.00.**Algorithm of communicative skills:**

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened

Student's independent work program:**Theme №1. Modern principles of diagnostics of surgical treatment of the ulcerative disease of stomach and duodenum.**

1. Anatomic and physiologic features of the stomach and the duodenum.
2. Factors of the ulcerative disease development.
3. Pathogenesis of the ulcerative disease of the stomach and the duodenum.
4. Classification of ulcerative disease of the stomach and the duodenum.
5. Diagnosis methods of the ulcerative disease of the stomach and the duodenum.
6. Curing tactics at the ulcerative disease.
7. Modern principles of conservative and surgical treatment of UDS and UDD.
8. Choice of the operative treatment method at UDS and UDD.
9. Types of radical (organ-sparing and organ-preserving) and palliative operations for the reason of UDS and UDD.
10. Peculiarities of the postoperative period course after the operations for UDS and UDD reason.
11. Evaluation of treatment results of patients with UDS and UDD.
11. Disablement expertise after the operations for UDS and UDD reason.

Theme №2. Perforative and bleeding ulcer of stomach and duodenum.

1. Risk factors of the perforative ulcer of stomach and duodenum.
2. Pathogenesis of the perforative ulcer.
3. Classification of perforative gastroduodenal ulcers.
4. Phases of clinical course of the perforative ulcer.
5. Objective signs of the perforative gastroduodenal ulcer.
6. Differential diagnosis of the perforative ulcer with the acute appendicitis, acute pancreatitis, acute cholecystitis, acute ileus, renal colic, basal pleuropneumonia, myocardial infarction.
7. Peculiarities of the untypical and covered perforation of the gastroduodenal ulcer.
8. Roentgenic signs of perforation.
9. Laparocentesis, laparoscopy and endoscopy in the diagnostics of the perforative ulcer.
10. Curing tactics at the perforative ulcer.
11. Taylor's method in the perforative ulcer treatment
12. Indications and methods of radical and palliative operations for the reason of the perforative ulcer.
13. Peculiarities of the preoperative preparation and postoperative period course at the operative treatment of the perforating ulcer.
14. Risk factors of bleeding from the ulcer.
15. Pathogenesis of the acute gastric-intestinal bleeding.
16. Classification of gastric-intestinal bleedings.
17. Main and additional symptoms of bleeding ulcer.
18. Phases of clinical course of the bleeding ulcer.
19. Differential diagnosis of the bleeding ulcer with pulmonary bleeding, atherosclerotic, medicamentation bleedings, bleedings at blood diseases, portal hypertension, stomach tumours, Mallory-Weiss syndrome, erosive gastritis, hernias of the esophageal diaphragm foramen.
20. Subsidiary methods of the bleeding ulcer diagnosis.
21. Curing tactics at bleeding gastroduodenal ulcer.
22. Indications to conservative treatment of bleeding ulcer.
23. Principles of the conservative treatment of bleeding ulcer.
24. Indications for the operative treatment of bleeding ulcer.
25. Types of radical operations.
26. Types of palliative operations.
27. Peculiarities of the postoperative period course after the operations for bleeding ulcers.

Theme №3. Stenosing ulcer. Malignization and penetration/

1. Classification of cicatricial ulcerative stenosis of stomach outlet.
2. Clinical signs of the ulcerative stenosis depending on its stage.
3. Differential diagnosis of the cicatricial ulcerative stenosis with acute ileus, hernia of the esophageal opening of the diaphragm, achalasia of esophagus, duodenostasis (chronic duodenal obstruction), cicatricial postburn stenosis, stomach foreign body, stomach cancer.
4. Peculiarities of water-electrolytic exchange at ulcerative stenosis.
5. Verification methods of diagnosis of ulcerative stenosis of stomach and duodenum.
6. Curing tactics at stenosis of stomach outlet. Conservative and surgical treatment.
7. Peculiarities of the preoperative preparation of patients with the ulcerative stenosis of stomach outlet.
8. Methods of operative treatment of the ulcerative stenosis of stomach outlet.
9. Peculiarities of the postoperative period course.
10. Disablement expertise after the operations for ulcerative stenosis of stomach outlet.
11. Conception definition. Classification of penetration.
12. General clinical characteristics of penetrating ulcer.
13. Clinical characteristics of typical versions of stomach and duodenum penetration.
14. Clinical characteristics of untypical versions of stomach and duodenum penetration.
15. Differential diagnosis of penetrating ulcer.
16. Verification methods of penetration diagnosis.

17. Choice of curing tactics at penetrating ulcer of stomach and duodenum.
18. Peculiarities of operative treatment of patients with penetrating ulcer of stomach and duodenum.
19. Conception definition of ulcer-cancer, cancer from ulcer.
20. Malignization frequency depending on the ulcer allocation.
21. General clinical signs of ulcer malignization.
22. Verification methods of diagnosis of malignant gastric ulcer.
23. Curing tactics and peculiarities of operative treatment of patients with malignant gastric ulcer.

BREAK 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.

Basic level of knowledge and skills:

The student must know:

1. Anatomic and physiologic features of stomach and duodenum.
2. Modern theories of appearance and pathogenesis stages of UDS and UDD.
3. Definition and classification of various clinical forms of UDS and UDD.
4. Modern examination methods of secretory and motor-evacuative functions of stomach and duodenum.
5. Verification methods of UDS and UDD diagnosis.
6. Clinics, diagnostics, differential diagnostics and curing tactics choice at uncomplicated and complicated UDS and UDD.
7. Modern principles of complex conservative treatment of patients with UDS and UDD.
8. Modern methods of operative treatment of UDS and UDD.
9. Clinics, diagnostics, differential diagnostics, choice of curing tactics and methods of operative treatment at perforative ulcer of stomach and duodenum.
10. Clinics, diagnostics, differential diagnostics, choice of curing tactics and methods of operative treatment at bleeding ulcer of stomach and duodenum.
11. Peculiarities of postoperative period course after operations for UDS and UDD.

The student has to be able to:

1. To take the history of the patient with the suspect for UDS and UDD.
2. To reveal main clinical features and symptoms at various clinical forms of UDS and UDD.
3. To define free gas in the abdominal cavity.
4. To define the presence of free liquid in the abdominal cavity.
5. To argue and formulate the preliminary diagnosis.
6. To make a plan of the examination of the patient and explain the examination results (general blood test, examination of gastric secretion, plain roentgenogram of abdominal organs, roentgenoscopy and roentgenography of stomach and duodenum).
7. To define indications and contraindications for operative intervention, to choose properly the preoperative preparation, anesthesia type, operative access and type of intervention according to the clinical form of UDS and UDD.

TEST EVALUATION AND SITUATIONAL TASKS 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions.
(the instructor has tests & situational tasks)

1. First-line therapy for routine peptic duodenal ulcer disease includes:
 - A. Vagotomy and antrectomy.
 - B. Upper endoscopy and biopsy to rule out tumor.
 - C. Evaluation for *Helicobacter pylori*.
 - D. Serum gastrin determination.
 - E. Cream or milk-based "Sippy" diet.
2. All of the following are complications of peptic ulcer surgery except:
 - A. Duodenal stump blowout.
 - B. Dumping.
 - C. Diarrhea.
 - D. Delayed gastric emptying.
 - E. Steatorrhea.
3. The presentation of Zollinger-Ellison syndrome includes all of the following except:
 - A. Hyperparathyroidism in patients with multiple endocrine neoplasia type 1 (MEN 1) syndrome.
 - B. Diarrhea.
 - C. Migratory rash.
 - D. Jejunal ulcers.
 - E. Duodenal ulcers.
4. In patients with bleeding duodenal ulcers, the endoscopic finding associated with the highest incidence of rebleeding is:
 - A. Visible vessel.
 - B. Cherry-red spot.
 - C. Clean ulcer bed.
 - D. Duodenitis.
 - E. Shallow, 3-mm. ulcer.
5. All of the following are contraindications for highly selective vagotomy except:
 - A. Intractable duodenal ulcer disease.
 - B. Peptic ulcer disease causing gastric outlet obstruction.
 - C. Fundic peptic ulceration.
 - D. Cigarette chain smoking.
 - E. Perforated peptic ulcer disease with more than 24 hours' soilage.
6. Appropriate management of severe vomiting associated with gastric outlet obstruction from peptic ulcer disease includes all of the following except:
 - A. Nasogastric suction.
 - B. Intravenous hydration.
 - C. Nutritional assessment; upper endoscopy to rule out malignancy.
 - D. Intravenous H₂ antagonist.
 - E. Oral antacid therapy.+

7. Which of the following statements about gastric polyps is/are true?
- Like their colonic counterparts, gastric epithelial polyps are common tumors.
 - They are analogous to colorectal polyps in natural history.
 - Endoscopy can uniformly predict the histology of a polyp based on location and appearance.
 - In a given patient, multiple polyps are generally of a single histologic type.+
 - Gastric adenomatous polyps greater than 2 cm. in diameter should be excised because of the risk of malignant transformation.
8. All of the following are contraindications for highly selective vagotomy except:
- Intractable duodenal ulcer disease.+
 - Peptic ulcer disease causing gastric outlet obstruction.
 - Fundic peptic ulceration.
 - Cigarette chain smoking.
 - Perforated peptic ulcer disease with more than 24 hours' soilage.
9. Numerous epidemiologic associations have been made between (1) environmental and dietary factors and (2) the incidence of gastric cancer, including all except:
- Dietary nitrites.
 - Dietary salt.
 - Helicobacter pylori infection.
 - Dietary ascorbic acid.+
10. All of the following benign conditions are associated with increased rates of gastric cancer except:
- Pernicious anemia.
 - Multiple endocrine neoplasia type I (MEN 1).+
 - Adenomatous polyps.
 - Chronic atrophic gastritis.

The answers for the self-checking tests.

- 1 – C.
- 2 – E.
- 3 – C.
- 4 – B.
- 5 – A.
- 6 – E.
- 7 – D.
- 8 – A.
- 9 – D.
- 10 – B.

POSTRESECTION AND POSTVAGOTOMY SYNDROMES. CLASSIFICATION. CLINICS. DIAGNOSTICS. CONSERVATIVE AND SURGICAL TREATMENT. PROPHYLAXIS.

DUMPING SYNDROME

Etiology and pathogenesis

Dumping syndrome is frequent complication of operations which are related to deleting or disturbance of function of goalkeeper (resection of stomach, vagotomy with antrectomy, vagotomy with drainage operations). It takes place in 10–30 % patients.

The rapid receipt (dumping) is considered the starting mechanism of dumping syndrome. During this concentrated, mainly carbohydrate, food passed from a stomach in an empty bowel.

In the phase changes of motility of thin bowel during dumping syndrome important part is acted by the hormones of thin bowel. In endocrine cells of APUD-системи on during dumping-syndrome observed degranulation and presence of hormones of mothiline, neurotensin and enteroglucagon.

The inadequate mechanical, chemical and osmotic irritation of mucous tunic of thin bowel by chymus results for the acute increase of blood flow in a bowel. The last is accompanied by the considerable redistribution of blood, especially in heavy case of dumping syndrome : blood supply of head, lower extremities is diminishes, a blood flow in a liver is multiplied.

The numeral examinations resulted in creation of osmotic theory –the principal reason of dumping syndrome is the decline of volume of circulatory plasma as a result of coming a plenty of liquid into the lumen of thin bowel from an of circulatory system and intercellular space.

Clinical management

For the clinical finding of dumping syndrome typical there is the origin of attacks of general weakness during acceptance of food or during the first 15–20 minutes after it. The attack begins from feeling of plenitude in a epigastric area and is accompanied by the unpleasant feeling of heat, that “spills” in the overhead half of trunk or on all body. Thus is acutely multiplied sweating. Then there is a fatigue, appear somnolence, dizziness, noise in ears, shaking of extremities and worsening of sight. These signs sometimes achieve such intensity, that patients forced to lie down. Loss of consciousness could be in the first months after operation. The attacks are accompanied by tachycardia, sometimes by the shortness of breath, headache, paresthesia of upper and lower extremities, polyuria and vasomotor rhinitis. At the end of attack or after it patients often notice grumbling in a stomach and diarrhea.

A milk or carbohydrate food is the most frequent provoking factor of dumping

syndrome. In a period between the attacks patients complain about rapid fatigueability, weakening of memory, decline of working capacity, change of mood, irritates, apathy. During roentgenologic examination after 5–15 minutes observed the increased evacuation of barium mixture through anastomosis by a wide continuous stream, expansion of efferent loop and rapid advancement of contrasting matter in the distal parts of thin bowel (Pic. 3.2.16).

By the expression of symptoms dumping syndrome is divided into three degrees of weight:

I degree is easy. Patients have the periodic attacks of weakness with dizziness, nausea, that appear after the use of carbohydrates and milk food and last no more than 15–20 min. During the attack a pulse becomes more frequent on 10–15 per min., arterial pressure rises or sometimes goes down on 1.3-2 KPa (10–15 mm Hg), the volume of circulatory blood diminishes on 200–300 ml. The deficit of mass of body of patient does not exceed 5 kg. A working capacity is well-kept. Medicinal and dietary treatment gives a good effect.

II degree — middle weight. Attacks of weakness with dizziness, pain in the region of heart, hyperhidrosis, diarrhea. Such signs last, usually, 20–40 min., arise up after the use of ordinary portions of some food. During such state a pulse becomes more frequent on 20–30 per min., arterial pressure is rises (sometimes goes down) on 2–2,7 KPa (15–20 mm Hg), the volume of circulatory blood diminishes on 300–500 ml. The deficit of mass of body of patient achieves 5–10 kg. A working capacity is reduced. Conservative treatment sometimes has a positive effect, but brief.

The III degree is hard. Patients are disturbed by the permanent, acutely expressed attacks with the collaptoid state, by a fainting fit, by diarrhea, which do not depend on character and amount of the accepted food and last about 1 hour. During the attack is multiplied frequency of pulse on 20–30 per 1 min; arterial pressure goes down on 2,7–4 KPa (20–30 mm Hg), the volume of circulatory blood diminishes more than on 500 ml. The deficit of mass of body exceeds 10 kg. Patients, as a rule, are disabled. Conservative treatment is ineffective.

Pic. 1. Dumping syndrome (quick evacuation of the contrast)

Tactic and choice of treatment method

The problem of treatment of patients with dumping syndrome is not easy. Before the surgical treatment, as a rule, must precede conservative. Patients with the disease of easy and middle degrees respond to conservative treatment, mainly with an enough quite good effect. At the heavy degree of disease such treatment more frequent serves as only preparation to operative treatment. If a patient does not give a consent for operation or at presence of contra-indications to operative treatment (disease of heart, livers, kidneys), conservative therapy is also applied. Such treatment must include dietotherapy, blood and plasma transfusion, correction of metabolism, hormonal preparations, symptomatic therapy, electro-stimulation of motility function of digestive tract.

The dietotherapy: using of high-calorie, various food rich in squirrel, by vitamins, by mineral salts, with normal content of fats and exception from the ration of carbohydrates which are easily assimilation (limitation of sugar, sweet drinks, honey, jam, pastry wares, kissel and

fruit compotes). All it is needed to use by small portions (5–6 times per days). If the signs of dumping syndrome appear after a food, such patients it is needed to lie down and be in horizontal position not less than 1 hour. At the heavy degree of dumping syndrome patients need to eat slowly, desirably lying on left. Such position creates the best terms for evacuation of food from a stomach. Thus recommend also to repudiate from too hot and cold foods.

Medicinal treatment must include sedative, replaceable, antiserotonin, hormonal and vitamin therapy. The indications to operative treatment of patients with dumping syndrome are: heavy passing of disease, combination of dumping syndrome of middle degree with other postgastrectomy syndromes (with the syndrome of efferent loop, hypoglycemic syndrome and progressive exhaustion) and uneffective of conservative treatment of the dumping syndrome of middle degree. Most methods of operative treatment of dumping syndrome are directed on renewal of natural way of passing of food on a stomach and intestine, improvement of reservoir function of stomach and providing of proportioning receipt of food in a thin bowel.

Depending on reasons and mechanisms of development of dumping syndrome there are different methods of the repeated reconstructive operations. All of them can be divided into four basic groups: I. Operations which slow evacuation from stump of stomach. II. Redoudenization. III. Redoudenization with deceleration of evacuation from stump of stomach. IV. Operations on a thin bowel and its nerves.

Basic stages of reconstructive operations: 1) disconnection of adhesions in an abdominal cavity, releasing of gastrointestinal and interintestinal anastomosis and stump of duodenum; 2) cutting or resection of efferent and afferent loops; 3) renewal of continuity of upper part of digestive tract.

For correction of the accompany postgastrectomy pathology it is better to apply combined anti- (iso-) peristaltic gastrojejunoplasty. Thus transplant by length 20–22 cm, located between a stomach and duodenum, must consist of two parts: antiperistaltic (7–8 cm), connected with a stomach, and isoperistaltic, connected with a duodenum. An antiperistaltic segment brakes dumping of stomach stump, and isoperistaltic — hinders the reflux of duodenum content.

HYPOGLYCEMIC SYNDROME

The attacks of weakness at a hypoglycemic syndrome arise up as a result of decline of content of sugar in a blood. It is accompanied by a acute muscular weakness, by headache, by falling of arterial pressure, by feeling of hunger and even by the loss of consciousness.

STAGES OF THE HYPOGLYCEVIC SYNDROME

I stage	Signs beghins after 2-2,5 h after food intake, 2-3 times per week. Patients does not feel it.
---------	---

II stage	Signs begins 2-3 times per week.
III stage	Signs begins every day. Patients always has sweet food and bread.

It is needed to remember, that at this pathology, unlike dumping-syndrome, acceptance of food especially sweet facilitates the state of patient. However in some patients both syndromes unite and the attacks of weakness can arise up as directly after food intake, so in a few hours after it. In patients with such pathology the best results are got after antiperistaltic gastrojejunoplasty (Fink, 1976).

POSTGASTRECTOMY (AGASTRIC) ASTHENIA

Etiology and pathogenesis

The postgastrectomy (agastric) asthenia arises up as a result of disturbance of digestive function of stomach, pancreas, liver and thin bowel.

In patients with such pathology stump of stomach almost fully loses ability to digest a food. It is related to the small capacity of stump and rapid evacuation of food from it, and also with the acute decline of production of hydrochloric acid and pepsin. In the mucous tunics of stump of stomach, duodenum and thin bowels as a result of fall of trophic role of gastrin and other hormones of digestive tract there are the progressive atrophy changes. Absence in gastric juice of free hydrochloric acid is the reason of acute diminishment of digestive ability of gastric juice and decline of it bactericidal. Such situation is assist in advancement to ascending direction of virulent flora, to development duodenitis, hepatitis, cholecystitis, dysbacteriosis, hypovitaminosis and decline of antitoxic function of liver. All it results in acute disturbance of evacuation from a stomach.

Clinical management

The clinical signs of postgastrectomy asthenia arise up after a some latent period which can last from a few months to some years. During this period patients often complain for a general weakness and bad appetite. The basic symptoms of postgastrectomy asthenia are: general weakness, edemata, acute weight loss, diarrhea, skin and endocrine abnormalities. The postgastrectomy asthenia more frequent meets at men at 40–50 years. In most cases diarrhea is the first symptom of disease, that can arise up in 2 months after operation. Diarrhea, usually, has permanent character and sometimes becomes profuse.

Weight loss appears too early, the deficit of mass of body achieves 20–30 kg. A patient quickly loses forces.

Tactic and choice of treatment method

Conservative treatment is the blood, plasma and albumen transfusions. These preparations are prescribed 2–3 times per a week. Correction of disturbances of electrolyte exchange is conducted at the same time (transfusion of solutions to potassium, calcium and others like that). For the improvement of processes of albumen synthesis anabolic hormones are prescribed.

Operative treatment foresees the inclusion in the digestion process of duodenum, increase of capacity of stump of stomach and deceleration of evacuation of its content.

SYNDROME OF AFFERENT LOOP

Etiology and pathogenesis

The afferent loop consists of part of duodenum, that stopped behind after a resection, area of empty bowel between a duodenojejunal fold and stump of stomach. The syndrome of afferent loop can arise up after the resection of stomach after the Bilrthoht-II method. Violation of evacuation from a afferent loop and vomiting by a bile are its basic signs.

Acute and chronic obstruction of afferent loop are distinguished. The reason of acute obstruction is mechanical factors: postoperative commissure, volvulus, internal hernia, invagination, jamming behind mesentery of loop of bowel and stenosis of anastomosis.

Frequency of origin of sharp obstruction of afferent loop hesitates within the limits of 0,5–2 %. The disease can arise up in any time after operation: in a few days or a few years.

Chronic obstruction of afferent loop (actually syndrome of afferent loop), as well as acute, can arise up in any time after operation, however more often it develop after the resection of stomach with gastroenteroanastomosis on a long loop, especially when operation is performed without entero-enteroanastomosis by Brown.

The etiologic factors of syndrome of afferent loop are divided into two groups: 1) mechanical (postoperative commissure, invagination, disturbance of evacuation on a afferent loop, wrong location of afferent loop, very long afferent loop, fall of mucous tunic of afferent loop into a stomach); 2) functional (hypertensive dyskinesia of bilious ways and duodenum, damage and irritation of trunks of vagus nerves, hypotensive and spastic states of upper part of digestive tract, heightened secretion of bile and juice of pancreas under act of secretin and cholecystokinin).

Clinical management

For the clinical picture of acute obstruction typical is permanent, with a tendency to strengthening, pain in a epigastric area or in right hypochondrium, nausea and vomiting. At complete obstruction a bile in vomiting masses is absent. The general condition of patient progressively gets worse, the temperature of body rises, leukocytosis grows, tachycardia grows.

At the objective examination painful and tension of muscles of abdominal wall is observed. In a epigastric area it is often possible to palpate tumular lump. Possible cases, when the increase of pressure in a bowel is passed on bilious ways and channels of pancreas. There can be pain and icterus in such patients. There are necrosis and perforation of duodenum with development of peritonitis during further progress of process. Acute obstruction of afferent loop in an early postoperative period can be the reason of insufficiency of stump of duodenum also.

During the roentgenologic examination of organs of abdominal cavity it is visible round form area of darkening and extended, filled by gas, bowels loop.

Patients, usually, complain for feeling of weight in a epigastric area and arching in right hypochondrium, that arises in 10–15 min. after acceptance of food and gradually grows. Together with that, appear nausea, bitter taste in a mouth, heartburn. Then there is increasing pain in a right to epigastric area. During this pain arises intensive, sometimes repeated vomiting by a bile, after which the all symptoms disappear. It could be after certain kind of food (milk, fats) or its big amount. Very rarely vomiting by bile unconnected with the feed. In heavy case patients lose up to 1 liter of bile with vomiting masses. During the objective examination observed subicteritiousness of the sclera, sign of dehydration of organism (decline of turgor of skin, dry tongue, oliguria, concentrated urine). Emptying is irregular, grey color, with considerable content of undigested fat and muscular fibres. Anaemia can develop at heavy passing of disease.

Distinguished easy, middle and heavy degrees of afferent loop syndrome. In patients with the easy degree of disease vomiting is 1–2 times per a month, and insignificant regurgitation arise up through 20 min – 2 hour after a food, more frequent after the use of milk or sweet food. At middle degree of afferent loop syndrome such attacks repeat 2–3 times per week, patients are disturbed by the considerably expressed pain syndrome, and with vomiting up to 200–300 ml of bile is lost. For a heavy degree the daily attacks of pain are typical, that is accompanied by vomiting by a bile (up to 500 ml and more).

DEGREES OF AFFERENT LOOP SYNDROME

easy	vomiting is 1–2 times per a month, and insignificant regurgitation arise up through 20 min – 2 hour after a food, more frequent after the use of milk or sweet food.
middle	attacks repeat 2–3 times per week, patients are disturbed by the considerably expressed pain syndrome, and with vomiting up to 200–300 ml of bile is lost.
heavy	the daily attacks of pain are typical, that is accompanied by vomiting by a bile (up to 500 ml and more).

A roentgenologic examination of the patients with the afferent loop syndrome is unspecific. Neither the passing of contrasting matter nor absence of filling of afferent loop can

be considered as pathognomic signs of syndrome of afferent loop.

Tactic and choice of treatment method

Treatment of acute obstruction of afferent loop is mainly operative. Essence of it is the removal of barriers of evacuation of content from an afferent loop. Adhesions are dissected, volvulus is straightened, invagination or internal hernia is liquidated. For the improvement of evacuation between afferent and efferent loops performs the entero-enteroanastomosis type “end-to-end” or after the Roux method.

Conservative treatment of syndrome of afferent loop is ineffective and, mainly, is mean the removal of hypoproteinemia and anaemia, spasmolytic preparations and vitamin are appointed. With this purpose a blood, plasma and glucose is poured with insulin, a novocaine lumbar blockade and blockade of neck-pectoral knot, washing of stomach is also done.

Рис. 2. Resection by Roux

All *operative methods* of treatment of afferent loop syndrome can be divided into three groups:

- I. Operations, that will liquidate the bends of afferent loop or shorten it.
- II. Drainage operations.
- III. Reconstructive operations. [video](#)

The operations of the first group, directed on the removal of bends and invagination of afferent loop, can not be considered as radical. They need to be performed only at the grave general condition of patient.

The widest application in clinical practice at the syndrome of afferent loop has the

operation offered by Roux.

For the prophylaxis of afferent loop syndrome it is necessary to watch after correct imposition of anastomosis during the resection of stomach: to use for the gastroenteroanastomosis short loop of thin bowel (6–8 cm from the Treits ligament) for imposition, to sew afferent loop to small curvature for creation of spur, to fix reliably stump of stomach in peritoneum of transverse colon.

REFLUX-ESOPHAGITIS

Etiology and pathogenesis

The origin of reflux after the distal resection of stomach is conditioned by some factors:

I. Traumatic factors: 1) traction of stomach during operation as reason of sprain of ligament of proximal part of stomach and mobilization of large curvature of stomach; 2) cutting of vessels of stomach and oblique muscles of it wall, in particular on small curvature; 3) vagotomy, that is accompanied by cutting of phrenico-esophageal and gastrophrenic ligaments; 4) imposition of gastrointestinal anastomosis, especially direct gastroduodenoanastomosis by Billroth-I, that results in smoothing of the Hisa corner; 5) frequent aspiration of gastric content in a postoperative period, that causes superficial esophagitis.

II. Trophic factors: 1) damage of vessels which are the reason of ischemia in the area of esophago-gastric connection, and thrombophlebitis of cardial part of stomach; 2) disturbance of influencing of neurohumoral factors which take part in innervations of esophagus; 3) disturbance of trophism of diaphragm as a result of hypoproteinemia and weight loss; 4) ulcerous diathesis and megascopic volume of gastric secretion (especially nightly); 5) regurgitation of alkaline content of duodenum in stump of stomach which reduces tone of it muscular shell.

III. Mechanical factors: 1) gastric stasis; 2) diminishment of volume of gastric reservoir, that is accompanied by the increase of intragastric pressure.

Clinical management

The clinical picture of gastroesophageal reflux is conditioned by the mechanical and chemical irritations of esophagus by content of stomach or thin bowel. As a result, there is esophagitis, which can be catarrhal, erosive or ulcerous-necrotic. The symptoms of reflux are very various and can simulate different diseases of both pectoral and abdominal cavity organs.

The basic complaint of patients with this pathology is a smart behind a breastbone, especially in the area of the its lower part. It, usually, spreads upwards and can be accompanied by considerable salivation. Strengthening of pain at inclinations of trunk gave to the French authors an occasion to name this sign the “symptom of laces”. Unendurable heartburn is the second complaint, that arises up approximately in 1–2 hours after the food intake. Patients forced often to drink, somehow to decrease the unpleasant feelings, however this, certainly, does not bring them facilitation. Some of them, in addition, complain for bitter taste in a

mouth.

Pain behind a breastbone often can remind the attack of stenocardia with typical irradiation. Sometimes such reflux is able to provoke real stenocardia.

Hypochromic anaemia is the frequent symptom of gastroesophageal reflux too.

The diagnosis of gastroesophageal reflux, mainly, is based on clinical information, results of roentgenologic examination, esophagoscopy.

The edema, hyperemia of mucous tunic of esophagus, easy bleeding and vulnerability it during examination, surplus of mucus and erosions covered by fibrin tape *is* considered *the endoscopic signs* of esophagitis. In doubtful case at the insignificantly expressed macroscopic changes the biopsy of mucous tunic helps to set a diagnosis.

Tactic and choice of treatment method

Treatment of patients with gastroesophageal reflux is mainly *conservative*. Very important is diet, which avoid spicy, rough and hot food. Eating is needed often, by small portions. It is impossible also to lie down after the food intake, because the gastric content can flow in a esophagus. A supper must be not later than for 3–4 hours before sleep. Between the reception of food does not recommend to use a liquid. Next to that, it is necessary to remove factors which promote intraperitoneal pressure (carrying to the bracer, belt, constipation, flatulence). Sleeping is needed in position with a lift head and trunk. From medicinal preparations it is useful to recommend enveloping preparation.

Operative treatment of gastroesophageal reflux, that arose up after the distal resection of stomach, it is needed to recommend to the patients with the protracted passing and uneffective of conservative treatment. During operation, mainly, performed renewal of the broken Hisa angle. In addition, performed esophagoplasty, fundoplication by Nessen's and esophagofrenofundoplication.

The prophylaxis of this complication consists in the study of the state of cardial part of stomach before and during every resection and fixing of bottom of stomach to the diaphragm and abdominal part of esophagus during leveling the Hisa angle.

ALKALINE REFLUX-GASTRITIS

Etiology and pathogenesis

Alkaline reflux-gastritis meets in 5–35 % operated patients after the resection of stomach, antrectomy, gastroenterostomy, vagotomy with pyloroplasty, and also cholecystectomy and papillosphincteroplasty.

The reason of this complication is influence of duodenum content for the mucous tunic of stomach (bilious acids, enzymes of pancreas and isolecithin). Last, forming from bile lecithin under act of phospholipase A, able to destroy the cells of superficial epithelium of mucous tunic of stomach by removing of lipid from their membranes. As a result the erosions and ulcers are formed in the patient organism. Bilious acids also has the expressed detergent's properties. As isolecithin and bilious acids, the very important bacterial flora which directly

and through toxins can cause the damage of mucous tunic of stomach stump. Also, alkaline environment and disturbance of evacuation from the operated stomach influence favourably on microflora growth.

Clinical management

For the clinical picture of alkaline reflux-gastritis the permanent poured out pain in a epigastric area, belch and vomiting by a bile are typical. At some patients heartburn and pain is observed behind a breastbone also. In majority patients so proof loss of weight takes place, that even the protracted complex therapy and valuable feed does not provide addition to the deficit of mass of body. There are typical signs also – anaemia, hypo- or achlorhydria.

Reliable diagnostics of alkaline reflux-gastritis became possible after wide introduction in clinical practice of endoscopic examination. In such patients during gastroscopy hyperemia of mucous tunic of stomach is observed. It is often possible to observe reflux in the stomach of duodenum content. During histological examination of biopsy material a chronic inflammatory process, intestinal metaplasia, diminishment of mass of coating cells and area of hemorrhages are found. All it testifies the deep degenerative changes in the mucous tunic of stomach. The some authors underlines that the inflammatory changes, at least in the area of anastomosis, are observed in most persons which carried the resection of stomach. So, endoscopic examination can not be considered deciding in diagnostics. Even the diffuse inflammatory changes can take place in absent of clinical symptoms and, opposite, in case with expressed clinical symptoms the minimum changes of mucous tunic of stomach are sometimes observed.

Tactic and choice of treatment method

Conservative treatment of reflux-gastritis (sparing diet, antacides, enveloping preparations), usually, is ineffective. Existent methods of surgical treatment, mainly, directed on the removal of reflux of duodenum content to the stomach. Most popular is operation by the Roux method. The some surgeons considers that distance from gastroenteroanastomosis to interintestinal anastomosis must be 45–50 cm.

PEPTIC ULCER OF THE ANASTOMOSIS

Etiology and pathogenesis

Main reason of origin of peptic ulcer of anastomosis is leaving of the hyperacid state of stomach mucous, even after the performed operation. Such phenomenon can be consequence of many reasons: primary economy resection, wrong executed resection (when the mucous tunic of pyloric part is abandoned in stump of duodenum or stomach), heightened tone of vagus nerves and the Zollinger-Ellison syndrome.

Clinical management

Peptic ulcers, usually, arise up after operation during the first year. Typical signs are pain, vomiting, weight loss, bleeding, penetration and perforation.

Pain is the basic symptom of peptic ulcer. Often it has the same character and

localization, as well as at peptic ulcer. However often observe it moving to the left or in the umbilical area. At first patients bind such feelings to the use of food, but then specify nightly and hungry pain. It at first is halted after a food, but in course of time is become permanent, unendurable, independent from food intake. It can increase during the flounces, the walk, can irradiate in the back, thorax or shoulder.

During the *objective examination* of patients is often possible to expose on a stomach hyperpigmentation from a hot-water bottle. During palpation to the left from epigastric area near a umbilicus the painful and moderate muscles tension of abdominal wall is observed. Sometimes is possible to palpate inflammatory infiltrate of different sizes. During the examination of patients with a peptic ulcer the important role has determination of gastric secretion against a background of histamine and insulin stimulation. There is a necessity also examination of basal secretion. These preoperative examinations in most patients enable to set the reason of hypersecretion which can be: 1) heightened tone of vagus nerves (positive Hollander test); 2) economy resection of stomach, often in combination with the heightened tone of vagus nerve (considerable increase of gastric secretion after histamine or pentagastrin stimulation in combination with the positive Hollander test); 3) abandoned part of mucous tunic of antral part of stomach (high basal secretion and small increase of secretion in reply to histamine and insulin stimulator); 4) the Zollinger-Ellison syndrome.

Roentgenologic diagnostics of peptic ulcer, usually, is difficult, especially at shallow, flat ulcers, bad mobility and insufficient function of anastomosis. A niche is the direct sign of a similar pathology, indirect are the expressed inflammatory changes of mucous tunic of stump of stomach and bowel, painful point in the projection of stump of stomach and anastomosis and bad function of anastomosis. The deciding value in diagnostics has endoscopic examination.

Tactic and choice of treatment method

Conservative treatment of peptic ulcers, as a rule, is ineffective. So, operation must be the basic type of treatment. The choice of method of operative treatment depends on character of previous operation and from abdominal cavity pathology found during the revision. For today the most important parts of the repeated operations is vagotomy. There is obligatory also during the resection of stomach on the exception the revision of duodenum stump for liquidation of possibly abandoned mucous tunic of antral area.

Operative treatment at a peptic ulcer must consist of certain stages. Laparotomy and disconnection of adhesions through a considerable spike process (increasing of stomach, loops of intestine and liver to the postoperative scar) almost always causes large difficulties.

After the selection of anastomosis with afferent and efferent loops the last cut by the “UKL-60 appliance”, within the limits of healthy tissues with renewal of intestine continuity by “end-to-end” type anastomosis.

At patients with a peptic ulcer, that developed after gastroenterostomy, cut a duodenum and sutured its stump by one of the described methods. During it there can be the difficulties related to the presence in it active ulcer. When peptic ulcers do not cause rough deformation of stomach, apply degastroenterostomy, vagotomy and drainage operations.

In the case of the considerably expressed spike process it is possible to execute trunk subdiaphragmatic vagotomy, and in case of the insignificantly changed topography of this area — selective gastric vagotomy.

It is important to note, that stomach resected together with anastomosis, peptic ulcer and eliminated area of empty bowel by one block.

GASTRIC-COLON FISTULA

This pathology arises up as a result of perforated of peptic ulcer in a transverse colon with formation of connection between a stomach, small or large intestine.

Clinical management

Diagnostics of gastro-colon fistula at patients with expressed clinical signs of disease does not difficult. However, symptoms are often formed and is indicated up slowly, so such patients with different diagnoses long time treat oneself in the therapeutic or infectious parts.

The typical signs of this pathology is considered diminishment or disappearance of pain, that was before, and profuse, that does not respond to treatment, diarrhea. Patients has emptying up to 10–15 times per days and even more frequent. An excrement contains a plenty of undigested muscular fibres and fat acids (steatorrhea). In case of wide fistula an undigested food can be with an excrement.

Excrement smell from a mouth, usually, notice surrounding. The patients does not feel it. However appearance of excrement belch is indicate the hit into the stomach of excrement masses and gases, and could confirm this pathology.

The such patients very quickly lose weight (mass of body goes down on 50–60 %), their skin becomes pale with a grey tint. The protein-free edemata, ascites, hydrothorax, anasarca, signs of avitaminosis appear in non-treated case.

Through the severe losses of liquid and nonassimilable food there can be the increased appetite and unendurable thirst in such patients. However, they adopt a plenty of liquid and food but the state of them continues to get worse.

Headache, apathy and depression is observed, and at the objective examination is exhaustion (ochre colour of skin, dryness and decline of it turgor, edemata or slurred of swelling extremities, atrophy of muscles). A stomach often moderately pigmented from hot-water bottles, subinflated, with the visible peristalsis of intestine. During the changes of patient position it is possible to hear grumbling, splash and transfusion of liquid. The examination of blood can expose hypochromic anaemia.

Roentgenologic examination is a basic diagnostic method. There are three varieties of such examinations of gastro-colon fistula. During the examination with introduction of barium mixture through a mouth the hit of contrasting matter directly from a stomach into a colon is the typical roentgenologic symptom of such pathology. Irrigoscopy is more perfect and effective method. With suspicion on gastro-colon fistula it is better to perform irrigoscopy. Passing of contrasting matter to the stomach at this manipulation testifies the presence of fistula. The third

method is insufflation of air in a rectum. With it help on the screen it is possible to observe the location and passing of fistula, and also, as a result, hit of air in a stomach, increase of it gas bubble. Thus there can be the belch with an excrement smell.

The important role played the tests with dyes: at peroral introduction of methylene-blue after the some time it found in excrement masses or, opposite, after an enema with methylene-blue dye appears in a stomach.

Tactic and choice of treatment method

Treatment of gastro-colon fistula is exceptionally operative. It needs to be conducted after intensive preoperative preparation with correction of metabolism. All operations which can be applied at treatment of patients with gastro-colon fistula divide into palliative and radical (single-stage operation and multi-stage operation).

During the *palliative operations* the place of fistula of stomach, transverse colon and jejunum is disconnected and then sutured the created defects. Other variant is disconnection of stomach and transverse colon and leaving the gastroenteroanastomosis. It is necessary to remember, that during such operations the only fistula always removed and does not performed the resection of stomach. Clearly, that such situation also does not eliminate possibility of relapse of peptic ulcer and development of its complications. Taking into account it, palliative operations can be recommended in those case only, when the general condition of patient does not allow to perform radical operation.

Single-stage operation radical operations. The most widespread is degastroenterostomy with the resection of stomach. However, it is needed to remember that operation of disconnection of fistula, suturing of opening in the jejunum and transverse colon on the lines of fistula and resection of stomach applies only in case of absent of infiltrate and deformation and in the conditions of possibility to close a defect in bowels without narrowing of their lumen. This operation is the simplest, is enough easily carried by patients and it is enough radical.

THE SCAR DEFORMATION AND NARROWING OF ANASTOMOSIS AFTER THE STOMACH RESECTION

Such complications appear through considerable time after operation (from 1 month to one year). Disturbances of function of gastrointestinal anastomosis can be caused by the reasons, related both to the technical mistakes during operation and with pathological processes which arose up in the area of anastomosis.

Clinical management

The clinical picture of disturbance of anastomosis function, mainly, depends from the degree of its closing. At complete it obstruction in patients arise up intensive vomiting, pain in a epigastric area, the symptoms of dehydration and other similar signs appear. In other words,

the clinic of stenosis of the stomach output develops. Clearly, that during incomplete narrowing the clinical signs will be expressed less, and growth of them — more slow. Sometimes disturbance of evacuation can unite with the syndrome of afferent loop with a inherent clinical picture. At the roentgenologic examination of such patients expansion of stomach stump is exposed with the horizontal level of liquid and small gas bubble. Evacuation from it is absent or acutely slow.

Tactic and choice of treatment method

Treatment of scar deformations and narrowing of anastomosis must be operative and directed for the disconnection of accretions and straightening of the deformed areas. In case of presence in patients large inflammatory infiltrate it does not need to perform disconnection. In such cases it is the best to apply roundabout anastomosis. If a resection by Finsterer was done in such patient, better to perform anterior gastroenteroanastomosis, and after a resection by Billroth-I — posterior. As a result of conducting of such operations the state of patient, as a rule, gets better, and often recovered the function of primary anastomosis.

CONSEQUENCES AND COMPLICATIONS OF GASTRECTOMY

Removing of all stomach and exception of duodenum from the process of digestion of food cause plural functional disturbances in an organism. Some of them meet already after the resection of stomach (dumping-syndrome, hypoglycemic syndrome), other more inherent for gastrectomy (anaemia, reflux- esophagitis and others like that).

Most patients, that carried gastrectomy, complain for a considerable physical weakness, heightened fatigueability, sometimes is complete weakness, loss of activity and acute decline of work capacity. Almost all of them notice bad sleep, worsening of memory and heightened irritates. The appearance of patients is typical. Their skin insignificantly hyperpigmentated, dry, its turgor reduced, noticeable atrophy of muscles. Can be the signs of chronic coronal insufficiency in such patients, and in older-year persons is typical picture of stenocardia. Except for it, can be hypotension, bradycardia and decline of voltage on EKG; during auscultation deafness of tones is observed. From the side of the hormonal system the decline of function of sexual glands is typical: in men — declines of potency, in women — disturbances of menstrual cycle, early climax. Can be the signs of hypovitaminosis A, B, C and decline of resistibility of organism to chill, infectious diseases and tuberculosis.

The decline of mass of body is observed in 75 % patients, that carried gastrectomy. It is conditioned by the decline of power value of food as a result of disturbance of digestion, bad appetite and wrong diet. As a result of progressive hypoproteinemia there can be the protein-free edemata.

Tactic and choice of treatment method

Patients with such pathology must be under the permanent clinical supervision and 1–2

times per year during a month to have the course of stationary prophylactic treatment which includes psycho-, diet-, vitaminotherapy, correcting and replaceable therapy, and also prophylaxis of anaemia.

Psychotherapy is especially indicated in the psychodepressive and asthenic states. It is performed in combination with medicinal treatment. Hypnotic preparation, bromide, tranquilizers are applied.

A food must be correctly prepared, without the protracted cooking. Patients need to feed on 6–10 times per days by small portions.

Next to dietotherapy, it is constantly necessary to apply replaceable therapy (Pancreatine, Pansinorm, Festal, Intestopan). In case of absent of esophagitis hydrochloric acid is appointed. For the improvement of albuminous exchange anabolic hormones are applied.

In case of reflux-esophagitis there are indicated feeds by small portions with predominance of liquid, ground, jelly-like foods, astringent, coating, anticholinergic preparations. Between the receptions of food does not recommend to use a liquid. In case of dysphagy appoints a sparing diet.

For the prophylaxis of iron-deficiency anaemia, that arises up in the first 2–3 years after gastrectomy, important the indication of iron preparations.

For warnings and treatments of pernicious anaemia applied cyanocobalamin for 200 mcg through a day and folic acid. Packed red blood cells is indicated in heavy case.

Differential diagnostics and clinical variants

Acute appendicitis is an inflammation of vermiform appendix caused by festering microflora.

Most frequent causes of acute appendicitis are festering microbes: intestinal stick, streptococcus, staphylococcus. Moreover, microflora can be in cavity of appendix or get there by hematogenic way, and for women – by lymphogenic one.

Factors which promote the origin of appendicitis, are the following: a) change of reactivity of organism; b) constipation and atony of intestine; c) twisting or bends of appendix; d) excrement stone in its cavity; e) thrombosis of vessels of appendix and gangrene of wall as a substance of inflammatory process (special cases).

Simple (superficial) and destructive (phlegmonous, gangrenous primary and gangrenous secondary) appendicitises which are morphological expressions of phases of acute inflammation that is completed by necrosis can be distinguished.

In simple appendicitis the changes are observed, mainly, in the distant part of appendix. There are stasis in capillaries and venule, edema and hemorrhages. Focus of festering inflammation of mucus membrane with the defect of the epithelium covering is formed in 1–2 hours (primary affect of Ashoff). This characterizes acute superficial appendicitis. The phlegmon of appendix develops to the end of the day. The organ increases, its serous tunic becomes dimmed, sanguineous, stratifications of fibrin appear on its surface, and there is pus in cavity.

In gangrenous appendicitis the appendix is thickened, its serous tunic is covered by dimmed fibrinogenous tape, differentiating of the layer structure through destruction is not

succeeded.

Four phases are distinguished in clinical passing of acute appendicitis: 1) epigastric; 2) local symptoms; 3) calming down; 4) complications.

The disease begins with a sudden pain in the abdomen. It is localized in a right iliac area, has moderate intensity, permanent character and not irradiate. With 70 % of patients the pain arises in a epigastric area - it is an epigastric phase of acute appendicitis. In 2–4 hours it moves to the place of appendix existence (the Kocher's symptom). At coughing patients mark strengthening of pain in a right iliac area – it is a positive cough symptom.

Together with it, nausea and vomiting that have reflex character can disturb a patient. Often there is a delay of gases. The temperature of body of most patients rises, but high temperature can occur rarely and, mainly, it is a low grade fever. The general condition of patients gets worse only in case of growth of destructive changes in appendix.

During the examination it is possible to mark, that the right half of stomach falls behind in the act of breathing, and a patient wants to lie down on a right side with bound leg.

Painfulness is the basic and decisive signs of acute appendicitis during the examination by palpation in a right iliac area, tension of muscle of abdominal wall, positive symptoms of peritoneum irritation. About 100 pain symptoms characteristic of acute appendicitis are known, however only some of them have the real practical value.

The Blumberg's symptom. After gradual pressing by fingers on a front abdominal wall from the place of pain quickly, but not acutely, the hand is taken away. Strengthening of pain is considered as a positive symptom in that place. Obligatory here is tension of muscles of front abdominal wall.

The Voskresenkyy Symptom. By a left hand the shirt of patient is drawn downward and fixed on pubis. By the taps of 2-4 fingers of right hand epigastric area is pressed and during exhalation of patient quickly and evenly the hand slides in the direction of right iliac area, without taking the hand away. Thus there is an acute strengthening of pain.

The Bartomier's symptom is the increase of pain intensity during the palpation in right iliac area of patient in position on the left side. At such pose an omentum and loops of thin intestine is displaced to the left, and an appendix becomes accessible for palpation.

The Sitkovsky's symptom. A patient, that lies on left, feels the pain which arises or increases in a right iliac area. The mechanism of intensification of pain is explained by displacement of blind gut to the left, by drawing of mesentery of the inflamed appendix.

The Rovsing's symptom. By a left hand a sigmoid bowel is pressed to the back wall of stomach. By a right hand by ballotting palpation a descending bowel is pressed. Appearance of pain in a right iliac area is considered as a sign characteristic of appendicitis.

The Obrazcov's symptom. With the position of patient on the back by index and middle fingers the right iliac area of most painful place is pressed and the patient is asked to heave up the straightened right leg. At appendicitis pain increases acutely.

The Rozdolsky's symptom. At percussion there is painfulness in a right iliac area.

The general analysis of blood does not carry specific information, which would specify the presence of acute appendicitis. However, much leukocytosis and change of formula to the left in most cases can point to the present inflammatory process.

Acute appendicitis in children. With children of infancy acute appendicitis can be seen infrequently, but, quite often carries atypical character. All this is conditioned, mainly, by the features of anatomy of appendix, insufficient of plastic properties of the peritoneum, short omentum and high reactivity of child's organism. The inflammatory process in the appendix of children quickly makes progress and during the first half of days from the beginning of disease there can appear its destruction, even perforation. The child, more frequent than an adult, suffers vomiting. Its general condition gets worse quickly, and already the positive symptoms of irritation of peritoneum can show up during the first hours of a disease. The temperature reaction is also expressed considerably acuter. In the blood test there is high leukocytosis. It is necessary to remember, that during the examination of calmless children it is expedient to use a chloral hydrate enema.

Acute appendicitis of the people of declining and old ages can be met not so often, as of the persons of middle ages and youth. This contingent of patients is hospitalized to hospital rather late: in 2–3 days from the beginning of a disease. Because of the promoted threshold of pain sensitiveness, the intensity of pain in such patients is small, therefore they almost do not fix attention on the epigastric phase of appendicitis. More frequent are nausea and vomiting, and the temperature reaction is expressed poorly. Tension of muscles of abdominal wall is absent or insignificant through old-age relaxation of muscles. But the symptoms of irritation of peritoneum keep the diagnostic value with this group of patients. Thus, the sclerosis of vessels of appendix results in its rapid numbness, initially-gangrenous appendicitis develops. Because of such reasons the destructive forms of appendicitis prevail, often there is appendiceal infiltrate.

With pregnant women both the bend of appendix and violation of its blood flow are causes of the origin of appendicitis. Increased in sizes uterus causes such changes. It, especially in the second half of pregnancy, displaces a blind gut together with an appendix upwards, and an overdistension abdominal wall does not create adequate tension. It is needed also to remember, that pregnant women periodically can have a moderate pain in the abdomen and changes in the blood test. Together with that, psoas-symptom and the Bartomier's symptom have a diagnostic value at pregnant women.

Clinical passing of acute appendicitis at the atypical placing (not in a right iliac area) will differ from a classic vermiform appendix (Pic. 3.3.1).

Appendicitis at retrocecal and retroperitoneal location of appendiceal appendix can be with 8–20 % patients. Thus an appendix can be placed both in a free abdominal cavity and retroperitoneal. An atypical clinic arises, as a rule, at the retroperitoneal location. The patients complain at pain in lumbus or above the wing of right ilium. There they mark painfulness during palpation. Sometimes the pain irradiates to the pelvis and in the right thigh. The positive symptom of Rozanov — painfulness during palpation in the right Pti triangle is characteristic. In transition of inflammatory process on an ureter and kidney in the urines analysis red corpuscles can be found.

Appendicitis at the pelvic location of appendix can be met in 11–30 % cases. In such patients the pain is localized above the right Poupart's ligament and above pubis. At the very low placing of appendix at the beginning of disease the reaction of muscles of front abdominal

wall on an inflammatory process can be absent. With transition of inflammation on an urinary bladder or rectum either the dysuric signs or diarrhea develops, mucus appears in an excrement. Distribution of process on internal genital organs provokes signs characteristic of their inflammation.

Appendicitis at the medial placing of appendix. The appendix in patients with such pathology is located between the loops of intestine, that is the large field of suction and irritation of peritoneum. At these anatomic features mesentery is pulled in the inflammatory process, acute dynamic of the intestinal obstruction develops in such patients. The pain in the abdomen is intensive, widespread, the expressed tension of muscles of abdominal wall develops, that together with symptoms of the irritation of peritoneum specify the substantial threat of peritonitis development.

For the subhepatic location of appendix the pain is characteristic in right hypochondrium. During palpation painfulness and tension of muscles can be marked.

Left-side appendicitis appears infrequently and, as a rule, in case of the reverse placing of all organs, however it can occur at a mobile blind gut. In this situation all signs which characterize acute appendicitis will be exposed not on the right, as usually, but on the left.

Among complications of acute appendicitis most value have appendiceal infiltrates and abscesses.

Appendiceal infiltrate is the conglomerate of organs and tissue not densely accrete round the inflamed vermiform appendix. It develops, certainly, on 3–5th day from the beginning of disease. Acute pain in the stomach calms down thus, the general condition of a patient gets better. Dense, not mobile, painful, with unclear contours, formation is palpated in the right iliac area. There are different sizes of infiltrate, sometimes it occupies all right iliac area. The stomach round infiltrate during palpation is soft and unpainful.

At reverse development of infiltrate (when resorption comes) the general condition of a patient gets better, sleep and appetite recommence, activity grows, the temperature of body and indexes of blood is normalized. Pain in the right iliac area calms down, infiltrate diminishes in size. In this phase of infiltrate physiotherapeutic procedure is appointed, warmth on the iliac area.

In two months after resorption of infiltrate appendectomy is conducted.

At abscessing of infiltrate the condition of a patient gets worse, the symptoms of acute appendicitis become more expressed, the temperature of body, which in most cases gains hectic character, rises, the fever appears. Next to that, pain in the right iliac area increases. Painful formation is felt there. In the blood test high leukocytosis is present with the acutely expressed change of leukocyte formula to the left.

Local abscesses of abdominal cavity, mainly, develops as a result of the atypical placing of appendix or suppuration. More frequent from other there are pelvic abscesses. Thus a patient is disturbed by pain beneath the umbilicus, there are dysuric disorders, diarrhea and tenesmus. The temperature of body rises to 38,0–39,0°C, and rectal — to considerably higher numbers. In the blood test leukocytosis, change of formula of blood is fixed to the left.

During the rectal examination the weakened sphincter of anus is found. The front wall of rectum at first is only painful, and then its overhanging is observed as dense painful infiltrate.

A subdiaphragmatic abscess develops at the high placing of appendix. The pain in the lower parts of thorax and in an upper quarter of abdomen to the right, that increases at deep inhalation except for the signs of intoxication, is characteristic of it. A patient, generally, occupies semisitting position. Swelling in an epigastric area is observed in heavy cases, smoothing and painful intercostal intervals. The abdomen during palpation is soft, although tension in the area of right hypochondrium is possible. Painfulness at pressure on bottom (9–11) ribs is the early and permanent symptom of subdiaphragmatic abscess (the Krukov's symptom).

Roentgenologically the right half of diaphragm can fall behind from left one while breathing, and there is a present reactive exudate in the right pleura cavity. A gas bubble is considered the roentgenologic sign of subdiaphragmatic abscess with the horizontal level of liquid, which is placed under the diaphragm.

Interloop abscesses are not frequent complications of acute appendicitis. As well as all abscesses of abdominal cavity, they pass the period of infiltrate and abscess formation with the recreation of the proper clinic.

The poured festering peritonitis develops as a result of the timely unoperated appendicitis. Diagnostics of this pathology does not cause difficulties.

Pylephlebitis is a complication of both appendicitis and after-operative period of appendectomy.

The reason of this pathology is acute retrocecal appendicitis. At its development the thrombophlebitis process from the veins of appendix, passes to the veins of bowels mesentery, and then on to the portal vein. Patients complain at the expressed general weakness, pain in right hypochondrium, high hectic temperature of body, fever and strong sweating. Patients are adynamic, with expressed subicteritiousness of the scleras. During palpation painfulness is observed in the right half of abdomen and the symptoms of irritation of peritoneum are not acutely expressed.

In case with rapid passing of disease the icterus appears, the liver is increased, kidney-hepatic insufficiency makes progress, and patients die in 7-10 days from the beginning of disease. At gradual subacute development of pathology the liver and spleen is increased in size, and after the septic state of organism ascites arises.

Acute appendicitis is differentiated with the diseases which are accompanied by pain in the abdomen.

Food toxicoinfection. Complaints for pain in the epigastric area of the intermittent character, nausea, vomitings and liquid emptying are the first signs of disease. The state of patients progressively gets worse from the beginning. Next to that, it is succeeded to expose that a patient used meal of poor quality. However, here patients do not have phase passing, which is characteristic of acute appendicitis, and clear localization of pain. Defining the symptoms of irritation of peritoneum is not succeeded, the peristalsis of intestine is, as a rule, increased.

Acute pancreatitis. In anamnesis in patients with this pathology there is a gallstone disease, violation of diet and use of alcohol. Their condition from the beginning of a disease is heavy. Pain is considerably more intensive, than during appendicitis, and is concentrated in the

upper half of abdomen. Vomiting is frequent and does not bring to the recovery of patients.

Perforative peptic and duodenum ulcer. Diagnostic difficulties during this pathology arise up only on occasion. They can be in patients with the covered perforation, when portion of gastric juice flows out in an abdominal cavity and stays too long in the right iliac area, or in case of atypical perforations. Taking it into account, it is needed to remember, that the pain in the perforative ulcer is considerably more intensive in epigastric, instead of in the right iliac area. On the survey roentgenogram of organs of abdominal cavity under the right cupula of diaphragms free gases can be found.

The apoplexy of ovary more frequent is with young women and, as a rule, on 10-14 day after menstruation. Pain appears suddenly and irradiate in the thigh and perineum. At the beginning of disease there can be a collapse. However, the general condition of patients suffers insignificantly. When not enough blood was passed in the abdominal cavity, all signs of pathology of abdominal cavity organs calm down after some time. Signs, which are characteristic of acute anaemia, appear at considerable hemorrhage. Abdomen more frequent is soft and painful down, (positive Kulenkampff's symptom: acute pain during palpation of stomach and absent tension of muscles of the front abdominal wall).

During paracentesis of back fornix the blood which does not convolve is got.

Extra-uterine pregnancy. A necessity to differentiate acute appendicitis with the interrupted extra-uterine pregnancy arises, when during the examination the patient complains at the pain only down in the stomach, more to the right. Taking it into account, it is needed to remember, that at extra-uterine pregnancy a few days before there can be intermittent pain in the lower part of the abdomen, sometimes excretions of "coffee" colour appear from vagina. In anamnesis often there are the present gynaecological diseases, abortions and pathological passing of pregnancy. For the clinical picture of such patient inherent sudden appearance of intensive pain in lower part of the abdomen. Often there is a brief loss of consciousness. During palpation considerable painfulness is localized lower, than at appendicitis, the abdomen is soft, the positive Kulenkampff's symptom is determined. Violations of menstrual cycle testify for pregnancy, characteristic changes are in milk glands, vagina and uterus. During the vaginal examination it is sometimes possible to palpate increased tube of uterus. The temperature of body more frequently is normal. If hemorrhage is small, the changes in the blood test are not present. The convincing proof of the broken extra-uterine pregnancy is the dark colour of blood, taken at puncture of back fornix of vagina.

Acute cholecystitis. The high placing of vermiform appendix in the right half of abdomen during its inflammation can cause the clinic somewhat similar to acute cholecystitis. But unlike appendicitis, in patients with cholecystitis the pain is more intensive, has cramp-like character, is localized in right hypochondrium and irradiate in the right shoulder and shoulder-blade. Also the epigastric phase is absent. The attack of pain can arise after the reception of spicy food and, is accompanied by nausea and frequent vomiting by bile. In anamnesis patients often have information about a gallstone disease. During examination intensive painfulness is observed in right hypochondrium, increased gall-bladder and positive symptoms Murphy's and Ortner's.

Right-side kidney colic. For this disease tormina at the level of kidney and in lumbus is

inherent, hematuria and dysuric signs which can take place at the irritation of ureter by the inflamed appendix. Intensity of pain in kidney colic is one of the basic differences from acute appendicitis. Pain at first appears in lumbus and irradiate downward after passing of ureter in genital organs and front surface of the thigh. In diagnostics urogram survey is important, and if necessary — chromocystoscopy. Absence of function of right kidney to some extent allows to eliminate the diagnosis of acute appendicitis.

As experience of surgeons of the whole world testifies, in acute appendicitis timely operation is the unique effective method of treatment.

Access for appendectomy must provide implementation of operation. McBurney's incision is typical.

When during operation the appendix without the special difficulties can be shown out in a wound, antegrade appendectomy is executed. On clamps its mesentery is cut off and ligated. Near the basis the appendix is ligated and cut. Stump is processed by solution of antiseptic and peritonized by a purse-string suture (Pic. 3.3.2).

If only the basis of appendix is taken in a wound, and an apex is fixed in an abdominal cavity, more rationally retrograde appendectomy is conducted (Pic. 3.3.3). Thus the appendix near basis is cut between two ligatures. Stump is processed by antiseptic and peritonized. According to it the appendix is removed in the direction from basis to the apex. According to indication operation is concluded by draining of abdominal cavity (destructive appendicitis, exudate in an abdominal cavity, capillary hemorrhage from the bed). In recent years the laparoscopy methods of appendectomy are successfully performed.

In patients with appendiceal infiltrate it is necessary to perform conservative-temporizing tactic. Taking it into account, bed rest is appointed, protective diet, cold on the area of infiltrate, antibiotic therapy. According to resorption of infiltrate, in two months, planned appendectomy is executed.

Treatment of appendiceal abscess must be only operative. Opening and drainage of abscess, from retroperitoneal access, is performed. To delete here the appendix is not necessary, and because of danger of bleeding, peritonitis and intestinal fistula — even dangerously.

Intestinal obstruction is a complete or partial violation of passing of maintenance by the intestinal tract.

The principal reasons of intestinal obstruction can be:

- 1) commissures of abdominal cavity after traumas, wounds, previous operations and inflammatory diseases of organs of abdominal cavity and pelvis;
- 2) long mesentery of small intestine or colon, that predetermines considerable mobility of their loops;
- 3) tumours of abdominal cavity and retroperitoneal space.

Such principal reasons can cause violation of passing of intestinal maintenance, disorder of suction from the intestine and loss of plenty of electrolytes both from vomiting and in the intestine cavity as a result of disorders of bloodflow in its wall.

The morphological signs of dynamic intestinal obstruction are: small thickening of wall (at considerable paresis is thinning), friability of tissue (the bowel breaks easily) and presence of liquid maintenance and gases in cavity of bowel. At mechanical obstruction it is always

possible to expose the obstacle: strang, commissures, tumours, jammings of hernia, cicatricial strictures, wrong entered drainages, tampons and others like that. In place of compression strangulation is exposed. The bowel loop higher strangulation is extended, and distally — collapsed. In case of released invagination on small distance two strangulation furrows are observed, and distally from the second ring cylinder expansion of bowel lumen is observed.

Beginning of clinical signs of intestinal obstruction is sudden — in 1–2 hours after taking the meal. The pain in the abdomen has the intermittent character and is met in all forms of mechanical intestinal obstruction. However, some types of strangulated intestinal obstruction (node formation, volvulus of thin and colons) can be accompanied by permanent pain. It is needed to mark that at spike intestinal obstruction, invagination and obturation cramp-like pain can be considered as pathognomic sign of disease. For paralytic intestinal obstruction more frequent is inherent permanent pain which is accompanied by the progressive swelling of abdomen. At spastic obstruction of intestine the pain is mainly acute, the abdomen is not blown away, sometimes pulled in.

Nausea and vomiting are met in 75–80 % patients with the heaviest forms of high level of intestinal obstruction (node formation, volvulus of small intestine, spike obstruction). At obturation obstruction and invagination they are observed not so often.

There is a characteristic thirst which can be considered as an early symptom. Besides, the higher intestinal obstruction, the greater the thirst.

Swelling of abdomen, the delay of emptying and gases are observed in 85–90% patients, mainly, with the high forms of obstruction (volvulus of small intestine, spike intestinal obstruction).

Together with that, for invagination emptying by liquid excrement with the admixtures of mucus and blood are more characteristic.

In patients during palpation the soft abdomen is observed, sometimes — with easy resistance of front abdominal wall, and at percussion — high tympanitis. At auscultation at the beginning of disease increased peristaltic noises are present, then gradual fading of peristalsis is positive (the Mondor's symptom, "noise of beginning, quietness of end").

There are other symptoms pathognomic for intestinal obstruction.

The Vala's symptom is the limited elastic sausage-shaped formation.

The Sklarov's symptom is the noise of intestinal splash.

The Kywul's symptom is the clang above the exaggerated bowel.

The Schlange's symptom is the peristalsis of bowel, that arises after palpation of abdomen.

The Spasokukotsky's symptom is "noise of falling drop".

The Hochenegg's symptom — incompletely closed anus in combination with balloon expansion of ampoule of rectum.

At survey roentgenoscopy or -graphy of the abdominal cavity in the loops of bowels liquids and gas are observed — the Klojber's bowl (Pic. 3.3.4).

Strangulated obstruction. The ischemic component is the characteristic feature of this form of intestinal obstruction, that is investigation of squeezing of mesentery vessels, which

determines the dynamics of pathomorphologic changes and clinical signs of disease, and the basic place among them belongs to the pain syndrome. Consequently, sudden appearance of disease, acuteness of pain syndrome and ischemic disorders in the wall of bowel cause necrosis changes of area of bowel pulling in a process. It is accompanied by the making progress worsening of the patient condition and origin of endotoxiosis.

Obturation intestinal obstruction, unlike strangulated, pass not so quickly. In its clinical picture on the first place there are the symptoms of violation of passage on the intestine (protracted intermittent pain, flatulence), instead of symptoms of bowel destruction and peritonitis.

For high, especially strangulated, intestinal obstruction progressive growth of clinical signs of disease and violation of secretory function of intestine is inherent. Thus the volume of circulatory blood diminishes, the level of haematocritis rises and leukocytosis grows. There are also deep violations of homeostasis (hypoproteinemia, hypokalemia, hyponatremia, hypoxia and others like that). In patients with low intestinal obstruction above-named signs are less expressed, and their growth is related to more protracted passing of disease. Invagination of bowel which can be characterized by the triad of characteristic signs is the special type of intestinal obstruction with the signs of both obturation and strangulation: 1) periodicity of appearance of the intermittent attacks of pain in the abdomen; 2) presence of elastic, insignificantly painful, mobile formation in an abdominal cavity; 3) appearance of blood in the excrement or its tracks (at rectal examination).

The special forms of obturation intestinal obstruction is the obstruction caused by gall-stones. The last are got in the small intestine as a result of bed sore in the walls of gall-bladder and bowel, that adjoins to it. It is needed to mention that intestinal obstruction can be caused by concrement with considerably more small diameter than bowel lumen. The mechanism of such phenomenon is related to irritating action of bilious acids on the bowel wall. The last answers this action by a spasm with the dense wedging of stone in the bowel lumen.

Development of intestinal obstruction caused by gall-stones the attack of colic and clinic of acute cholecystitis precede always. Characteristically, that in the process of development of disease the pain caused by acute cholecystitis calms down, whereupon the new pain characteristic of other pathology — intestinal obstruction appears.

Dynamic intestinal obstruction is divided into paralytic and spastic. Paralytic obstruction often arises after different abdominal operations, inflammatory diseases of organs of abdominal cavity, traumas and poisonings. The reason of spastic intestinal obstruction can be the lead poisonings, low-quality meal, neuroses, hysterias, helminthiasis and others like that. Clinic of dynamic intestinal obstruction is always variable in signs and depends on a reason, that caused it. Disease is characterized by pain in the abdomen, delay of gases and emptying. During palpation the abdomen is blown away, painful, however soft. To diagnose this form of intestinal obstruction is not difficult, especially, if its etiology is known.

Hemostatic intestinal obstruction develops after embolism or thromboses of mesenteric arteries and thromboses of veins, there can be mixed forms. Embolism of mesenteric arteries arises in patients with heart diseases (mitral and aortic failings, heart attack of myocardium,

warty endocarditis) and declared by damaging, mainly, upper mesentery arteries. Beginning of disease, certainly, is acute, with nausea, sometimes — vomiting. At first there is a picture of acute abdominal ischemic syndrome, that is often accompanied by shock (frequent pulse, decline of arterial and pulse pressure, death-damp, cyanosis of mucus membranes and acrocyanosis). Patients become excitative, uneasy, occupy the forced knee-elbow position or lie on the side with bound legs.

During the examination the abdomen keeps symmetry, abdominal wall is soft, the increased peristalsis is heard from the first minutes during 1–2 hours (hypoxic stimulation of peristalsis), which later goes out gradually (“grave quiet”). According to the phenomena of intoxication peritonitis grow quickly. At the beginning of disease the delay of gases and emptying is observed, later there is diarrhea with the admixtures of blood in an excrement. When the last is heavy to set macroscopically, it is needed to explore scourage of intestine.

Intestinal obstruction must be differentiated with the acute diseases of organs of abdominal cavity.

The perforation of gastroduodenal ulcer, as well as intestinal obstruction, passes acutely with inherent to it by sudden intensive pain and tension of muscles of abdomen. However, in patients with this pathology, unlike intestinal obstruction, the abdomen is not exaggerated, and pulled in with “wooden belly” tension of muscles of front abdominal wall. There is also characteristic ulcerous anamnesis. Roentgenologic and by percussion pneumoperitoneum is observed. Certain difficulties in conducting of differential diagnostics of intestinal obstruction can arise at atypical passing and in case of the covered perforations.

Acute pancreatitis almost always passes with the phenomena of dynamic intestinal obstruction and symptoms of intoxication and repeated vomiting, with rapid growth. During the examination in such patients, unlike intestinal obstruction, rigidity of abdominal wall and painfulness is observed in the projections of pancreas and positive Korte's symptom and Mayo-Robson's. The examination of diastase of urine and amylase of blood have important value in establishment of diagnosis.

Acute cholecystitis. Unlike intestinal obstruction, patients with this pathology complain for pain in right hypochondrium, that irradiate in the right shoulder-blade, shoulder and right subclavian area. Difficulties can arise, when the symptoms of dynamic intestinal obstruction appear on the basis of peritonitis.

The clinic of kidney colic in the signs and character of passing are similar to intestinal obstruction, however, attacks of pain in the lumbar area with characteristic irradiation in genital parts, the thigh and dysuric disorders help to set the correct diagnosis. Certain difficulties in conducting of differential diagnostics also can arise in difficult patients, at frequent vomiting which sometimes can be observed in patients with kidney colic.

During the first 1,5–2 hours after hospitalization of patient complex conservative therapy which has the differential-diagnostic value and can be preoperative preparation is conducted.

It is directed on warning of the complications related to pain shock, correction of homeostasis and, simultaneously, is the attempt of liquidation of intestinal obstruction by unoperative methods.

1. The measures directed for the fight against abdominal pain shock include conducting of neuroleptanalgesia, procaine paranephric block and introduction of spasmolytics. Patients with the expressed pain syndrome and spastic intestinal obstruction positive effect can be attained by epidural anaesthesia also.

2. Liquidation of hypovolemia with correction of electrolyte, carbohydrate and albuminous exchanges is achieved by introduction of salt blood substitutes, 5–10 % solution of glucose, gelatinol, albumen and plasma of blood. There are a few methods suitable for use in the urgent surgery of calculation of amount of liquid necessary for liquidation of hypovolemia. Most simple and accessible is a calculation by the values of hematocrit. If to consider 40 % for the high bound of hematocrit norm, on each 5 % above this size it is needed to pour 1000 ml of liquids.

3. Correction of hemodynamic indexes, microcirculation and disintoxication therapy is achieved by intravenous infusion of Reopolyhukine and Neohemodes.

4. Decompression of intestine tract is achieved by conducting of nasogastric drainage and washing of stomach, and also conducting of siphon enema. It is needed to underline that technically the correct conducting of siphon enema has the important value for the attempt of liquidation of intestinal obstruction by conservative facilities, therefore this manipulation must be conducted in presence of a doctor. For such enema the special device is used with the rectal tip, by a PVC pipe by a diameter of 1,5–2,0 cm and watering-can of very thin material. A liquid into the colon is brought to appearance of the pain feeling, then drop the watering-can below the level of patient who lies. The passage of gases and excrement is looked after. As a rule, this manipulation is to repeat repeatedly with the use of plenty of warm water (to 15–20 and more litres).

Liquidating of the intestinal obstruction by such conservative facilities is succeeded in 50–60 % patients with mechanical intestinal obstruction.

Patients with dynamic paralytic intestinal obstruction are expedient to stimulation of peristalsis of intestine to be conducted, besides, necessarily after infusion therapy and correction of hypovolemia. A lot of kinds of stimulation of intestine peristalsis are offered. Most common of them are:

1) hypodermic introduction of 1,0 ml of 0,05 % solution of proserin; 2) through 10 min — 60 ml intravenously stream of 10 % solution of chlorous sodium; 3) hypertensive enema.

Surgical treatment of intestinal obstruction must include such important moments:

1. According to middle laparotomy executed the novocaine blockade of mesentery of small and large intestine and operative exploration of abdominal cavity organs during which the reason of intestinal obstruction and expose viability of intestine is set.

The revision at small intestine obstruction begins from the Treitz' ligament to iliocecal corner. At large intestine obstruction the hepatic, splenic and rectosigmoid parts are observed intently. Absence of pathological processes after revision needs the examination of places of cavity and jamming of internal hernia: internal inguinal and femoral rings, obturator openings, pockets of the Treitz' ligament, Winslow's opening, diaphragm and periesophageal opening.

2. Liquidation of reasons of obstruction (scission of connection, that squeezes a bowel,

violence of volvulus and node formation of loops, desinvagination, deleting of obturative tumours and others like that).

It is needed to mark that the unique method of liquidation of acute intestinal obstruction does not exist. At the lack of viability of bowel the resection of nonviable area is executed with 30–40 cm of afferent and 15–20 cm of efferent part with imposition of “side-to-side” anastomosis (Pic. 3.3.5) or “end-to-end” (Pic. 3.3.6).

3. Intubation. Decompression of intestine foresees conducting in the small intestine of elastic probe by thickness of 8–9 mm and length of 3–3,5 m with the plural openings by a diameter 2–2,5 mm along all probe, except for part, that will be in the oesophagus, pharynx and outwardly. A few methods of conducting of probe are offered in a bowel (nasogastric, through gastrostomy, ceco- or appendicostoma). Taking it into account, such procedure needs to be executed individually and according to indications.

Each of them has the advantages and failings. In connection with the threat of origin of pneumonia, entering an intubation probe to the patients of old ages is better by means of gastrostomy. Most surgeons avoid the method of introduction of probe through ceco- or appendicostoma because of technical difficulties of passing in a small intestine through a Bauhin's valve. Today the most wide clinical application has intubation of intestine extracted by the nasogastric method with the use of other thick probe as explorer of the first (by L.J. Kovalchuk, 1981). Such method not only simplifies procedure of intubation but also facilitates penetration through the piloric sphincter and duodenojejunal bend, and also warns passing of intestinal maintenance in a mouth cavity and trachea. Thus probe is tried to be conducted in the small intestine as possible farther and deleted the next day after appearance of peristalsis and passage of gases, however not later than on 7th days, because more protracted sign of probe carries the real threat of formation of bedsores in the wall of bowel.

4. Sanation and draining of abdominal cavity is executed by the generally accepted methods of washing of antiseptic. Draining of the abdominal cavity it is needed from four places: in both iliac areas and both hypochondrium, better by the coupled synthetic drainpipes.

Crohn's disease is an unspecific inflammatory process of submucosal membrane of gastrointestinal tract with propensity to the segmental lesions and recurrent passing. The local signs of disease exist in different areas of digestive tract organs, however, most frequent and most intensive they are in the distal segment of small intestine, therefore it was named terminal ileitis.

The reason of origin of the Crohn's disease for today is not finally found out. An infection and allergy are infringement factors. Together with that, granuloma, which is exposed at histological examination with present in its lymphocytic and protoplasmatic infiltrations, grounds to consider that the defined value in the origin of the Crohn's disease have immune factors. Thus inflammation begins in the submucosal membrane, and afterwards engulfs all bowel walls. The mucus membrane acquires the crimson colouring, there are deep cracks and ulcers. Combination of the damaged areas of mucus membrane with healthy creates a picture similar to the roadway. In future granuloma appears, an inflammatory process goes out outside the wall of bowel and gets to the contiguous organs (large and small intestines, urinary bladder, abdominal wall). In the eventual result there are infiltrate, abscesses and fistula. Finally, it is

needed to mark that the people of young ages mainly are ill by terminal ileitis.

The morphological changes are concentrated, mainly, in the terminal part of iliac bowel, anal segment of rectum and appendix. Internal surface is hilly, thickened, swelling, deep ulcers are intermittent with the unchanged areas of mucus. The serous tunic is covered by plural, similar on tuberculosis, knots. Mesentery is sclerosed, regional lymphatic knots are hyperplastic, of whiter-rose color. By the most characteristic microscopic sign of Crohn's disease is presence of unspecific sarcoid granuloma. Hyperplasia of lymphoid elements of submucosal membrane and formation of fissured ulcers is observed also.

The Crohn's disease begins from the insignificant signs as a general weakness, increase of temperature of body, intermittent pain, that arises after the reception of meal, diarrhea without some visible features or with the admixture of blood. As this process strikes the terminal segment of small intestine, pain is concentrated in the right iliac area. Together with that, at localization of pathological focus in a colon with an anal segment pain is concentrated by its passing to the anal opening. A granuloma process takes place in the area of oesophagus, abdomen or duodenum, pain can arise up in the area of lesions. With progress of disease on endoscopy examination (proctosigmoidoscopy, fiberoptic colonoscopy, fiberoptic gastroscopy) hyperemia and deep cracks of mucus membrane, ulcers, symptom of "roadway" and stenosis are observed. At roentgenoscopy survey of organs of abdominal cavity in patients with the perforation it is possible to expose pneumoperitoneum, and at contrasting sciagraphy — stenosis of initial part of stomach, presence of ulcers or granuloma in the oesophagus. The examination of the passage on the small intestine enables to eliminate or confirm stenosis (Pic. 3.3.7). Irrigoscopy determines the defect of filling.

At acute passing of terminal ileitis, the pain appears acute in the right iliac area, sometimes intermittent, accompanied by nausea, vomitings, emptying by a liquid excrement with the admixture of blood or delay of emptying. During the examination of patient the abdomen can be exaggerated, tension of muscles and positive symptoms of irritation of peritoneum, high temperature is observed. In the general analysis of blood leukocytosis is present with the change of leukocyte formula to the left. In such difficult situation often only laparotomy helps to specify the diagnosis. The swollen segment of iliac bowel is thus observed with increased mesentery lymphatic knots. The changed area of bowel can perforate in the free abdominal cavity or penetrate in the contiguous loops of large or small intestine. It causes forming of inflammatory infiltrate, and in future — abscess formation. The unoperated abscesses are always inclined to the independent opening in surrounding organs with subsequent formation of fistula ducts.

The disease with the lesions of other parts of small and large intestine passes acutely (granulomatous enteritis, colitis). By palpation in these patients painful infiltrate is exposed, which by the character remind the clinic of invagination. Only the meticulous examination and present data analysis enable to set correct diagnosis. At granulomatous proctitis the plural cracks of mucus membrane without the signs of spasm of sphincter appear often, on the basis of which afterwards there are ulcers, that badly granulate. The same changes can develop on skin round the anal opening.

The chronic forms of disease often pass with insignificant symptoms. From the

beginning of disease to establishment of diagnosis sometimes 1–2 years and more pass. Such patients periodically complain for pain, diarrhea, weight loss, increase of body temperature, nausea, vomitings and bleeding from a rectum.

Objectively in the abdominal cavity painful infiltrate is determined, and at laboratory examination — anaemia and hypoproteinemia.

Complications of the Crohn's disease can be divided into local and general. Among local, formations of fistula which arise on the front abdominal wall between the damaged bowel and surrounding organs are most characteristic (ileoileal fistula, entero-entero, enterovesical fistula). Sometimes fistulas are opened in the area of scars after the operations on the lateral wall of abdomen or in the area of anus. Next to that, stenosis inflammatory infiltrate of bowel can be transformed in acute or chronic intestinal obstruction. Some patients have the obvious threat of perforation of the changed wall of bowel or intestinal bleeding. The protracted passing of disease can be also complicated by malignization. The aphthous ulcers of tongue, node erythema, arthritises and chronic lesions of liver are general complications.

The Crohn's disease must be differentiated with the unspecific ulcerous colitis and cancer of colon.

An unspecific ulcerous colitis mainly initially strikes the mucus membrane of all colon. The disease is accompanied by the excreta with the excrement of plenty of blood and mucus. For Crohn's disease languid passing of disease is characteristic. Acute passing of disease is met considerably rarer, than chronic. The modern methods of endoscopic examination with the biopsy of mucus membrane, which helps to specify diagnosis, are helpful in differential diagnostics.

The cancer of colon is mostly accompanied by formation of deep ulcers and infiltrate. However, for the cancer process slowly progressive passing without the periods of remission is more inherent, thus the disease more frequently ends with the phenomena of intestinal obstruction. At roentgenologic examination on the background the relatively unchanged colon the lonely defect of filling is observed, and during colonoscopy — thrusting out in the lumen of bowel with an erosive surface or signs of disintegration. Histological examination of biopsy material enables to expose cancer cells.

Conservative treatment. The diet of patient, generally, must be ordinary, except for products with bad intestinal uptake. The medicine of the first row is 5-ASK (aminosalicylic acid, sulfasalazone and glucocorticoid). The medicines of the second row are: 6-mercaptopurine, azatiopurine and metronidazole. At diarrhea diphenoxilate is used — 5 ml peroral three times per days, loperamide — 2 mg peroral 3–4 times per days, smecta — 1 pack 3 times per days. At the expressed anaemia, to the considerable loss of weight, system complications, relapse of disease after operation prednisolone is applied — for 40–60 mg peroral every day during 1–2 weeks. After that its day's dose is diminished to 10–20 mg during 4–6 weeks and, in the end, stopped. For patients which are irresponsive to steroid, asatioprine is appointed (2 мг/кг) peroral. Metronidazole in a dose of 400 mg twice a days is used in the case of granulomatous disease of perineum.

The presence of external and internal fistula, stenosis of bowel, perforation and recurrent bleeding is an indication to operative treatment. The method of choice of operation is the

segmental resection of the pathologically changed bowel in the distance of 30–35 cm of proximal and distal from the damaged area. The regional lymph nodes is also deleted. In case of the perforation of bowel with poured peritonitis, it is recommend not to perform primary anastomosis because of possible insolvency of stitches after the resection. In this connection, afferent and efferent loops exteriorizes on the wall of abdomen as two-channel stoma (Pic. 3.3.8). The passage by an intestine (liquidation of stoma) is restored in 2–4 months after liquidation of the peritonitis signs.

An unspecific ulcerous colitis is a diffuse inflammatory process that is accompanied by the ulcerous-necrosis changes in the mucus membrane of colon and rectums.

Etiology of unspecific ulcerous colitis to this time is not finally found out. This disease is suffered by people in the age from 20 to 40 years. An infectious factor in development of disease for today is not confirmed. However, as the exception of meal of food allergens (milk, eggs) results in the improvement of passing of disease, it is possible to consider that allergy assists to development of inflammatory process. Important significance in genesis of this pathology is also attached to immunological violations. In the blood of patient sensibilizing on the antigen of mucus membrane of colon specifically lymphocytes and immune complexes are found. The antigen-antibody reaction can cause colitis. In most patients with the chronic recurrent unspecific ulcerous colitis a stress situation causes the process of acutening. In future, obviously, there are violations of microcirculation and cellular structures, and also the transport system of cells membranes suffers, that carries potassium and sodium ions. Taking it into account, the timely exposure of disease in which the process is localized and has a reverse tendency, can result in the positive therapeutic effect.

In patients with an unspecific ulcerous colitis the relatively isolated damages of rectum and sigmoid colon, sigmoid colon and transverse colon, so total colitis are met. The necrosis component prevails as the acute form. The wall of bowel in such cases is swollen, hyperemic, with plural erosions and ulcers of irregular form. Its infiltration by lymphocytes, plasmocytes and eosinophils with characteristic formation of granulation, crypt and abscesses are microscopically observed. In patients with a chronic process prevail, mainly, reparative-sclerotic processes. A bowel is deformed, dense, segmentally narrowed. As a result of the disfigured regeneration plural granulomatous and adenomatous pseudopolypuses appear.

Pain in the abdomen and diarrhea is one of basic signs of unspecific ulcerous colitis with emptying from 3 to 20 and more times per days. Thus during defecation the mixture of liquid excrement, mucus and blood are observed. As far as progress of disease the pain has the intermittent character and is localized by the passing of colon. By palpation it is spastic and painful. Frequent diarrhea is brought to dehydration, loss of electrolytes, albumen and anaemia. Patients are weak, there are the strongly expressed signs of intoxication, the temperature of body rises to 40 oC and the psyche is repressed. Characteristic also are tachycardia, decline of arterial pressure, avitaminosises and edemata. Hypochromic anaemia is exposed in the general analysis of blood, leukocytosis, change of leukocyte formula to the left and increased ESR. In plasma of blood the decline of maintenance of potassium and sodium ions and level of general protein, especially albumen are marked. In future there are the progressive degenerative changes of parenchymatous organs.

At endoscopic examination (proctoscopy, fiberoptic colonoscopy) hyperemia of mucus membrane, swollen, contact bleeding, plural erosions, ulcers, festering and necrosis stratifications, are observed. At heavy passing of disease fiberoptic colonoscopy or irrigoscopy always has the danger of perforation or acute bowel dilatation, therefore more rationally it is to conduct it in the period of calming down of inflammatory process. During roentgenoscopy survey of organs of abdominal cavity in case of disease, complicated of acute toxic dilatation, the extended (from 10 to 20 cm and more) pneumatized bowel is exposed. During the perforation of bowel signs of pneumoperitoneum are present (air under the right cupula of diaphragm). Contrasting irrigoscopy examination in such patients enables to establish the presence of “water-pipe” symptom. Thrusting out of tailings of well-kept mucus membrane on the background of plural ulcers and cicatricial changes of bowel walls at pseudopolyposis creates roentgenologic reality of “shot target through” symptom (Pic. 3.3.9). Often in case of transformation of ulcerous colitis in the cancer on roentgenograms, stenosis cavity of bowel or defect of filling is observed (Pic. 3.3.10).

Acute, especially fulminant form of the unspecific ulcerous colitis passes the heaviest, so the prognosis is always doubtful. Taking it into account, death can come in the first days of disease. Thus an inflammatory process will strike all colon. During 1–2 days the heavy clinical picture is observed with frequent diarrhea with mucus, blood and pus, vomiting, dehydration and loss of weight of body. Next to that, deep intoxication, darkened consciousness, and the temperature of body rises to 39–40 oC is present. The expressed anaemia, tachycardia and hypovolemia are observed. The loss of albumens causes the decline of oncotic pressure and causes dehydration. The disbalance of electrolytes grows with progress of disease, microcirculation gets worse and day's diuresis goes down. In most cases this form of disease requires urgentoperative treatment (absolute indications).

A chronic recurrent unspecific ulcerous colitis is characterized by the periods of acuteening and remission. Thus in patients with the total lesions of colon in the period of acuteening the heavy degree of disease is observed, and in the period of remission— middle or even easy degree of disease, thus, such “calming down” can last 6 months and more.

A chronic continuous unspecific ulcerous colitis at the total lesions of intestine in most patients passes as middle heavy degree, and in the period of worsening the disease takes heavy shape. The easy form is met, mainly, at presence of inflammatory process in the rectum and sigmoid colon, considerably rarer it is at the lesions of left half of colon and quite rarely — at the total lesions in the period of calming down of the process. Conventionally, the unspecific ulcerous colitis begins from the rectum and engulfs all parts of colon. Thus emptying are 2–3 times per days with the admixtures of mucus, sometimes blood. Thus, diarrhea can be intermittent with constipation. The temperature of body remains within the limits of norm. From the side of global and biochemical analysis of blood noticeable changes do not arise. Weight of body does not diminish. At endoscopic examination hyperemia of mucus membrane, contact bleeding, expressed vascular picture, erosions, point hemorrhages and superficial ulcers are observed. It is needed also to mark that in this situation the presence of erosions must be equated with an ulcerous process.

The middle heavy form of disease of the unspecific ulcerous colitis can be met in

patients with the ulcerous colitis and proctosigmoiditis in the period of process acutening. Thus there are the subjective feelings with considerable expression of tenesmus and heartburns.

The chronic forms of unspecific ulcerous colitis both at total and at the left-side lesions of colon, pass at the level of middle heavy degree. Frequency of emptying reaches to 5–10 times with mucus, blood and pain. Low grade fever, general weakness, nausea and loss of appetite appear, and weight of body diminishes on 5–8 kg. Moderate anaemia is exposed in the general analysis of blood, leukocytosis, increased ESR. Among the biochemical indexes of blood hypoproteinemia and hypokalemia are marked. At endoscopic examination of colon there is a considerable hyperemia and edema of mucus membrane, plural erosions, contact bleeding and superficial ulcers.

The heavy form of unspecific ulcerous colitis is at the total lesions, especially with acute, and also chronic recurrent passing of disease. The temperature of body in such patient rises to 39–40 °C, there is diarrhea (more than 10 times per days) with mucus, blood and pus, vomitings, heavy intoxication grows, weight loss on 25–30 kg, acutely expressed anaemia, leukocytosis with the change of leukocyte formula to the left, considerable changes of albuminous and electrolyte exchanges. At endoscopic examination of colon the blood is exposed in its cavity, slid, pus, fibrin incrustation, often pseudopolypuses and almost complete absence of mucus membrane. Roentgenologically some signs of complications of unspecific ulcerous colitis are confirmed.

The complications are divided into local and general. Local complications are: profuse intestinal bleeding, perforation, acute toxic dilatation, stenosis and malignization. To general the following are included: damage of liver (hepatitis, cirrhosis), stomatitis, ulcer of lower extremities, lesions of joints, eyes and skin.

Acute dysentery passes with bloody diarrheas, increased temperature of body, pain in the abdomen. Bacteriological examination of excrement enables to expose dysenteric bacillus and specify diagnosis.

Crohn's disease (granulomatous colitis) is this local process, that begins from the submucosal layer of bowel and distributes outside of walls with subsequent formation of infiltrate, abscesses and fistula. Exposure of granulomas, and during microscopic examination — accumulation of lymphocytes, neutrophils, protoplasmatic cells and the Pyrohov-Lunghans' cells are confirmed diagnosis.

The cancer of colon, in particular its enterocolitis and toxicoanemic forms, also often can simulate an unspecific ulcerous colitis. Irrigoscopy, fiberoptic colonoscopy with biopsy and subsequent histological examination almost always help to diagnose cancer process.

Treatment of unspecific ulcerous colitis, certainly, begins with application of conservative facilities. Thus patients with easy and middle heavy forms must be under protracted conservative treatment.

The leading role is taken to the parenteral feed of patients with heavy common exhaustion (hydrolyzate of casein, aminopeptid, amynosol, vamin, alvesin, moriamin, intralipid, lipofundin, glucose and others like that). Electrolytes (chloride of sodium, sulfate of magnesium, chloride of potassium, panangin) and vitamins are entered (B6, B12, C, K, PP and others). Intensity and methods of conservative therapy always must depend on the phase of

disease:

a) moderately expressed passing of disease or proctitis — corticosteroid enema and sulfasalazone peroral;

б) at heavy passing is parenteral introduction of liquids, nutritives, blood transfusion, system use of corticosteroids, surgical treatment;

в) at chronic passing is corticosteroids peroral, asatioprine, surgical treatment;

г) at remission is preparations of 5-aminosalicylic acid peroral, examination for the exception of cancer of colon.

The heavy form of passing of disease is absent of effect from the conducted conservative treatment during two weeks and progress of process testifies to the necessity of surgical treatment.

The conservative treatment must include antibacterial agent, antidiarrheal preparations, steroid hormone.

A diet is considered an important factor in treatment of such patient (diet № 4). Thus it is recommended to take a meal to 6 times per days by small portions, withdrawing milk, fruit, vegetables, wheat and rye bread from it. It is possible to appoint unfat meat and fish. Parenteral introduction of vitamins B, C, A, folic acid are helpful.

The basic antiinflammatory facilities are: sulfasalazopreparations (sulfasalazone, salazopirine), salicylazosulfanilamide (salazosulfa-pyridine, salazodimetoxine) and corticosteroids. Practice showed that sulfasalazone was one of the best antirecurrent facilities.

In patients with easy and middle heavy forms (distal or left-side lesions of colon) sulfasalazone is applied in a dose about 5 g per days, and salazopiridazine and salazodimetoxine — about 2 g during that time. The course of treatment must proceed 1–2 months. For local steroid therapy prednisolone is used as powder in a dose 60–80 mg or hydrocortisone — to 125 mg. It is dissolved in 100 ml physiologic saline and entered rectal dropwise one time per days during 3–4 weeks.

At erosive proctitis and proctosigmoiditis 5 % (100,0 ml) solution of kolargole or extract of camomile in microclyster is applied.

At the heavy forms of ulcerous colitis with fulminant passing and frequent vomiting the treatment is needed to begin with intravenous introduction of 350–380 mg hydrocortisone per day. Thus procedures must proceed to appearance of positive clinical effect and realization of possibility of transition on enteral treatment. Such period lasts on the average of 6–7 days. In future it is recommended to adopt prednisolone peroral.

Sulfasalazopreparations is used in the same dose, as at the middle heavy form of flow of disease. As in patients at this form of disease water-electrolyte and albuminous exchanges are considerably violated, there are the expressed intoxication and anaemia, it is expedient to conduct adequate therapy (intravenously - NaCl solution, glucose, chlorous potassium, albumen, hemodes, protein, whole blood), and also hemodialysis and oxygenotherapy is used.

An absolute indication for surgical treatment is the presence of such complications of unspecific ulcerous colitis as: perforation of wall of bowel, acute toxic dilatation, stenosis, profuse bleeding and malignization. By the choice of method of operation at such pathology it is needed to count colproctectomy with exteriorization of ileostomy.

However, during the perforation of colon or toxic dilatation the operative treatment can be limited to colectomy because proctectomy will be conducted as the next stage.

For patients with total ulcerous colitis with chronic heavy passing and without the tendency to the visible improvement expedient radical operative treatment — colproctectomy with exteriorization of ileostomy. At such tactic postoperative lethality is diminished in 5-6 times, comparative with palliative operations which were conducted earlier.

In Western Europe and North America colorectal cancer (CRC) is one of most widespread malignant neoplasm. Morbidity in these regions exceeds 20,0 on a 100000 of population. In Japan, South America, Africa and countries of Asia this tumour is met rarer (6,0:100000). There is an annual increase of frequency of cancer of colon approximately by 3 % in the developed countries. Morbidity of population of Ukraine by malignant neoplasm in 1995 was 16,3:100000.

Approximately 85 % of patients for CRC are of over 50 years old, with age frequency of cancer is increased.

The nutrition by fat and albuminous food promotes the elimination to the intestine of bile. Under the act of bacterial flora there is transformation of primary bilious acids to the secondary, which has the carcinogenic and mutagenic activity. A meal with vitamins A, C and that which contains plenty of vegetable cellulose has a braking carcinogenic influence.

The factors of risk which predetermine the origin of cancer of bowel are:

- 1) diffuse (family) poliposis, which is considered obligate precancer;
- 2) plural and single adenomatous polypuses;
- 3) chronic unspecific ulcerous colitis (anamnesis more than 10 years);
- 4) Crohn's disease (granulomatous colitis).

Localization. A tumour is mostly localised in sigmoid (35–40 % cases) and blind (20–25 % cases) bowels.

Macroscopic forms. Exophytic tumours grow in the lumen of bowel as a polypus or knot and at disintegration have the appearance of ulcer with a dense bottom that is swelling by edges which come forward above the surface of the damaged mucus (saucer-shaped cancer). The endophytic (infiltrate) cancer grows in walls of bowel. The tumour spreads on the perimeter of bowel and engulfs it circular, causing narrowing of its lumen. In the right half of colon exophytic tumours grow, as a rule, in left — endophytic tumours.

Histological structure. Cancer of colon in 95 % cases has the structure of adenocarcinoma. Metastasis takes place by lymphatic and hematogenic ways in regional retroperitoneal lymphatic knots, liver, lungs.

The symptoms of cancer of colon are so numerous and various, that many authors group them in such clinical forms: toxico-anemic, dyspeptic, enterocolitic, obturation, pseudoinflammatory and tumular.

A toxico-anemic form shows up by indisposition, weakness, rapid fatigability, increase of temperature, progressive anaemia. Characteristic for the cancer of right half of colon.

The enterocolitic form is characterized by symptom of complex intestinal disorders: diarrhea, constipation, swelling, grumbling, pain.

The dyspeptic form is characterized by functional disorders of gastrointestinal tract.

An obturation form shows up by intestinal obstruction.

A pseudoinflammatory form is characterized by the symptoms of inflammatory process in the abdominal cavity.

A tumour form passes asymptomatic. A tumour is exposed by chance by a patient or doctor.

Obturation and enterocolitic forms more characteristic for the cancer of left half, other ones — of the right. For the cancer of right half of colon tendency to gradual progress is characteristic, and the tumours of left half often show up suddenly by intestinal obstruction.

Intestinal obstruction, germination in neighbouring organs and tissue, perforation, bleeding are considered as the most frequent complications of colon cancer.

Depending on the clinical signs of colon cancer, a differential diagnosis is to be conducted with appendiceal infiltrate, by different chronic specific and unspecific diseases of colon, and also other organs of abdominal cavity and retroperitoneal space (gall-bladder, pancreas, kidneys, genital organs and others like that), with the tumours of other organs of abdominal cavity and retroperitoneal space.

Radical treatment. Operative treatment is the unique method of radical treatment of colon cancer. The choice of method of operation depends on localization of tumour (Pic. 3.3.11). At cancer of right half of colon right hemicolectomy, (deleting of all right half of colon, including right third of transversal colon and distal segment of iliac bowel by length 20–25 cm) is conducted. In patients with tumours of left half of colon left hemicolectomy (segment from middle or from left third of transversal colon to overhead part of sigmoid is resected) is executed. At cancer of transversal colon, middle and distal parts of sigmoid bowels the resection of the damaged area is conducted, stepping back 5-6 cm from the edge of tumour. In patients who are hospitalized in an urgent order with the signs of intestinal obstruction, perforations and peritonitis, after intensive preoperative preparation the Hartmann operation is executed (at tumours of left half of colon). It is the resection of the damaged area of intestine and exteriorization of proximal segment on a front abdominal wall as colostomy. A distal end is sutured and is remained in the abdominal cavity. Through half-year there is a possibility of reconstructive operation. To the patients with the damage of right half of colon operation in a radical volume can be executed (right hemicolectomy).

During treatment with palliative purpose (at presence of solitary metastases) operations in a radical volume with removing of metastatic knot (in a liver) or subsequent chemotherapy (by 5- fluorouracil) can be used.

In recent years for the improvement of remote results treatment is applied by the adjuvant chemotherapy and intensive preoperative gamut-therapy.

The remote results of treatment of patients on the initial stages of CRC are fully satisfactory. At I stages the five-year survival is 85-100 %, at II — 65–70 %, at III — 25–30 %. On the whole at the I–III stages the five-year survival is 45 %.

Persons who refused from operative treatment perish in a short time. The combined treatment improves remote results approximately on 15–20%.

The basis of disease of pancreas is degenerative-inflammatory processes which are considered to be acute pancreatitis, the so called autolysis tissue by its own enzymes. In the

structure of acute pathology of organs of abdominal cavity this disease takes the third place after acute appendicitis and cholecystitis. Women suffer from acute pancreatitis 3–3,5 times more frequently than men.

Acute pancreatitis is a polyetiology disease. Its secondary forms, which arise on the background of pathologies of bile-excreting system and duodenum are closely associated with anatomic and functionally with pancreas, and are met in clinical practice.

Among the “starting” factors of origin of cholelithiasis disease (biliary pancreatitis) abuse by an alcohol and food overloads (fat and irritating products), traumas of pancreas, operating-room in particular, and also separate infectious diseases (parotitis, mononucleosis) are most frequent, especially infection of bilious ways. However, in 10–20 % of patients the reason of acute pancreatitis remains unknown (cryptogenic form).

In the basis of such damages of pancreas and enzymic toxemia lies mainly activating of pancreatic, and then the tissue enzymes (trypsin, lipase, amylase). Often the combination of the broken outflow of pancreatic secret and promoted secretion takes place, which provokes intraductal hypertension.

Among explanations of primary mechanisms of activating of pancreatic enzymes the most value belongs to: a) theory of “general duct” with reflux of bile in the ducts of pancreas; b) blockade of outflow of pancreatic juice with development of intraductal hypertension and penetration of secret in interstitial tissue; in) violation of blood flow of pancreas (vasculitis, thrombophlebitis and embolisms, cardiac insufficiency and others like that); g) toxic and allergic damages of gland. The role of alcohol in such situations can be dual: stimulation of secretion of pancreas and direct damaging action on its tissue.

The process of acute inflammation of pancreas consistently passes the stages of edema, pancreatonecrosis and festering pancreatitis. In the stage of edema there is pancreas of hyperemic, increased in volume, with the shallow hearths of necrosis or, as it is in swingeing majority of cases, without them.

Pancreatonecrosis can pass with fatty or hemorrhagic character. In the first case, as a rule, pancreas is increased, dense, cut whity-yellow hearths are selected to necrosis. Increase of crimson-black pancreas with darkly-brown infiltrate on a cut is characteristic for hemorrhagic pancreatonecrosis.

Dystrophy of parenchyma is exposed microscopically, up to necrosis, hemorrhages, thromboses of vessels and signs of inflammatory infiltration.

The disease begins suddenly, after the surplus reception of rich spicy food and use of alcohol. Pain, vomiting and phenomena of dynamic intestinal obstruction are considered the most characteristic signs of acute pancreatitis.

A stomach-ache is permanent and so strong, that can result in shock, localized in an epigastric area and left hypochondrium. Some patients feel pain in right hypochondrium with irradiation in the back, loin or breastbone.

In a short period of time after appearance of pain there is a repeated strong vomiting, that does not facilitate the state of patient.

In general vomiting is considered a frequent and characteristic symptom. It is repeated or continuous and never brings facilitation. Vomit masses contain bile, as admixture, and at the

difficult form of acute pancreatitis remind “coffee-grounds”.

Nausea, hiccup, belch and dryness in a mouth are attributed as less characteristic symptoms of this pathology.

During the examination the skin is pale, often subicterus. Some patients have cyanosis with a “marble picture” as a result of violation of microcirculation. Later the component of respiratory insufficiency can join it. At progressive general condition the patient quickly gets worse to passing of acute pancreatitis, intoxication grows. The skin takes shelter with sticky sweat.

The temperature of body of patients at the beginning of disease can be normal. It rises at resorption of products of autolysis tissue and development of inflammatory process in biliary ways.

The pulse in most cases is at first slow, then becomes frequent, notably passing ahead the increase of temperature of body.

Arterial pressure goes down.

The tongue in the first hour of disease is moist, assessed by white and grey raid. At vomiting by bile the raid has yellow or greenish tint.

The abdominal is blown away, peristaltic noises are loosened. The signs of paresis of stomach and intestine demonstrate early. They need to be included in the pathological process of mesentery root of bowel. At palpation painfulness in an epigastric area and in right, and sometimes and in left, hypochondrium is marked. However, in spite of great pain in stomach, it remains soft for a long time. A little later there is moderate tension or resistance of muscles of front abdominal wall.

Poor local symptoms during heavy intoxication are characteristic for the early period of acute pancreatitis. Later there are symptoms of irritation of peritoneum, and at percussion dulling is marked in lateral parts of abdominal as a result of accumulation of liquid, and also the sign of aseptic phlegmon of retroperitoneal cellulose as slurred or edema of lumbar area is seen. For diagnostics of acute pancreatitis there is the row of characteristic symptoms which have different clinical value.

The Mondor's symptom is violet spots on face and trunk.

The Lagermph's symptom is acute cyanosis of person.

The Halsted's Symptom is cyanosis of abdominal skin.

The Gray's symptom is cyanosis of lateral walls of abdomen.

The Kullen's symptom is the yellow colouring of skin near a belly-button.

The Korte's symptom is painful resistance as a lumbar bar in a epigastric area on 6–7 cm higher belly-button.

The Voskresynskyy's symptom is absence of pulsation of abdominal aorta in an epigastric area.

The Mayo-Robson's symptom is feeling of pain at pressure by fingers in the left costal-vertebral corner.

The Rozdolskyy's symptom — painfulness at percussion above pancreas.

The Blumberg's symptom — in patients with acute pancreatitis more frequently is low-grade. Such feature of this sign of irritation of peritoneum needs to be explained by

character of localization of pathological process, mainly in retroperitoneal spacious.

In clinical passing of pancreatonecrosis it is possible to select three periods (V.S. Saveljev, 1978).

The I period (hemodynamic violations and pancreatogenic shock) lasts during 2–3 days. Violation of central hemodynamics, diminishment of volume of circulatory blood and disorders of microcirculation, which at first arise as a result of angiospasm, are considered the most characteristic signs, and later as a result of joining of the intravascular rolling up and laying of elements of blood.

The II period (insufficiency of parenchymatous organs) lasts from 3rd to the 7th day of disease. Violation of functions of basic organs and systems, sign of cardio-vascular, hepatic and kidney insufficiency and growth of violations of breathing are thus observed. In this period there is possible damaging of the central nervous system, which is erected mainly to disorders of psyche, appearances of delirium and commas which in the eventual result are the main reasons of patients' death.

The III period (postnecrosis dystrophic and festering complications) comes in 1–2 weeks after the beginning of disease. During it, on the background of progress of necrosis processes in pancreas, the regenerative changes develop, there are parapancreatic infiltrate and cysts, cystic fibrosis of pancreas. Aseptic retroperitoneal phlegmon which strengthens intoxication can also develop. There is festering pancreatitis at joining of infection. During this period such complications, as erosive bleeding, internal or external fistula, retroperitoneal phlegmon, can develop in patients.

From laboratory information leucocytosis which at the necrosis and hemorrhagic forms of pancreatitis sometimes arrives at $25-30 \times 10^9$, lymphopenia, change of leukocytic formula to the left and the increased ESR are characteristic. Growth of activity of amylase of blood and urine is very often marked, and is the important sign of pancreatitis. For estimation of the state of other organs maintenance of general albumen and its factions, glucose of blood, bilirubin, urea, electrolytes, acid-base equilibrium (ABE), and also the state of blood coagulation are determined. It is necessary to mark that the exposure of hypocalcemia is considered a bad predictive sign of heavy passing of acute pancreatitis.

Ultrasonic examination (Pic. 3.5.1) of gall-bladder and pancreas often specifies the increase of their sizes, bulge of walls and presence or absence of concrement of gall-bladder and general bilious duct.

Computer tomography enables to describe in details the changes in pancreas and surrounding organs.

At sciagraphy survey of organs of abdominal cavity gives a possibility to expose the unfolded "horseshoe" of duodenum, pneumatization, expansion of transverse colon (the Gobia's symptom). On the 1st stage of diagnostics in the plan of differential diagnosis of acute destructive pancreatitis with other diseases of abdominal cavity, diagnostics of distribution of destructive damaging of different parts of pancreas and estimation of distribution of parapancreatitis is possible only by the method of computer tomography which depending on clinico-laboratory signs and weight of passing is needed to apply in a different period, and sometimes a few times in dynamics with interval of 4–5 days.

Laparoscopy and laparocentesis are often used for a doubtful diagnosis or necessity of taking away the exudation of abdominal cavity for biochemical or bacteriological examination.

Retrograde endoscopic cholangiopancreatography is used in case of mechanical icterus and suspicion of choledocholithiasis. The last methods are invasive and can if it is necessary transform from diagnostic to manipulation treatments: laparoscopic draining of abdominal cavity at pancreatogenic peritonitis and endoscopic papillotomy at choledocholithiasis and biliary pancreatitis.

Clinical passing of disease can be abortive, slowly or quickly progressive. At abortive passing the process is limited to acute edema of pancreas with convalescence in 7–10 days.

Rapid progress is characteristic for pancreatonecrosis. In patients expressed toxemia, impregnation by exudation of retroperitoneal cellulose and development of fermentative hemorrhagic peritonitis can be seen. Strengthening of stomachache, continuous vomiting, proflaccid paresis of intestine, positive symptoms of irritation of peritoneum and growth of hemodynamic violations are the clinical signs of necrosis of pancreas.

There is a formation of parapancreatic infiltrate at slow progress.

Among early complications of acute pancreatitis shock, peritonitis and acute cardiac, pulmonary, hepatic and kidney insufficiency can be distinguished.

Before later complications it is needed to deliver the abscesses of pancreas, subdiaphragmatic, interintestinal abscesses, pyogenic abscess omentum bag, phlegmons of retroperitoneal space and erosive bleeding.

In future formations of pseudocysts, fistula of pancreas, intestinal fistula and development of saccharine diabetes are possible.

Acute pancreatitis needs to be differentiated with the row of acute diseases of organs of abdominal cavity.

Acute mechanical intestinal obstruction. In patients with this pathology pain is of the alternated character and is accompanied by nausea, vomiting, delay of gases and emptying. It is possible to see the Kloyber bowls on the sciagram survey of organs of abdominal cavity.

Acute cholecystitis runs with characteristic localization of pain and muscular defense, with presence of increased, painful gall-bladder or infiltrate in right hypochondrium. Often acute (especially lately) pancreatitis develops on the background of gallstone disease (biliary pancreatitis).

Thrombosis or embolism of mesenteric vessels. Both for pancreatitis and for the thrombosis of mesenteric vessels great pain at soft abdomen (absence of defense muscles of front abdominal wall), that precedes to development of peritonitis, is inherent. Yet from the beginning the disease gains heavy character of passing. In anamnesis in such patients a heart disease or heart attack of myocardium rheumatic is met. As a result of gangrene of intestine, the symptoms of peritonitis appear very quickly and intoxication grows. The fragments of mucus shell are found in flushing waters of intestine at the detailed examination, which have the appearance of "meat flushing".

A perforated gastric and duodenum ulcer is distinguished by the presence of dagger pain, defense of abdominal wall, ulcerous anamnesis.

The conservative method is considered the basic one for treatment of acute pancreatitis,

but in connection with that unsuccessful conservative treatment of patients with acute pancreatitis can often put a question about the necessity of operation, therefore patients must be in permanent surgical establishment. Thus acute pancreatitis with heavy passing is necessary to be treated under the conditions of separation of intensive therapy.

Before conservative treatment hunger, bed rest, fight against pain and enzymic toxemia, conducting of acid-base state, prophylaxis of festering infection and acute ulcers of digestive duct are to be entered .

Patient's stomach is washed by cold soda solution and a cold on an epigastric area and left hypochondrium is used. Medicinal therapy is prescribed also: spasmolytics (papaverine, platyphyllin, no-shparum, baralgin, atropine); inhibitor of protease (contrical, trasilol, gordox, antagosan); cytostatic agent (5-fluorouracil, ftorafur). Positive action of inhibitor of protease is marked only in the first days of disease which are subject to conditioned application of large doses. Antibiotics of wide spectrum of action: a) tienam, which most effective in the prophylaxis of festering pancreatitis, as is selected by pancreatic juice; b) cephalosporins (kefzol, cefazoline); c) cefamizine (mefoxine).

Disintoxication therapy is conducted also (5 % but 10 % solutions of glucose, hemodes, reopolyhukine, polyhukine, plasma of blood, only from 3 to 5 liters on days, in accordance with a necessity).

For the improvement of rheological properties of blood heparine is prescribed (5 000 ODES every 4 hours).

If patients have the expressed pain syndrome and phenomena of general intoxication during all pain period plus 48 hours (by Bakulev), hunger is used. Such mode lasts on the average of 2–4 days. The parenteral feed of albuminous hydrolyzate is thus conducted, by the mixtures of amino acid and fatty emulsion. Alkaline water of to 1–2 l. and albuminous-carbohydrate diet are also appointed. Infusion therapy is complemented by plasma, by albumen, hemodes, reopolyhukine. The improvements of microcirculation in pancreas are achieved due to introduction of reopolyhukine, komplamine, trental and heparin 5000 ODES 6 times per days under the control the indexes of the coagulation system of blood. Anticholinergic drug (sulfate of atropine, methacin, platyphyllin), H₂-histamin blocker (cimetidine, ranisan, ranitidine, famotidine, omeprazol) are also applied. For the removal of pain: 1) sulfate of the atropine 0,1 % — 1 ml + promedol 2 % — 1 ml + papaverine 2 % — 2 ml + analgin 50 % — 2 ml; 2) isotonic solution of chloride of sodium — 500 ml + baralgin — 5 ml + diphenhydramine hydrochloride 1 % — 1 ml + papaverine 2 % — 2 ml + magnesium the sulfate 25 % — 5 ml + ascorbic acid — 5 ml + lipoic acid 0,5 % — 2 ml + novocaine 0,5 % — 10 ml. are used. From the first days by a nasogastral probe the permanent aspiration of gastric maintenance is conducted also. The Motility function of gastro-intestinal highway gets better at application of cerucal or primperane. With the same purpose forced diuresis (maninil, furosemide, aminophylline) is used on the background of intravenous introduction of plenty of liquid.

At uneffective conservative treatment of patients with acute pancreatitis of middle weight and heavy form it is expedient to apply surgical treatment.

Surgical treatment is carried out for patients with biliary pancreatitis (for a day long

from the beginning of disease) in combination with the destructive forms of cholecystitis, at complications of acute pancreatitis by peritonitis, abscess of omentum bag or phlegmon of retroperitoneal cellulose.

Overhead-middle laparotomy, which allows to estimate the state of pancreas, biliary ways and other organs of abdominal cavity, is the best access in this situation. In case of destructive pancreatitis the possible use of lumbar laparotomy from left to right hypochondrium through a mesogastric area is useful.

Cholecystectomy is executed at calculous cholecystitis, phlegmonous inflammation of walls of gall-bladder and biliary pancreatitis. If there are more than 0,9 cm at expansion of choledochus, presence of concrement, ointment-like bile in it, increase of concentration of bilirubin in the whey of blood over 21 mmol/L, choledocholithotomy is complemented by external draining of choledochus. Information of lithiasis of general biliary duct is absent, cholecystectomy in patients with acute pancreatitis is complemented by external draining of choledochus, better by Pikovskyy method (through stump of cystic duct).

Transduodenal sphincteroplasty is shown at fixed concrement of large duodenal papilla (Pic. 3.5.2), if they are diagnosed intraoperative, and also in the cases of papillotomy with extraction of concrement when there is no possibility to execute endoscopic operation .

Omentopancreatopexy. After laparotomy and cutting of gastro-colon and gastro-pancreatic ligament mobile part of large omentum through opening in gastro-colon ligament is conducted and fixed by separate stitches to the peritoneum along the overhead and lower edges of pancreas. Such operation needs to be considered rational at the expressed edema of pancreas and presence of necrosis in it.

Abdominisation of pancreas. A cellulose round pancreas (along the lower and overhead edges of body and tail) is infiltrated by solution of novocaine, after it parietal peritoneum is cut. Under the body and tail glands free end of omentum is conducted and is bundled by a gland. This operation is able to warn the hit of enzymes and products of disintegration in retroperitoneal space.

Sequestrectomy is deleting of necrosis part of gland within the limits of nonviable tissue. Operation is executed in a dull way.

Necrectomy (deleting of necrosis part of gland within the limits of healthy tissue) is executed by an acute way: tissue of gland is cut on verge of necrosis and bleeding vessels are carefully bandaged.

The resection of pancreas is deleting the part of organ with its transversal cutting within the limits of the unchanged (ad oculus) tissue of gland. The resections of tail and body of pancreas are distinguished (Pic. 3.5.3).

Pancreatectomy is a complete deleting of pancreas. Operative treatment is applied infrequently. After the resection of pancreas adequate draining of its bed is very responsible.

The prognosis of disease depends on character of morphological changes of parapancreatic to the cellulose in pancreas. The more difficult destructive changes, the worst the prognosis.

Chronic pancreatitis is a progressive inflammation of pancreas with the periodic acutening and remission, related to the process of autolysis, that shows up by pain, by violation

of exocrine and endocrine functions of gland with the eventual result of fibrosis of organ and high risk of malignization.

A gallstone disease is considered the most frequent reason of chronic pancreatitis. Pathogenesis of cholangiogenic pancreatitis acted in pancreatic ducts (theory of general duct) is in part of difficulty of outflow of pancreatic secret and reflux of infected bile or maintenance of duodenum. Dyskinesia, spasms and stenosis of the Vater's papilla of duodenum are instrumental in reflux. Bile or duodenal maintenance, that gets Wirsung's duct, activates the enzymes of pancreas and is instrumental in the origin of its inflammation. Development of pancreatitis potentiates infection. The last can penetrate pancreas not only due to reflux but also in a hematogenic or lymphogenic way.

Thus, chronic pancreatitis develops as a result of functional violations of pancreas, which with the flow of time pass to organic. The reasons of such violations are the attack of acute pancreatitis suffered the in past, alcoholism, traumas of gland, pathology of its vessels, gastroduodenal ulcers, gastritis or duodenostasis.

The morphological changes in pancreas at chronic pancreatitis are mainly taken to development of passionately-degenerative processes and atrophy of parenchyma. Connecting tissue in such cases develops both in the particles of gland and between them. In one case the process has diffuse character, in the other it is limited. Thus pancreas becomes dense as a result of excrescence of connecting tissue. It can be multiplied, taking shape of chronic hypertrophy pancreatitis. Atrophy of gland comes in other cases, besides, not evenly in different parts.

The inflammatory edema of parenchyma is exposed in case of acutening of process. Hemorrhages, fatty necrosis and pseudocysts are exposed on the surface of cut.

As passing of disease has cyclic character with the periodic changes of remission and acutening, the clinic of chronic pancreatitis depends on the phase of development of inflammatory process. Violation of excretory and incretory functions of pancreas influences polymorphic of symptoms which remission is especially determining in the phase.

Pain, dyspepsia phenomena and progressive loss of weight of body are the basic signs of chronic pancreatitis. Besides, pain, is permanent, changes only its intensity, mainly in epigastric region, sometimes on the left, burning, squeezing or prickly, comes forward the unique symptom of disease, complaints about it precede other symptoms. In some patients the pain feelings increase in lying position. Therefore patients occupy forced sitting position. Intensity of pain can change throughout a day. Patients explain it by acceptance of rich, fried food, boiled eggs, coffee. The last is the principal reason of acutening of process with acute pain syndrome.

It is needed to mark, that occasionally passing of chronic pancreatitis can take hidden, smooth shapes, with the moderately expressed pain syndrome or pain, that has atypical character, for example, stenocardia. In such patients the symptoms related to violations of exogenous function of pancreas come forward. They complain about absence of appetite, nausea, belch, sometimes vomiting and diarrhea with putrid smell. Thirst, general weakness and progressive loss of weight is observed also.

At palpation of abdomen pain does not arise, or it is quite insignificant. It is sometimes succeeded to palpate horizontally placed pancreas as dense, moderately painful tension bar.

The transmission of pulsation of aorta at palpation in a epigastric area count characteristic for pathology.

During intervals between the attacks the feeling of patients remains satisfactory.

Development of saccharine diabetes is the basic sign of endocrine insufficiency, hypoglycemia is rarer. The feature of this form of saccharine diabetes consists in the fact that it shows up in a few years after the beginning of disease, runs easier and often carries latent character. There can be hypoglycemia at the insufficient products of glucagon.

The syndrome of biliary hypertension with development of mechanical icterus and cholangitis determining it can develop in some patients. The reasons for such cholestasis more frequently are tubular stenosis of choledochus, choledocholithiasis or stenotic papillitis. There is duodenal obstruction in some cases.

Important information about it can be given by the laboratory and instrumental methods of examination.

Examination of excretory function of pancreas is based on establishment of level of amylase in the whey of blood and urine. In acutening period of chronic pancreatitis this level of amylase rises, the numbers of tripsin and lipase grow.

Coprologic examination. Macroscopic picture of excrement gets greyish color, in large masses — with unpleasant smell. Steatorrhea (increase of amount of neutral fat) and creatorrhea are characteristic for it (a plenty of muscular fibres).

Examination of incretory function of pancreas includes: 1) determination of sugar in blood and urine (characteristic is hyperglycemia and glycosuria); 2) radioimmunoassay of hormones (insulin, C-peptide and glucagon).

Sciagraphy survey of organs of abdominal cavity in two projections enables to expose existent concrement in ducts and calcificat in parenchyma of pancreas.

Relaxation duodenography. Thus the development of “horseshoe” of duodenum and change of relief of its mucus can be seen (Pic. 3.5.4).

Cholecystocholangiography with the purpose of diagnostics of gallstone disease and second damaging of bilious ways is conducted.

Ultrasonic examination (sonography) is one of the basic methods of diagnostics. With the help of symptoms of chronic pancreatitis it is possible to expose inequality of contours of gland, increase of closeness of its parenchyma, increase or diminishment of sizes of organ, expansion of pancreatic duct and wirsungolithiasis or presence of concrement of parenchyma. Thus it is necessary to inspect gall-bladder, liver and bile-excreting ways for diagnostics of gallstone disease and choledocholithiasis (Pic. 3.5.5).

Scintigraphy of pancreas. On early stages strengthening of scintigraphic picture is observed, on later ones — defects of accumulation to radionuclide (symptom of “sieve” or “bee honeycomb”).

Computer tomography allows to expose the increase or diminishment of sizes of gland, presence of calcificats, concrement, inequality of contours of organ, focuses or diffuse changes of its structure (Pic. 3.5.6, Pic. 3.5.7).

Endoscopic retrograde cholangiopancreatography (ERCPG). Expansion of pancreatic duct its deformation, wirsungolithiasis is marked, (Pic. 3.5.8).

It is expedient to apply laparoscopy in the phase of acutening of chronic pancreatitis at development of fatty and hemorrhagic pancreatonecrosis (“stearin name-plates”, exudation).

The puncture biopsy of pancreas under sonography control can have an important value for differential diagnostics of pancreatitis and cancer.

Percutaneous transhepatic cholangioduodenography and -stomy. This method is used both for differential diagnostics of pseudo tumor-like form of chronic pancreatitis and cancer of pancreas and with the purpose of preoperative preparation at presence of icterus. During it there is a possibility to expose expansion of intra- and out-of-hepatic ducts, localization and slowness of their stricture.

Chronic recurrent pancreatitis. The changes of periods of acuteening and remission are characteristic for it. The first period shows up by the attacks of pain of different frequency and duration, and during remission patients feel satisfactory.

Chronic pain pancreatitis. Intensive pain in the overhead half of abdomen with an irradiation in loin and region of heart is inherent for this form. Also belting pain often appears.

Chronic painless (latent) pancreatitis. In patients with this form of pathology for a long time the pain is either absent in general or arises after the reception of spicy food rich and can be insignificantly expressed. Violation of excretory or incretory function of pancreas come forward on the first plan.

Chronic pseudo tumor-like pancreatitis. Dull pain in the projection of head of pancreas, dyspepsia disorders and syndrome of biliary hypertension are clinical its signs.

Chronic cholangiogenic pancreatitis. Both clinic of chronic cholecystitis and cholelithiasis and clinic of pancreatitis are characteristic for this form.

Chronic indurative pancreatitis. In patients with this diseases symptoms of excretory and incretory insufficiency of pancreas are present. The low indexes of amylase in blood and urine are characteristic. At the expressed sclerosis of head of pancreas the with including process of general bilious duct, development of mechanical icterus is possible.

Among complications of chronic pancreatitis, fatty dystrophy and cirrhosis of liver, stricture of terminal part of general bilious duct, ulcers of duodenum, thrombosis of splenic vein, saccharine diabetes, pseudocysts of pancreas, exudation pleurisy and pericarditis and heart attack of myocardium are observed.

Disease of gall-bladder and bilious ways (gallstone disease, dyskinesia of bilious ways). For these diseases pain in right hypochondrium is inherent, that irradiates in right shoulder-blade and shoulder. At chronic pancreatitis pain is localized in epigastric area, left hypochondrium, often is of belting character. One of the basic additional methods of inspection for confirmation of diseases of gall-bladder and ducts is sonography.

Ulcerous disease of stomach and duodenum. Pain at ulcerous disease is seasonal (relapses more frequent in spring and autumn), unites with heartburn and has tendency to diminishment after vomiting. In patients with chronic pancreatitis pain arises after faults in a diet, often is of belting character. Frequent vomiting is determining, that does not bring facilitation to the patient. Also violations of excretory and incretory functions of pancreas can take place.

Abdominal ischemic syndrome. Patients with this pathology complain about pain, that

arises at once after the reception of meal, somewhat diminishes after application of spasmolytics. For the disease considerable weight loss and waiver of meal in connection with dread of pain attack can be characteristic. The basic method of examination, with a necessity for differential diagnostics, celiacography is useful, which enables to expose occlusion of abdominal trunk or its compression. During conducting of differential diagnostics with two last nosologies it is necessary to state a possibility of origin of secondary pancreatitis.

Cancer of pancreas. Mechanical icterus and presence of Courvoisier's symptom are considered the clearest and most important displays of cancer of head of pancreas, and carcinoma of body and tail is a proof pain syndrome. For the cancer the damage of pancreas, rapid progress of symptomatology are characteristic, and for chronic pancreatitis the protracted passing with proper clinical symptomatology and changes which can be exposed by the laboratory, roentgenologic and instrumental methods of examination are characteristic. The most informative among methods of diagnostics of cancer of pancreas are sonography (echo-producing formations in parenchyma of pancreas), computer tomography (tumor knots) and puncture biopsy of gland with the histological examination (reliable diagnostics of cancer).

Heart attack of myocardium. In anamnesis of patients with the heart attack of myocardium it is possible to expose pain behind breastbone, that arises at the physical activity and emotional stress, it is irradiated in left shoulder-blade and left shoulder, unrelated with the reception of meal and disappears as a result of action of coronarolytics. The typical changes of ECG confirm the diagnosis of heart attack of myocardium. In addition, no violations of external and incretions of pancreas are characteristic. The roentgenologic and instrumental methods of examination can help in differential diagnostics.

Treatment is conducted in the phase of acutening of chronic pancreatitis, as well as at its acute form. In the first days the bed rest and medical starvation is prescribed without limitation of alkaline drink (mineral water). The fight against pain syndrome includes application of anaesthetic preparations and spasmolytics (promedol, analgin, baralgin, papaverine, no-shparum, platyphyllin). Preparation action is directed on the decline of pancreatic secretion (atropine, methacin, sandostatine, dalargin, stilamine, somatostatine) or on oppression of gastric secretion: H₂-blockers (hystodil, cimetidine, hastrocepin, ranisan, tagamet and others like that), antiacides (almagel, gastropan). Appoint, next to it, and antihistaminic preparations (diphenhydramine hydrochloride, suprastine, fenkarol, tavegil). Antienzymic therapy is also important: a) inhibitor of protease (contrical, trasilol, hordox, antagosan), the dose of which must depend on the level of hyperenzymeemia; b) cytostatic agent (ftorafur, 5-fluorouracil); c) chemical inhibitor of tripsin (aminocapronic acid, pentoxil). For the improvement of microcirculation at this pathology heparin, reopolyhlucline and reohluman are applied. The ponderable value is achieved by disintoxication therapy (hemodes, hluconeodes, enterodes). With the purpose of parenteral feed 5–10–40 % glucose with insulin, plasma, albumen, alvesyn, polyamin and lipofundine are used. Normalization of agile function of organs of digestion is achieved by settings of cerucal and reglan. In complex treatment it is necessary to include vitamins (C, B₁, B₆, B₁₂) and anabolic hormones (retabolil, nerobol).

At calming down of the inflammatory phenomena a diet № 5 is prescribed in pancreas and conduct correction of excretory insufficiency of pancreas (festal, pansinorm,

pancreosymin, digestal and others like that). With the purpose of stimulation of function of pancreas it is possible to apply secretin.

Correction of endocrine insufficiency of pancreas. At development of the secondary saccharine diabetes of easy degree a diet is recommended with limitation of carbohydrates, bukaran, maninil and other peroral preparations, at middle and heavy degrees — insulinotherapy.

Physical therapy procedures. Except medical treatment it is possible to apply inductothermy, microwave therapy (high frequency) and electro-stimulation of duodenum. For spa treatment visiting of Morshyn, Husjatyn, Shidnytsja is recommend.

Indication to operation and its volume depend on the form of pancreatitis. Acutening of chronic cholangiogenic pancreatitis at presence of gallstone disease must be examined as indication to operation in first 24 hours since disease's beginning. Operative treatment is done in case of:

- 1) calcinosis pancreas with the expressed pain syndrome;
- 2) violation of patency of duct of pancreas;
- 3) presence of cyst or fistula of resistance to conservative therapy during 2–4 months;
- 4) mechanical icterus on soil of tubular stenosis of distal part of general bilious duct;
- 5) compression and thrombosis of portal vein;
- 6) gallstone disease complicated by chronic pancreatitis;
- 7) ulcerous disease of stomach and duodenum complicated by secondary pancreatitis;
- 8) duodenostasis, complicated by chronic pancreatitis;
- 9) impossibility of exception to operation tumors or violations of arterial circulation of blood of pancreas.

Cholecystectomy at presence of calculous cholecystitis and secondary pancreatitis, acute destructive cholecystitis or hydropsy of gall-bladder.

Choledocholithotomy is executed for patients with cholangiolithiasis: a) with the deaf stitch of general bilious duct (use rarely); b) with its external draining for taking of infected bile (cholangitis), decline of biliary hypertension (at the edema of head of pancreas); c) with internal draining (at tubular stenosis of distal part of general bilious duct, acute expansion of choledochus with the complete loss of elasticity of its wall (execute one of variants of choledochoduodenostomy).

Papillosphincterotomy: a) execute transduodenal with papillosphincteroplasty; b) endoscopic is recommended at the isolated or connected with choledocholithiasis stenosis of large duodenal papilla, fixed concrement of large papilla of duodenum.

Wirsungoplasty is scission of plastic arts of narrow part or distal part of main pancreatic duct (apply at patients with stricture of proximal part of duct by a slowness no more than 2 cm). Lately at the isolated stenosis of bee-entrance of main pancreatic duct endoscopic wirsungotomy is executed.

Pancreatojejunostomy: a) longitudinal (it is executed at considerable expansion of pancreatic duct);) caudal (by Duval) with the resection of distal part of pancreas (Pic. 3.5.9).

Resection of pancreas: a) distal or caudal; b) distal subtotal; c) pancreatoduodenal (PDR); e) total duodenopancreatectomy heads or bodies of gland (execute in case of fibrous-

degenerative pancreatitis).

Oklusion of ducts of pancreas by polymeric connections (cianocrylat, prolamine, neopren and others like that) results in atrophy of exocrine parenchyma, but keeps to the islet of tissue.

Operations on the nervous system are used in case of the pain forms of chronic indurative pancreatitis, resistant to conservative therapy, in default of rough morphological changes of parenchyma, stroma of gland and deformation of main pancreatic duct: a) left-side splanchnicectomy; b) bilateral pectoral splanchnicectomy and sympathectomy; c) postganglionic neurotomy of pancreas.

Cyst of pancreas is a cavity, filled by liquid (pancreatic juice, exudation, pus), intimately soldered with head, body or tail of organ, is limited by capsule, which has epithelium on internal surface.

Pseudocyst (unreal cyst) is a cavity in pancreas which appears as a result of its destruction, limited by capsule, that does not have epithelium on internal surface.

The reasons of pseudocysts are destructive pancreatitis, traumas of pancreas, oklusion of Wirsung's duct by parasite, concrement, tumors, innate anomalies of development.

To the real cysts belong: innate (dysontogenetic) cysts which are anomalic in development; acquired retention cysts which develop as a result of difficult outflow of pancreatic juice, cystadenoma and cystadenocarcinoma (by mechanism the origins belong more frequently to proliferative, sometimes — degenerative cysts).

The mechanism of development of pseudocysts consists in the focus necrosis of gland, difficult normal outflow of its secret, there is a destruction of walls of pancreatic ducts with overrun of pancreatic juice gland that causes reactive inflammation of peritoneum of surrounding organs which form the walls of pseudocyst.

Morphologically the cysts of pancreas are divided into: pseudocysts retention to the duct are innate, single and multiple.

Pseudocysts are fresh and old. The internal surface of fresh pseudocyst is rough, granulating, grey-red. The table of contents is alkaline, grey or with a brown tint. In an old pseudocyst the wall is smooth and shiny, pale-grey. The table of contents is lighter. Epithelium pseudocysts is absent. More frequently they are met in body and tail of gland and are not connected with ducts.

Retention cysts connected with an obturated duct. The cavity has smooth, grey-white surface, maintenance is transparent, watery or mucous-like. Innate cysts are mainly multiple and shallow. A simple retention cyst differ from those that are always connected with the anomalies of development of ducts and are unite with polycystosis buds and liver.

Rarely there are echinococcus cysts, which have a clear chitinous shell, liquid in cavity and daughter's blisters. They are localized in the area of head of pancreas.

According to clinical passing pseudocysts are divided into acute, subacute and chronic.

According to weight of passing — into simple (uncomplicated) and complicated.

In patients with the cystic damaging of pancreas there can be pain of different character and intensity (dull, permanent, cramp-like and belting). It is localized more frequently in right hypochondrium, epigastric area (cyst of head and body of gland), left hypochondrium (cyst of

tail of pancreas). Pain is irradiated in the back, left shoulder-blade, shoulder and spine.

Dyspepsia violations are characteristic. Nausea, vomiting and belch are observed.

The syndrome of functional insufficiency of pancreas shows up by disorders of exocrine and endocrine insufficiency and depends on the degree of damage of organ. The unsteady emptying, replacement of diarrhea of constipation, steatorrhea and creatorrhea, development of the second diabetes are marked.

Compression syndrome. Arises as a result of compression of neighbouring organs. Clinically the compression of organs of gastro-intestinal highway shows up by complete or partial obstruction of general bilious duct (mechanical icterus), vein (portal hypertension) gate, splenic vein (splenomegaly).

During the examination patients with large cysts are marked by asymmetry of abdomen in epigastric and mesogastric areas. At palpation of abdomen tumular formation of elastic consistency with an even, immobile surface is found.

Sonography examination shows echo-free formation with a clear capsule, determines localization and sizes of cyst (Pic. 3.5.10).

Contrasting roentgenologic examination of stomach and duodenum with the sulfate of barium at the cyst of head of pancreas exposes moving of pyloric part of stomach upwards and breeding of „horseshoe” duodenum (at relaxation duodenography in the conditions of low artificial blood pressure). If a cyst is localized in the area of body of gland, displacement of stomach is marked forward and upwards or downward, rapprochement of its walls, moving of duodenal transition and loops of thin bowel downward and to the right; at lateral projection the distance between stomach and spine is increased. The cyst localized in the area of tail of gland, displaces the stomach forward and upwards, to the left or to the right (Pic. 3.5.11).

Cholecystocholangiography exposes calculous cholecystitis and cholelithiasis.

Retrograde pancreatocholangiography exposes the changed and deformed, infrequently extended pancreatic duct, occasionally there can be filling of cavity of cyst by the contrasting matter.

Computer tomography shows accumulation of liquid limited by the capsule of different closeness and thickness (Pic. 3.5.12).

Laboratory examinations exposes hyperamylasemia, steatorrhea and creatorrhea, sometimes — hyperglycemia and glycosuria.

Clinical passing of cysts of pancreas depends on their kind, localization, size, stage of forming and complications.

Four stages of forming of pseudocyst are distinguished (P.G. Karaguljan, 1972).

I stage (1–1,5 months last) — in the center of inflammatory process the cavity of disintegration, which takes surrounding tissue, appears in an omentum bag.

The II stage (2–3 months) is characterized by the beginning of forming of capsule of pseudocyst. Cyst is magnificent, unformed, acute inflammatory phenomena calms down.

The III stage (3–12 months) is completion of forming of capsule of pseudocyst. Last accretes with surrounding organs.

The IV stage (begins an in year from the origin of cyst) is a separated cyst. The cyst is mobile, easily selected from connections with surrounding organs.

Retention cysts arise at closing of lumen of pancreatic duct (concrement, sclerosis). The internal surface of cyst is covered with epithelium. Pain syndrome, violation of exocrine function of gland are characteristic.

Traumatic cysts belong to the pseudocysts with similar passing and clinic, as well as inflammatory pseudocysts.

Parasite cysts (to echinococcus, cysticercotic) are met as casuistry. In such patients Kaconi test and serological Weinberg's reaction are positive.

The variants of clinical passing of the real and unreal cysts depend on their complications.

Perforation in free abdominal cavity. Clinic of the poured peritonitis is characteristic. Tormina, positive symptoms of irritation of peritoneum, possible shock state as a result of irritation of peritoneum by pancreatic juice arise.

Perforation in stomach, duodenum, small, rarer in large intestine is accompanied by diminishment of cyst in sizes or complete disappearance, sometimes diarrhea appears.

Suppuration of maintenance of cyst is accompanied by pain which becomes more intensive, temperature rises, leucocytosis grows.

The erosive bleeding appears suddenly and is accompanied by the symptoms of internal bleeding (expressed general weakness, dizziness). The pallor of skin and mucus shells, sticky death-damp, tachycardia and anemia are observed.

Mechanical icterus arises as a result of compression of cyst on the terminal part of choledochus. The icterus of skin and mucus shells, acholic excrement, dark urine, hyperbilirubinemia, increase of the ALT and AsT level are exposed.

Portal hypertension develops as a result of compression of portal vein. Ascites, varicose expansion of veins of esophagus and stomach, moderate icterus are diagnosed.

Reactive exudation pleurisy more frequently arises in left pleura cavity, where roentgenologic exudation is diagnosed with high maintenance of amylase.

At malignization the walls of cyst specific symptoms are absent, a diagnosis is set during operation (surgical biopsy of cyst wall).

The cysts of pancreas are differentiated with the tumors of abdominal cavity and of retroperitoneal space.

Cancer of pancreas. For the cancer tumor of pancreas syndrome of "small signs" (discomfort in epigastric area, loss of appetite, general weakness), permanent dull pain, unrelated with the reception and composition of meal, icterus (cancer of head of gland), Courvoisier's symptom (increased, unpainfully gall-bladder) are characteristic. Inconstant pain at cysts of pancreas is more frequently related to faults in a diet; in anamnesis destructive pancreatitis, traumas of gland are carried. Sonography examination, retrograde pancreatocholangiography and computer tomography help in establishment of diagnosis.

Tumors of retroperitoneal space are passed asymptomatic, clinic shows up by a considerable compression on neighbouring organs. Nausea, vomit, chronic intestinal obstruction, dysuric disorders arise. Clinic of cysts of pancreas, on the opposite, are expressed on early stages. Pain, dyspepsia syndromes, syndrome of exocrine and endocrine insufficiency of pancreas are characteristic. Pain is related to the reception of meal and alcohol.

Aneurism of abdominal aorta. Dull, indefinite pain in abdomen which is unrelated with the reception of meal, pulsation and pulsating formation in abdomen are characteristic, auscultatory is systolic murmur. Aortography allows to confirm a diagnosis.

The cyst of mesentery of thin bowel has painless passing, at palpation it is mobile, easily changes position in abdomen. The cysts of pancreas are practically immobile, pain, anamnesis and laboratory information are characteristic.

The cyst of liver has protracted asymptomatic passing. Pain appears at infection of cyst. For this pathology symptoms which take place at the cysts of pancreas are not typical (pain related to the reception of rich food, alcohol, hyperamylasemia). Topic diagnostics is carried out at ultrasonic examination, scintigraphy, computer tomography.

Conservative treatment. Treatment of acute or chronic pancreatitis is conducted in accordance with principles. At the unfavorable dynamics of passing the diseases hunger with the permanent sucking of gastric maintenance, parenteral feed and intravenous introduction of liquids are appointed. Puncture of cysts is used through abdominal wall under sonography control with aspiration of maintenance.

Surgical treatment is the method of choice of treatment of cysts of pancreas. The choice of treatment method depends on the stage of forming of pancreas cysts.

On the I stage operation is not used, conservative treatment of pancreatitis is conducted. On the II stage it is used at suppuration of pseudocyst (external draining of cyst). On the III — internal draining of cyst is used. More frequently cystojejunostomy on the eliminated loop of thin bowel by Roux (Pic. 3.5.13), cystojejunostomy with entero-entero anastomosis by Brawn and closing of afferent loop by Shalimov. Cystogastrostomy (Pic. 3.5.14) are executed and cystoduodenostomy is now not applied because of possible complications (infection of cyst, erosive bleeding). Marsupialization (opening and sewing down of cyst to the parietal peritoneum and skin) is used infrequently (at suppuration of cyst is seriously patientsing with the septic state). On the IV stage external and internal draining of cyst and radical operations are applied: a) enucleation of cysts (executed very rarely); b) distal resection of pancreas with a cyst.

The cancer of pancreas is a malignant tumor of epithelium tissue. Its specific gravity among all malignant tumors makes 10 %. Greater part of patients with cancer of pancreas (to 80 %) is made by the persons of capable working age.

The origin of cancer of pancreas is related to character of nutrition: with the promoted maintenance of albumens and fats in meal.

Shortage of vitamins, especially B and C, harmful habits (abuse of alcohol, smoking), presence of carcinogenic matters in food (nitrite, nitrates and others like that), tonsillectomy suffered in the past also belong to etiologic factors. The cancer tumor of pancreas can arise on the background of protracted period of chronic pancreatitis.

A cancer tumor is localized in the head. Rarer — in the area of body or tail, rarer there is a diffuse damage of pancreas.

A tumor has the appearance of a dense knot or conglomerate of knots of different sizes. It resembles epithelium of pancreatic ducts or epithelium of acinous tissue, sometimes — the Langerhans' islet.

Adenocarcinoma (50–55 %) is exposed microscopically, carcinoid (32–35 %), epidermoid cancer or skin is seldom met.

The cancer of pancreas gives metastases quickly enough which spread in lymphogenic way in parapancreatic lymphatic knots, and afterwards — in the gate of liver. The hematogenic metastases are often exposed in lungs, bones, buds and brain. Possible also remote metastases to the type of Virhov's, Shnitsler's, Krukenberg's.

The clinical signs and passing of cancer of pancreas are various. They depend both on localization of tumor in pancreas and the mutual relations of pathological process with surrounding organs or tissue.

Pain is a permanent symptom on which 60–90 % patients specify. It is conditioned by involvement in the process of nervous elements of pancreas and retroperitoneum space. The pain feelings at cancer of pancreas are unrelated with acceptance of meal, can be periodic with irradiation in the back. The insignificant loss of weight makes progress and for a short time becomes considerable enough. Such is clinic of cancer of body and tail of pancreas.

Icterus is characteristic of the cancer of head of pancreas, that arises as a result of obturation of general bilious duct and develops slowly but with steady growth. At palpation of abdomen Courvoisier's symptom is observed. Protracted, to 3–4 weeks, icterus results in piling up of products of disintegration of bile in blood and tissue, causing heavy intoxication of organism, violation of liver unction, buds and coagulation system of blood. Obturation of duct of pancreas causes dyspepsia disorders: belch, nausea, vomiting, diarrhea (“fat” emptying). Distributions of tumor on duodenum and narrowing of its lumen show up by the signs of stenosis of exit from the stomach of a different degree (feeling of plenitude in a epigastric area, periodic pain, belch and vomiting).

Bilirubinemia grows gradually, mainly due to direct bilirubin. The increase of activity of alkaline phosphatase and level of cholesterol are observed in blood. As at mechanical icterus a bile does not get the intestine, stercobilin in excrement is absent (acholic excrement). There is also no urobiliny in urine, although bilious pigments are present there (bilirubin). It is possible to expose steatorrhea and kreatorrhea in excrement as a result of obturation of pancreatic duct and exception of enzymes of pancreas from digestion.

With the help of radioimmunoassay it is sometimes succeeded to mark the increase of level of tumor markers in the whey of blood: cancer-embryo to the antigen, ferritin.

Sciagraphy of gastro-intestinal highway can expose the cancer heads of pancreas, the unfolded “horseshoe” of duodenum, and in case of localization of tumor in the body of gland — displacement of back wall of stomach forward. At duodenoscopy rigidity of mucus shell of descending part of duodenum, narrowing of its lumen are determined, and sometimes there is germination of bowel by tumor.

Scanning is an informing method of examination with the use of ^{75}Se -methionine. Such examinations can expose the hearths of reduced accumulation of isotope or its absence in tissue of gland at the damage by tumor.

During laparoscopy the cancer of pancreas is visualized infrequently, however, dissemination of peritoneum and its metastatic hearths in liver are diagnosed without difficulties.

By ultrasonic (sonography) examination it is succeeded to expose the places of promoted closeness of tissue of gland, sign of mechanical icterus at localization of tumor in the head.

Most informing among all is computer tomography (Pic. 3.5.15). It is possible to define both the tumor of gland and its size and metastatic knots. The changes of main duct of pancreas as segmental stenosis or breaking are fixed on retrograde endoscopic pancreatography.

Clinical passing of cancer of pancreas in 70 % patients is marked by the background diseases and complications. This circumstance allows to select a few clinical forms of the cancer of pancreas before appearance of icterus: pancreatitic, diabetogenic, cholangitic and gastritis-like. The names specify the feature of clinical signs of different forms of disease.

Mechanical icterus is the heaviest complication of cancer of pancreas. With the increase of duration and growth of its intensity development of such dangerous complications, as hepatic or hepatic-kidney insufficiency, cholemic bleeding is possible.

Anamnesis has an important value for differential diagnostics. The presence of attacks of pain or intermittent icterus testifies its calculous origin. A pain syndrome at the cancer of pancreas does not have such acuteness and intensity, as at gallstone disease. Icterus in cancer patients, unlike cholelithiasis, develops gradually, incessantly grows and is of proof character.

Often substantial difficulties arise during conducting the differential diagnostics of obturative and infectious icterus. It is necessary to remember, that at viral hepatitis the level of transaminase and aldolase in the whey of blood rises by 2–3 times. At obturation icterus their level does not change substantially, and the increase of activity of alkaline phosphatase and instead of that the level of cholesterol is marked.

However, most operation difficulties are met during conducting the differential diagnosis of the cancer of pancreas and chronic indurative pancreatitis. In fact both processes during examination and palpation produce similar pictures. In such cases puncture of the densest area of pancreas is executed and cytologic examination is quickly conducted.

Treatment of cancer of pancreas is mainly surgical. The choice of method and volume of operation depends on localization of tumor, stage of process, age of patient and his general condition.

Taking it into account, as practice shows, radical operations in the moment of establishment of final diagnosis are successfully executed only in 15–20 % of patients. Pancreatoduodenal resection is the method of choice of operation in patients with the damage of head of pancreas. Operation foresees deleting one block of head of pancreas, distal part of stomach, duodenum and distal part of general bilious duct. Four anastomosis are thus imposed: gastroenteroanastomosis, cholecysto-enteroanastomosis or choledochenteroanastomosis, pancreatoentero-anastomosis and enteroenteroanastomosis. Sometimes this operation is executed in two stages. On the first one biliary-enteric anastomosis is formed for taking bile and improvement of function of liver, and the second stage is carried out in 3–4 weeks. However, more frequently symptomatic operations are to be executed: cholecysto-enteroanastomosis or choledochoduodenoanastomosis. They are able to liquidate icterus and prolong the life of patients for 5–9 months. In case of damage of body and tail of pancreas the distal subtotal resection of gland with spleen is radical.

POSTVAGOTOMY SYNDROMES

RELAPSE OF ULCER

Etiology and pathogenesis

The relapse of ulcer is enough frequent complication of vagotomy. It meets in 8–12 % patients. The reasons of such relapses of ulcer can be: 1) inadequate decline of products of hydrochloric acid (incomplete vagotomy, reinnervation); 2) disturbance of emptying of stomach (ulcerous pylorostenosis after selective proximal vagotomy or after pyloroplasty); 3) local factors (duodenogastric reflux with development of chronic atrophy gastritis, disturbance of circulation of blood and decline of resistibility of mucous tunic); 4) exogenous factors (alcohol, smoking, medicinal preparations); 5) endocrine factors (hypergastrinaemia: hyperplasia of antral G-cells, the Zollinger-Ellison syndrome; hyperparathyroidism).

Clinical management

Three variants of clinical passing of relapse of ulcer are distinguished after vagotomy: 1) symptomless, when an ulcer is found during endoscopic examination; 2) recurrent with protracted lucid space; 3) persisting ulcer with typical periodicity and seasonality of exacerbation.

It is needed to underline that the clinical signs of this pathology during the relapse are less expressed, than before operation, and absence of pain does not eliminate the presence of ulcer. Sometimes bleeding can be first its sign. Complex examination, that includes roentgenologic, endoscopic examination, study of gastric secretion and determination of content of gastrin in the blood, allows not only to expose an ulcer but also, in most cases, to set its reason. The interpretation the results of gastric secretion examination in such patients are heavy. Taking into account it, it is needed to study both a basal secretion and secretion in reply to introduction of insulin and pentagastrin, and also level of pepsin.

Pic 3. Postvagotomy dilatation of the stomach.

Tactic and choice of treatment method

Approximately in 35 % patients, mainly with the first two variants of clinical passing of disease, the relapses of ulcers, are treated by ordinary methods of conservative therapy. Yet in 30–40 % cicatrization of ulcers comes after application of preparations which stop a gastric secretion (cimetidine, ranitidine—150 mg for night). At other 10–20 % patients, mainly with the third variant of clinical passing, is necessary operative treatment.

The question of choice of the repeated operation in patients with the relapse of ulcer after vagotomy still does not decided. Some surgeons execute revagotomy, trunk vagotomy with drainage operation, revagotomy with antrectomy or resection of stomach. However much majority from them in case of relapse ulcer after vagotomy performed antrectomy in combination with trunk vagotomy.

Postvagotomy diarrhea

Etiology and pathogenesis

Frequency of postvagotomy diarrhea hesitates from 2 to 30 %. The basic sign of complication in patient is present the liquid watery emptying about three times per days. The reasons of diarrhea are: gastric stasis and achlorhydria, denervation of pancreas, small intestine and liver, and also disturbance of motility of digestive tract. Discoordination of evacuations from a stomach, stagnation and hypochlorhydria assist to development in it different microorganisms, and it also can be the reason of diarrhea.

Clinical management

The clinical signs of postvagotomy diarrhea are specific. Acute beginning are typical –patient often does not have time to reach to the rest room. Such suddenness repressing operates on patients. As a result they are forced whole days to be at home, expecting the duty attack. An excrement changes colorings as a result of breeding of pigment and becomes more light.

Tactic and choice of treatment method

Treatment of diarrhea must be complex. Above all things it is needed to recommend a diet with the exception of milk and other provoking products. For the removal of bacterial factor antibiotics are applied. Favourable action in case of the signs of stagnation in a stomach are had weak solutions of organic acids (lemon, apple and others like that).

Among other most distribution was got by the A.A. Kuragin and S.D. Hroismann (1971) suggestion to treat postvagotomy diarrhea by benzohexamethonium (for 1 ml 2,5 % solution 2–3 times per a day). Reported also about successful application of cholesteramine (for 4 g 3 times per a day with the subsequent decline of dose to 4 g per days).

At heavy passing of postvagotomy diarrhea, that does not respond to conservative treatment, it is needed to recommend operative treatment — degastroenterostomy with pyloroplasty. However, the type of drainage operation, as practice shows, does not influence on frequency of diarrhea origin. In this connection, some surgeons with success applied the inversion of the segment of thin bowel, located distal from the area of maximal absorption.

Differential diagnostics and clinical variants

Menetrie syndrome is pseudotumor gastritis. The disease rarely. Etiology and pathogenesis is unknown. During disease observed the increasing of folds of mucus stomach by the height up to 3 cm and thickness up to 2 cm. Deep cracks, which the massive bleeding are from, appear between folds. Diagnostics of bleeding is confirmed by endoscopy. Treatment is conservative, including the hemostatic therapy. If conservative treatment are uneffective, indicated resection of stomach. During operation round a stomach the megascopic lymphatic knots with soft consistency are observed.

Hemobilia is bleeding from bilious ways and liver to the intestine. Meets in 0,01 % all gastric bleeding of unulcerous genesis.

The most frequent reason of hemobilia is the traumas of liver. Among other reasons are inflammatory processes of liver, external bilious ways (abscesses, cholangitis), vascular anomalies as aneurism of hepatic artery and vein gate.

The typical signs of hemobilia: attack-like pain in right hypochondrium, moderate icterus, anaemia, presence of grume in vomiting masses and in the excrement which looks like a pencil or worm (imprints of bilious ducts). Bleeding have cyclic passing (repeat oneself in

6–8 days). A diagnosis is based on the clinical signs, information of endoscopy, at which founded the blood flow to the duodenum from a general bilious duct or bloody clot in the papilla Vateri. The most diagnostic value has selective angiography of the hepatic artery and cholangiography, which allow to expose the flowline of contrasting matter in tissues of liver.

Bleeding from biliary tracts during the damage of large vessels can be severe. So, operation is the unique treatment method in such cases. In patients with hemobilia performed opening, draining and tamponade of the haematomas with obligatory draining of general bilious channel for decompression of biliary tracts. The most radical method some surgeons count opening of haematoma with bandaging of bleeding vessel and bilious channel or resection of liver. Bandaging of hepatic artery after angiographic study of the intraorgan arterial vessels is sometimes recommended only. Better to bandage that branch of hepatic artery from which observed bleeding.

The particle of the rare extragastric diseases complicated by the acute gastrointestinal bleeding is 2 %. Among them the diseases of blood are met, blood vessels, system diseases (leukosis, haemophilia, autoimmune thrombocytopenia, hemorrhagic vasculitis, the Werlhof's disease and others like that).

Leukosis are tumours which developed from hemopoietic cells. Etiology and pathogenesis to this time is not exposed. Patients with a leucosis with the gastrointestinal bleeding is 1 % of all patients with the un ulcerous bleeding.

During leucosis in the process of extramedullar hematosis the cells of vascular wall and vessel are pulled in and from the circulatory changed into hemopoietic, that results in disturbance of permeability of vessel wall. In development of hemorrhage diathesis large part is acted the changes of thrombocytopenia, declines of growth of tissue's basophiles, which produce heparin, that shows up by wide hemorrhages in a gastrointestinal tract. Bleeding can be both insignificant and threatening to life of patient. In establishment of diagnosis sometimes there is enough simple examination of blood (hyperleukocytosis), to suspect leucosis bleeding. During endoscopy in such patients observe the presence of flat, superficial defects of mucus stomach. A final diagnosis is based on the results of biopsy and haematological examination of bone marrow.

Treatment includes complex application of hemostatic, preparations of blood and cytostatic agents, that results in the stop of bleeding and even to bring a patient into remission.

Haemophilia is the innate form of bleeding which caused by the deficit of one of three antihemophilic factors (VIII, IX, XI). The gastrointestinal bleeding is observed in 6–24 % patients with haemophilia. Absence or insufficient content in the blood of antihemophilic globulin lies in basis of disease. At diminishment of it level below 30 % there is bleeding. Haemophilia is inherited, men are ill more frequent.

Pointing in anamnesis on bleeding from babyhood allow to suspect haemophilia. Roentgenologic information and results of fibergastroscopy does not expose the substantial changes in a gastrointestinal tract. Main in diagnostics of haemophilia — examination of the system of blood coagulation. Time of blood coagulation continued to 10–30 minutes, sometimes a blood does not coagulate by hours.

Treatment is directed on compensation of insufficient components of the of blood

coagulation system. In patients with haemophilia A, for which typical deficit of antihemophilic globulin, fresh blood transfusion is indicated, because in a banked blood a antihemophilic globulin collapses during a few hours. At haemophilia B and C are used dry and native plasma, cryoprecipitate, banked blood, because factors IX, XI, which predetermine the form of haemophilia, is kept in them long. ordinary hemostyptic preparation (vicasol, the C vitamin, chloride of calcium and others like that) does not give the effect. So, if form of haemophilia does not established, the treatment is necessary to begin from fresh blood transfusion, antihemophilic plasma and antihemophilic globulin transfusion.

Autoimmune thrombocytopenia, or idiopathic thrombocytopenic purpura, is accompanied by the gastrointestinal bleeding and is arisen up in 0,5–2 % patients. Often bloody vomiting and black excrement conditioned by swallowing of blood from a nose and gums.

The disease shows up by plural hypodermic hemorrhages and hemorrhages into submucous membrane. At girls and women the uterine bleeding is often observed. Thrombocytopenia on very low numbers and it is the most pathognomonic sign of disease. Typical acute increase of duration of bleeding, especially in the period of acute hemorrhage.

Fresh blood and thrombocyte mass transfusion is the most effective treatment in the case of the gastrointestinal bleeding during autoimmune thrombocytopenia. Other hemostatic preparations are indicated also. During operative treatment performed splenectomy. The absolute indications to it are frequent and protracted bleeding, threat of hemorrhage in a brain.

The Schonlein-Henoch disease is hemorrhagic vasculitis, which caused by plural microfocus microthrombovasculitis. The gastrointestinal bleeding at the Schonlein-Henoch disease is observed in 0,5–1 % cases and accompanied with great pain in a epigastric area like “abdominal colic”. For this disease typical presence of purpura which has the symmetric location on the external surface of feet, legs, shoulders, buttocks, also joint syndrome with pain and edema in large joints, kidney syndrome by the type of acute or chronic glomerulonephritis. Women have the possible uterine bleeding. The intestinal bleeding can be accompanied by the edema of wall of intestine, that results in invagination or perforation of wall of bowel.

The basic and pathogenetic treatment method of patients is early application of heparin with blood transfusion, introduction of heparinized blood under the control of blood coagulation, which after adequate therapy must be increased in two times, comparative with a norm. For a patient in the initial form of disease indicated introduction of antibiotics of wide spectrum of action, hormones of adrenal glands cortex.

The diseases of the operated stomach (postgastrectomy and postvagotomy syndromes) are the diseases which arise up after surgical treatment of peptic or duodenum ulcer or other pathology of these organs.

Dumping syndrome is frequent complication of operations which are related to deleting or disturbance of function of goalkeeper (resection of stomach, vagotomy with antrectomy, vagotomy with drainage operations). It takes place in 10–30 % patients.

The rapid receipt (dumping) is considered the starting mechanism of dumping syndrome. During this concentrated, mainly carbohydrate, food passed from a stomach in an empty bowel.

In the phase changes of motility of thin bowel during dumping syndrome important part is acted by the hormones of thin bowel. In endocrine cells of APUD-системи on during dumping-syndrome observed degranulation and presence of hormones of mothiline, neurotensin and enteroglucagon.

The inadequate mechanical, chemical and osmotic irritation of mucous tunic of thin bowel by chymus results for the acute increase of blood flow in a bowel. The last is accompanied by the considerable redistribution of blood, especially in heavy case of dumping syndrome : blood supply of head, lower extremities is diminishes, a blood flow in a liver is multiplied.

The numeral examinations resulted in creation of osmotic theory —the principal reason of dumping syndrome is the decline of volume of circulatory plasma as a result of coming a plenty of liquid into the lumen of thin bowel from an of circulatory system and intercellular space.

For the clinical finding of dumping syndrome typical there is the origin of attacks of general weakness during acceptance of food or during the first 15–20 minutes after it. The attack begins from feeling of plenitude in a epigastric area and is accompanied by the unpleasant feeling of heat, that “spills” in the overhead half of trunk or on all body. Thus is acutely multiplied sweating. Then there is a fatigue, appear somnolence, dizziness, noise in ears, shaking of extremities and worsening of sight. These signs sometimes achieve such intensity, that patients forced to lie down. Loss of consciousness could be in the first months after operation. The attacks are accompanied by tachycardia, sometimes by the shortness of breath, headache, paresthesia of upper and lower extremities, polyuria and vasomotor rhinitis. At the end of attack or after it patients often notice grumbling in a stomach and diarrhea.

A milk or carbohydrate food is the most frequent provoking factor of dumping syndrome. In a period between the attacks patients complain about rapid fatigueability, weakening of memory, decline of working capacity, change of mood, irritates, apathy. During roentgenologic examination after 5–15 minutes observed the increased evacuation of barium mixture through anastomosis by a wide continuous stream, expansion of efferent loop and rapid advancement of contrasting matter in the distal parts of thin bowel (Pic. 3.2.16).

By the expression of symptoms dumping syndrome is divided into three degrees of weight:

I degree is easy. Patients have the periodic attacks of weakness with dizziness, nausea, that appear after the use of carbohydrates and milk food and last no more than 15–20 min. During the attack a pulse becomes more frequent on 10–15 per min., arterial pressure rises or sometimes goes down on 1.3-2 KPa (10–15 mm Hg), the volume of circulatory blood diminishes on 200–300 ml. The deficit of mass of body of patient does not exceed 5 kg. A working capacity is well-kept. Medicinal and dietary treatment gives a good effect.

II degree — middle weight. Attacks of weakness with dizziness, pain in the region of heart, hyperhidrosis, diarrhea. Such signs last, usually, 20–40 min., arise up after the use of ordinary portions of some food. During such state a pulse becomes more frequent on 20–30 per min., arterial pressure is rises (sometimes goes down) on 2–2,7 KPa (15–20 mm Hg), the volume of circulatory blood diminishes on 300–500 ml. The deficit of mass of body of patient

achieves 5–10 kg. A working capacity is reduced. Conservative treatment sometimes has a positive effect, but brief.

The III degree is hard. Patients are disturbed by the permanent, acutely expressed attacks with the collaptoid state, by a fainting fit, by diarrhea, which do not depend on character and amount of the accepted food and last about 1 hour. During the attack is multiplied frequency of pulse on 20–30 per 1 min; arterial pressure goes down on 2,7–4 KPa (20–30 mm Hg), the volume of circulatory blood diminishes more than on 500 ml. The deficit of mass of body exceeds 10 kg. Patients, as a rule, are disabled. Conservative treatment is uneffective.

The problem of treatment of patients with dumping syndrome is not easy. Before the surgical treatment, as a rule, must precede conservative. Patients with the disease of easy and middle degrees respond to conservative treatment, mainly with an enough quite good effect. At the heavy degree of disease such treatment more frequent serves as only preparation to operative treatment. If a patient does not give a consent for operation or at presence of contraindications to operative treatment (disease of heart, livers, kidneys), conservative therapy is also applied. Such treatment must include dietotherapy, blood and plasma transfusion, correction of metabolism, hormonal preparations, symptomatic therapy, electro-stimulation of motility function of digestive tract.

The dietotherapy: using of high-calorie, various food rich in squirrel, by vitamins, by mineral salts, with normal content of fats and exception from the ration of carbohydrates which are easily assimilation (limitation of sugar, sweet drinks, honey, jam, pastry wares, kissel and fruit compotes). All it is needed to use by small portions (5–6 times per days). If the signs of dumping syndrome appear after a food, such patients it is needed to lie down and be in horizontal position not less than 1 hour. At the heavy degree of dumping syndrome patients need to eat slowly, desirably lying on left. Such position creates the best terms for evacuation of food from a stomach. Thus recommend also to repudiate from too hot and cold foods.

Medicinal treatment must include sedative, replaceable, antiserotonin, hormonal and vitamin therapy. The indications to operative treatment of patients with dumping syndrome are: heavy passing of disease, combination of dumping syndrome of middle degree with other postgastrectomy syndromes (with the syndrome of efferent loop, hypoglycemic syndrome and progressive exhaustion) and uneffective of conservative treatment of the dumping syndrome of middle degree. Most methods of operative treatment of dumping syndrome are directed on renewal of natural way of passing of food on a stomach and intestine, improvement of reservoir function of stomach and providing of proportioning receipt of food in a thin bowel.

Depending on reasons and mechanisms of development of dumping syndrome there are different methods of the repeated reconstructive operations. All of them can be divided into four basic groups: I. Operations which slow evacuation from stump of stomach. II. Redoudenization. III. Redoudenization with deceleration of evacuation from stump of stomach. IV. Operations on a thin bowel and its nerves.

Basic stages of reconstructive operations: 1) disconnection of adhesions in an abdominal cavity, releasing of gastrointestinal and interintestinal anastomosis and stump of duodenum; 2) cutting or resection of efferent and afferent loops; 3) renewal of continuity of upper part of digestive tract.

For correction of the accompany postgastrectomy pathology it is better to apply combined anti- (iso-) peristaltic gastrojejunoplasty. Thus transplant by length 20–22 cm, located between a stomach and duodenum, must consist of two parts: antiperistaltic (7–8 cm), connected with a stomach, and isoperistaltic, connected with a duodenum. An antiperistaltic segment brakes dumping of stomach stump, and isoperistaltic — hinders the reflux of duodenum content.

The attacks of weakness at a hypoglycemic syndrome arise up as a result of decline of content of sugar in a blood. It is accompanied by a acute muscular weakness, by headache, by falling of arterial pressure, by feeling of hunger and even by the loss of consciousness. It is needed to remember, that at this pathology, unlike dumping-syndrome, acceptance of food especially sweet facilitates the state of patient. However in some patients both syndromes unite and the attacks of weakness can arise up as directly after food intake, so in a few hours after it. In patients with such pathology the best results are got after antiperistaltic gastrojejunoplasty (Fink, 1976).

The postgastrectomy (agastric) asthenia arises up as a result of disturbance of digestive function of stomach, pancreas, liver and thin bowel.

In patients with such pathology stump of stomach almost fully loses ability to digest a food. It is related to the small capacity of stump and rapid evacuation of food from it, and also with the acute decline of production of hydrochloric acid and pepsin. In the mucous tunics of stump of stomach, duodenum and thin bowels as a result of fall of trophic role of gastrin and other hormones of digestive tract there are the progressive atrophy changes. Absence in gastric juice of free hydrochloric acid is the reason of acute diminishment of digestive ability of gastric juice and decline of it bactericidal. Such situation is assist in advancement to ascending direction of virulent flora, to development duodenitis, hepatitis, cholecystitis, dysbacteriosis, hypovitaminosis and decline of antitoxic function of liver. All it results in acute disturbance of evacuation from a stomach.

The clinical signs of postgastrectomy asthenia arise up after a some latent period which can last from a few months to some years. During this period patients often complain for a general weakness and bad appetite. The basic symptoms of postgastrectomy asthenia are: general weakness, edemata, acute weight loss, diarrhea, skin and endocrine abnormalities. The postgastrectomy asthenia more frequent meets at men at 40–50 years. In most cases diarrhea is the first symptom of disease, that can arise up in 2 months after operation. Diarrhea, usually, has permanent character and sometimes becomes profuse.

Weight loss appears too early, the deficit of mass of body achieves 20–30 kg. A patient quickly loses forces.

Conservative treatment is the blood, plasma and albumen transfusions. These preparations are prescribed 2–3 times per a week. Correction of disturbances of electrolyte exchange is conducted at the same time (transfusion of solutions to potassium, calcium and others like that). For the improvement of processes of albumen synthesis anabolic hormones are prescribed.

Operative treatment foresees the inclusion in the digestion process of duodenum, increase of capacity of stump of stomach and deceleration of evacuation of its content.

The afferent loop consists of part of duodenum, that stopped behind after a resection, area of empty bowel between a duodenojejunal fold and stump of stomach. The syndrome of afferent loop can arise up after the resection of stomach after the Bilroth-II method. Violation of evacuation from a afferent loop and vomiting by a bile are its basic signs.

Acute and chronic obstruction of afferent loop are distinguished. The reason of acute obstruction is mechanical factors: postoperative commissure, volvulus, internal hernia, invagination, jamming behind mesentery of loop of bowel and stenosis of anastomosis.

Frequency of origin of sharp obstruction of afferent loop hesitates within the limits of 0,5–2 %. The disease can arise up in any time after operation: in a few days or a few years.

Chronic obstruction of afferent loop (actually syndrome of afferent loop), as well as acute, can arise up in any time after operation, however more often it develop after the resection of stomach with gastroenteroanastomosis on a long loop, especially when operation is performed without entero-enteroanastomosis by Brown.

The etiologic factors of syndrome of afferent loop are divided into two groups: 1) mechanical (postoperative commissure, invagination, disturbance of evacuation on a afferent loop, wrong location of afferent loop, very long afferent loop, fall of mucous tunic of afferent loop into a stomach); 2) functional (hypertensive dyskinesia of bilious ways and duodenum, damage and irritation of trunks of vagus nerves, hypotensive and spastic states of upper part of digestive tract, heightened secretion of bile and juice of pancreas under act of secretin and cholecystokinin).

For the clinical picture of acute obstruction typical is permanent, with a tendency to strengthening, pain in a epigastric area or in right hypochondrium, nausea and vomiting. At complete obstruction a bile in vomiting masses is absent. The general condition of patient progressively gets worse, the temperature of body rises, leukocytosis grows, tachycardia grows. At the objective examination painful and tension of muscles of abdominal wall is observed. In a epigastric area it is often possible to palpate tumular lump. Possible cases, when the increase of pressure in a bowel is passed on bilious ways and channels of pancreas. There can be pain and icterus in such patients. There are necrosis and perforation of duodenum with development of peritonitis during further progress of process. Acute obstruction of afferent loop in an early postoperative period can be the reason of insufficiency of stump of duodenum also.

During the roentgenologic examination of organs of abdominal cavity it is visible round form area of darkening and extended, filled by gas, bowels loop.

Patients, usually, complain for feeling of weight in a epigastric area and arching in right hypochondrium, that arises in 10–15 min. after acceptance of food and gradually grows. Together with that, appear nausea, bitter taste in a mouth, heartburn. Then there is increasing pain in a right to epigastric area. During this pain arises intensive, sometimes repeated vomiting by a bile, after which the all symptoms disappear. It could be after certain kind of food (milk, fats) or its big amount. Very rarely vomiting by bile unconnected with the feed. In heavy case patients lose up to 1 liter of bile with vomiting masses. During the objective examination observed subicteritiousness of the sclera, sign of dehydration of organism (decline of turgor of skin, dry tongue, oliguria, concentrated urine). Emptying is irregular, grey color, with considerable content of undigested fat and muscular fibres. Anaemia can develop at heavy

passing of disease.

Distinguished easy, middle and heavy degrees of afferent loop syndrome. In patients with the easy degree of disease vomiting is 1–2 times per a month, and insignificant regurgitation arise up through 20 min – 2 hour after a food, more frequent after the use of milk or sweet food. At middle degree of afferent loop syndrome such attacks repeat 2–3 times per week, patients are disturbed by the considerably expressed pain syndrome, and with vomiting up to 200–300 ml of bile is lost. For a heavy degree the daily attacks of pain are typical, that is accompanied by vomiting by a bile (up to 500 ml and more).

A roentgenologic examination of the patients with the afferent loop syndrome is unspecific. Neither the passing of contrasting matter nor absence of filling of afferent loop can be considered as pathognomic signs of syndrome of afferent loop.

Treatment of acute obstruction of afferent loop is mainly operative. Essence of it is the removal of barriers of evacuation of content from an afferent loop. Adhesions are dissected, volvulus is straightened, invagination or internal hernia is liquidated. For the improvement of evacuation between afferent and efferent loops performs the entero-enteroanastomosis type “end-to-end” or after the Roux method.

Conservative treatment of syndrome of afferent loop is ineffective and, mainly, is mean the removal of hypoproteinemia and anaemia, spasmolytic preparations and vitamin are appointed. With this purpose a blood, plasma and glucose is poured with insulin, a novocaine lumbar blockade and blockade of neck-pectoral knot, washing of stomach is also done.

All operative methods of treatment of afferent loop syndrome can be divided into three groups:

- I. Operations, that will liquidate the bends of afferent loop or shorten it.
- II. Drainage operations.
- III. Reconstructive operations.

The operations of the first group, directed on the removal of bends and invagination of afferent loop, can not be considered as radical. They need to be performed only at the grave general condition of patient.

The widest application in clinical practice at the syndrome of afferent loop has the operation offered by Roux (Pic. 3.2.17).

For the prophylaxis of afferent loop syndrome it is necessary to watch after correct imposition of anastomosis during the resection of stomach: to use for the gastroenteroanastomosis short loop of thin bowel (6–8 cm from the Treits ligament) for imposition, to sew afferent loop to small curvature for creation of spur, to fix reliably stump of stomach in peritoneum of transverse colon.

The origin of reflux after the distal resection of stomach is conditioned by some factors:

- I. Traumatic factors: 1) traction of stomach during operation as reason of sprain of ligament of proximal part of stomach and mobilization of large curvature of stomach; 2) cutting of vessels of stomach and oblique muscles of it wall, in particular on small curvature; 3) vagotomy, that is accompanied by cutting of phrenico-esophageal and gastrophrenic ligaments; 4) imposition of gastrointestinal anastomosis, especially direct gastroduodenoanastomosis by Billroth-I, that results in smoothing of the Hisa corner; 5) frequent aspiration of gastric content

in a postoperative period, that causes superficial esophagitis.

II. Trophic factors: 1) damage of vessels which are the reason of ischemia in the area of esophago-gastric connection, and thrombophlebitis of cardial part of stomach; 2) disturbance of influencing of neurohumoral factors which take part in innervations of esophagus; 3) disturbance of trophism of diaphragm as a result of hypoproteinemia and weight loss; 4) ulcerous diathesis and megascopic volume of gastric secretion (especially nightly); 5) regurgitation of alkaline content of duodenum in stump of stomach which reduces tone of its muscular shell.

III. Mechanical factors: 1) gastric stasis; 2) diminishment of volume of gastric reservoir, that is accompanied by the increase of intragastric pressure.

The clinical picture of gastroesophageal reflux is conditioned by the mechanical and chemical irritations of esophagus by content of stomach or thin bowel. As a result, there is esophagitis, which can be catarrhal, erosive or ulcerous-necrotic. The symptoms of reflux are very various and can simulate different diseases of both pectoral and abdominal cavity organs.

The basic complaint of patients with this pathology is a smart behind a breastbone, especially in the area of the its lower part. It, usually, spreads upwards and can be accompanied by considerable salivation. Strengthening of pain at inclinations of trunk gave to the French authors an occasion to name this sign the “symptom of laces”. Unendurable heartburn is the second complaint, that arises up approximately in 1–2 hours after the food intake. Patients forced often to drink, somehow to decrease the unpleasant feelings, however this, certainly, does not bring them facilitation. Some of them, in addition, complain for bitter taste in a mouth.

Pain behind a breastbone often can remind the attack of stenocardia with typical irradiation. Sometimes such reflux is able to provoke real stenocardia.

Hypochromic anaemia is the frequent symptom of gastroesophageal reflux too.

The diagnosis of gastroesophageal reflux, mainly, is based on clinical information, results of roentgenologic examination, esophagoscopy.

The edema, hyperemia of mucous tunic of esophagus, easy bleeding and vulnerability it during examination, surplus of mucus and erosions covered by fibrin tape is considered the endoscopic signs of esophagitis. In doubtful case at the insignificantly expressed macroscopic changes the biopsy of mucous tunic helps to set a diagnosis.

Treatment of patients with gastroesophageal reflux is mainly conservative. Very important is diet, which avoid spicy, rough and hot food. Eating is needed often, by small portions. It is impossible also to lie down after the food intake, because the gastric content can flow in a esophagus. A supper must be not later than for 3–4 hours before sleep. Between the reception of food does not recommend to use a liquid. Next to that, it is necessary to remove factors which promote intraperitoneal pressure (carrying to the bracer, belt, constipation, flatulence). Sleeping is needed in position with a lift head and trunk. From medicinal preparations it is useful to recommend enveloping preparation.

Operative treatment of gastroesophageal reflux, that arose up after the distal resection of stomach, it is needed to recommend to the patients with the protracted passing and uneffective of conservative treatment. During operation, mainly, performed renewal of the broken Hisa

angle. In addition, performed esophagoplasty, fundoplication by Nessen's and esophagofrenofundoplication.

The prophylaxis of this complication consists in the study of the state of cardiac part of stomach before and during every resection and fixing of bottom of stomach to the diaphragm and abdominal part of esophagus during leveling the Hisa angle.

Alkaline reflux-gastritis meets in 5–35 % operated patients after the resection of stomach, antrectomy, gastroenterostomy, vagotomy with pyloroplasty, and also cholecystectomy and papillosphincteroplasty.

The reason of this complication is influence of duodenum content for the mucous tunic of stomach (bilious acids, enzymes of pancreas and isolecithin). Last, forming from bile lecithin under act of phospholipase A, able to destroy the cells of superficial epithelium of mucous tunic of stomach by removing of lipid from their membranes. As a result the erosions and ulcers are formed in the patient organism. Bilious acids also has the expressed detergent's properties. As isolecithin and bilious acids, the very important bacterial flora which directly and through toxins can cause the damage of mucous tunic of stomach stump. Also, alkaline environment and disturbance of evacuation from the operated stomach influence favourably on microflora growth.

For the clinical picture of alkaline reflux-gastritis the permanent poured out pain in a epigastric area, belch and vomiting by a bile are typical. At some patients heartburn and pain is observed behind a breastbone also. In majority patients so proof loss of weight takes place, that even the protracted complex therapy and valuable feed does not provide addition to the deficit of mass of body. There are typical signs also – anaemia, hypo- or achlorhydria.

Reliable diagnostics of alkaline reflux-gastritis became possible after wide introduction in clinical practice of endoscopic examination. In such patients during gastroscopy hyperemia of mucous tunic of stomach is observed. It is often possible to observe reflux in the stomach of duodenum content. During histological examination of biopsy material a chronic inflammatory process, intestinal metaplasia, diminishment of mass of coating cells and area of hemorrhages are found. All it testifies the deep degenerative changes in the mucous tunic of stomach. The some authors underlines that the inflammatory changes, at least in the area of anastomosis, are observed in most persons which carried the resection of stomach. So, endoscopic examination can not be considered deciding in diagnostics. Even the diffuse inflammatory changes can take place in absent of clinical symptoms and, opposite, in case with expressed clinical symptoms the minimum changes of mucous tunic of stomach are sometimes observed.

Conservative treatment of reflux-gastritis (sparing diet, antacides, enveloping preparations), usually, is ineffective. Existent methods of surgical treatment, mainly, directed on the removal of reflux of duodenum content to the stomach. Most popular is operation by the Roux method. The some surgeons considers that distance from gastroenteroanastomosis to interintestinal anastomosis must be 45–50 cm.

Main reason of origin of peptic ulcer of anastomosis is leaving of the hyperacid state of stomach mucous, even after the performed operation. Such phenomenon can be consequence of many reasons: primary economy resection, wrong executed resection (when the mucous tunic of pyloric part is abandoned in stump of duodenum or stomach), heightened tone of vagus

nerves and the Zollinger-Ellison syndrome.

Peptic ulcers, usually, arise up after operation during the first year. Typical signs are pain, vomiting, weight loss, bleeding, penetration and perforation.

Pain is the basic symptom of peptic ulcer. Often it has the same character and localization, as well as at peptic ulcer. However often observe it moving to the left or in the umbilical area. At first patients bind such feelings to the use of food, but then specify nightly and hungry pain. It at first is halted after a food, but in course of time is become permanent, unendurable, independent from food intake. It can increase during the flounces, the walk, can irradiate in the back, thorax or shoulder.

During the objective examination of patients is often possible to expose on a stomach hyperpigmentation from a hot-water bottle. During palpation to the left from epigastric area near a umbilicus the painful and moderate muscles tension of abdominal wall is observed. Sometimes is possible to palpate inflammatory infiltrate of different sizes. During the examination of patients with a peptic ulcer the important role has determination of gastric secretion against a background of histamine and insulin stimulation. There is a necessity also examination of basal secretion. These preoperative examinations in most patients enable to set the reason of hypersecretion which can be: 1) heightened tone of vagus nerves (positive Hollander test); 2) economy resection of stomach, often in combination with the heightened tone of vagus nerve (considerable increase of gastric secretion after histamine or pentagastrin stimulation in combination with the positive Hollander test); 3) abandoned part of mucous tunic of antral part of stomach (high basal secretion and small increase of secretion in reply to histamine and insulin stimulator); 4) the Zollinger-Ellison syndrome.

Roentgenologic diagnostics of peptic ulcer, usually, is difficult, especially at shallow, flat ulcers, bad mobility and insufficient function of anastomosis. A niche is the direct sign of a similar pathology, indirect are the expressed inflammatory changes of mucous tunic of stump of stomach and bowel, painful point in the projection of stump of stomach and anastomosis and bad function of anastomosis. The deciding value in diagnostics has endoscopic examination.

Conservative treatment of peptic ulcers, as a rule, is ineffective. So, operation must be the basic type of treatment. The choice of method of operative treatment depends on character of previous operation and from abdominal cavity pathology found during the revision. For today the most important parts of the repeated operations is vagotomy. There is obligatory also during the resection of stomach on the exception the revision of duodenum stump for liquidation of possibly abandoned mucous tunic of antral area.

Operative treatment at a peptic ulcer must consist of certain stages. Laparotomy and disconnection of adhesions through a considerable spike process (increasing of stomach, loops of intestine and liver to the postoperative scar) almost always causes large difficulties.

After the selection of anastomosis with afferent and efferent loops the last cut by the "UKL-60 appliance", within the limits of healthy tissues with renewal of intestine continuity by "end-to-end" type anastomosis.

At patients with a peptic ulcer, that developed after gastroenterostomy, cut a duodenum and sutured its stump by one of the described methods. During it there can be the difficulties related to the presence in it active ulcer. When peptic ulcers do not cause rough deformation of

stomach, apply degastroenterostomy, vagotomy and drainage operations.

In the case of the considerably expressed spike process it is possible to execute trunk subdiaphragmatic vagotomy, and in case of the insignificantly changed topography of this area — selective gastric vagotomy.

It is important to note, that stomach resected together with anastomosis, peptic ulcer and eliminated area of empty bowel by one block.

This pathology arises up as a result of perforated of peptic ulcer in a transverse colon with formation of connection between a stomach, small or large intestine.

Diagnostics of gastro-colon fistula at patients with expressed clinical signs of disease does not difficult. However, symptoms are often formed and is indicated up slowly, so such patients with different diagnoses long time treat oneself in the therapeutic or infectious parts.

The typical signs of this pathology is considered diminishment or disappearance of pain, that was before, and proof, profuse, that does not respond to treatment, diarrhea. Patients has emptying up to 10–15 times per days and even more frequent. An excrement contains a plenty of undigested muscular fibres and fat acids (steatorrhea). In case of wide fistula an undigested food can be with an excrement.

Excrement smell from a mouth, usually, notice surrounding. The patients does not feel it. However appearance of excrement belch is indicate the hit into the stomach of excrement masses and gases, and could confirm this pathology.

The such patients very quickly lose weight (mass of body goes down on 50–60 %), their skin becomes pale with a grey tint. The protein-free edemata, ascites, hydrothorax, anasarca, signs of avitaminosis appear in non-treated case.

Through the severe losses of liquid and nonassimilable food there can be the increased appetite and unendurable thirst in such patients. However, they adopt a plenty of liquid and food but the state of them continues to get worse.

Headache, apathy and depression is observed, and at the objective examination is exhaustion (ochre colour of skin, dryness and decline of it turgor, edemata or slurred of swelling extremities, atrophy of muscles). A stomach often moderately pigmented from hot-water bottles, subinflated, with the visible peristalsis of intestine. During the changes of patient position it is possible to hear grumbling, splash and transfusion of liquid. The examination of blood can expose hypochromic anaemia.

Roentgenologic examination is a basic diagnostic method. There are three varieties of such examinations of gastro-colon fistula. During the examination with introduction of barium mixture through a mouth the hit of contrasting matter directly from a stomach into a colon is the typical roentgenologic symptom of such pathology. Irrigoscopy is more perfect and effective method. With suspicion on gastro-colon fistula it is better to perform irrigoscopy. Passing of contrasting matter to the stomach at this manipulation testifies the presence of fistula. The third method is insufflation of air in a rectum. With it help on the screen it is possible to observe the location and passing of fistula, and also, as a result, hit of air in a stomach, increase of it gas bubble. Thus there can be the belch with an excrement smell.

The important role played the tests with dyes: at peroral introduction of methylene-blue after the some time it found in excrement masses or, opposite, after an enema with

methylene-blue dye appears in a stomach.

Treatment of gastro-colon fistula is exceptionally operative. It needs to be conducted after intensive preoperative preparation with correction of metabolism. All operations which can be applied at treatment of patients with gastro-colon fistula divide into palliative and radical (single-stage operation and multi-stage operation).

During the palliative operations the place of fistula of stomach, transverse colon and jejunum is disconnected and then sutured the created defects. Other variant is disconnection of stomach and transverse colon and leaving the gastroenteroanastomosis. It is necessary to remember, that during such operations the only fistula always removed and does not performed the resection of stomach. Clearly, that such situation also does not eliminate possibility of relapse of peptic ulcer and development of its complications. Taking into account it, palliative operations can be recommended in those case only, when the general condition of patient does not allow to perform radical operation.

Single-stage operation radical operations. The most widespread is degastroenterostomy with the resection of stomach. However, it is needed to remember that operation of disconnection of fistula, suturing of opening in the jejunum and transverse colon on the lines of fistula and resection of stomach applies only in case of absent of infiltrate and deformation and in the conditions of possibility to close a defect in bowels without narrowing of their lumen. This operation is the simplest, is enough easily carried by patients and it is enough radical.

Such complications appear through considerable time after operation (from 1 month to one year). Disturbances of function of gastrointestinal anastomosis can be caused by the reasons, related both to the technical mistakes during operation and with pathological processes which arose up in the area of anastomosis.

The clinical picture of disturbance of anastomosis function, mainly, depends from the degree of its closing. At complete it obstruction in patients arise up intensive vomiting, pain in a epigastric area, the symptoms of dehydration and other similar signs appear. In other words, the clinic of stenosis of the stomach output develops. Clearly, that during incomplete narrowing the clinical signs will be expressed less, and growth of them — more slow. Sometimes disturbance of evacuation can unite with the syndrome of afferent loop with a inherent clinical picture. At the roentgenologic examination of such patients expansion of stomach stump is exposed with the horizontal level of liquid and small gas bubble. Evacuation from it is absent or acutely slow.

Treatment of scar deformations and narrowing of anastomosis must be operative and directed for the disconnection of accretions and straightening of the deformed areas. In case of presence in patients large inflammatory infiltrate it does not need to perform disconnection. In such cases it is the best to apply roundabout anastomosis. If a resection by Finsterer was done in such patient, better to perform anterior gastroenteroanastomosis, and after a resection by Billroth-I — posterior. As a result of conducting of such operations the state of patient, as a rule, gets better, and often recovered the function of primary anastomosis.

Removing of all stomach and exception of duodenum from the process of digestion of food cause plural functional disturbances in an organism. Some of them meet already after the

resection of stomach (dumping-syndrome, hypoglycemic syndrome), other more inherent for gastrectomy (anaemia, reflux- esophagitis and others like that).

Most patients, that carried gastrectomy, complain for a considerable physical weakness, heightened fatigueability, sometimes is complete weakness, loss of activity and acute decline of work capacity. Almost all of them notice bad sleep, worsening of memory and heightened irritates. The appearance of patients is typical. Their skin insignificantly hyperpigmented, dry, its turgor reduced, noticeable atrophy of muscles. Can be the signs of chronic coronal insufficiency in such patients, and in older-year persons is typical picture of stenocardia. Except for it, can be hypotension, bradycardia and decline of voltage on EKG; during auscultation deafness of tones is observed. From the side of the hormonal system the decline of function of sexual glands is typical: in men — declines of potency, in women — disturbances of menstrual cycle, early climax. Can be the signs of hypovitaminosis A, B, C and decline of resistibility of organism to chill, infectious diseases and tuberculosis.

The decline of mass of body is observed in 75 % patients, that carried gastrectomy. It is conditioned by the decline of power value of food as a result of disturbance of digestion, bad appetite and wrong diet. As a result of progressive hypoproteinemia there can be the protein-free edemata.

Patients with such pathology must be under the permanent clinical supervision and 1–2 times per year during a month to have the course of stationary prophylactic treatment which includes psycho-, diet-, vitaminotherapy, correcting and replaceable therapy, and also prophylaxis of anaemia.

Psychotherapy is especially indicated in the psychodepressive and asthenic states. It is performed in combination with medicinal treatment. Hypnotic preparation, bromide, tranquilizers are applied.

A food must be correctly prepared, without the protracted cooking. Patients need to feed on 6–10 times per days by small portions.

Next to dietotherapy, it is constantly necessary to apply replaceable therapy (Pancreatine, Pansinorm, Festal, Intestopan). In case of absent of esophagitis hydrochloric acid is appointed. For the improvement of albuminous exchange anabolic hormones are applied.

In case of reflux-esophagitis there are indicated feeds by small portions with predominance of liquid, ground, jelly-like foods, astringent, coating, anticholinergic preparations. Between the receptions of food does not recommend to use a liquid. In case of dysphagy appoints a sparing diet.

For the prophylaxis of iron-deficiency anaemia, that arises up in the first 2–3 years after gastrectomy, important the indication of iron preparations.

For warnings and treatments of pernicious anaemia applied cyanocobalamin for 200 mcg through a day and folic acid. Packed red blood cells is indicated in heavy case.

The relapse of ulcer is enough frequent complication of vagotomy. It meets in 8–12 % patients. The reasons of such relapses of ulcer can be: 1) inadequate decline of products of hydrochloric acid (incomplete vagotomy, reinnervation); 2) disturbance of emptying of stomach (ulcerous pylorostenosis after selective proximal vagotomy or after pyloroplasty); 3) local factors (duodenogastric reflux with development of chronic atrophy gastritis, disturbance of

circulation of blood and decline of resistibility of mucous tunic); 4) exogenous factors (alcohol, smoking, medicinal preparations); 5) endocrine factors (hypergastrinaemia: hyperplasia of antral G-cells, the Zollinger-Ellison syndrome; hyperparathyroidism).

Three variants of clinical passing of relapse of ulcer are distinguished after vagotomy: 1) symptomless, when an ulcer is found during endoscopic examination; 2) recurrent with protracted lucid space; 3) persisting ulcer with typical periodicity and seasonality of exacerbation.

It is needed to underline that the clinical signs of this pathology during the relapse are less expressed, than before operation, and absence of pain does not eliminate the presence of ulcer. Sometimes bleeding can be first its sign. Complex examination, that includes roentgenologic, endoscopic examination, study of gastric secretion and determination of content of gastrin in the blood, allows not only to expose an ulcer but also, in most cases, to set its reason. The interpretation the results of gastric secretion examination in such patients are heavy. Taking into account it, it is needed to study both a basal secretion and secretion in reply to introduction of insulin and pentagastrin, and also level of pepsin.

Approximately in 35 % patients, mainly with the first two variants of clinical passing of disease, the relapses of ulcers, are treated by ordinary methods of conservative therapy. Yet in 30–40 % cicatrization of ulcers comes after application of preparations which stop a gastric secretion (cimetidine, ranitidine—150 mg for night). At other 10–20 % patients, mainly with the third variant of clinical passing, is necessary operative treatment.

The question of choice of the repeated operation in patients with the relapse of ulcer after vagotomy still does not decided. Some surgeons execute revagotomy, trunk vagotomy with drainage operation, revagotomy with antrectomy or resection of stomach. However much majority from them in case of relapse ulcer after vagotomy performed antrectomy in combination with trunk vagotomy.

Frequency of postvagotomy diarrhea hesitates from 2 to 30 %. The basic sign of complication in patient is present the liquid watery emptying about three times per days. The reasons of diarrhea are: gastric stasis and achlorhydria, denervation of pancreas, small intestine and liver, and also disturbance of motility of digestive tract. Discoordination of evacuations from a stomach, stagnation and hypochlorhydria assist to development in it different microorganisms, and it also can be the reason of diarrhea.

The clinical signs of postvagotomy diarrhea are specific. Acute beginning are typical –patient often does not have time to reach to the rest room. Such suddenness repressing operates on patients. As a result they are forced whole days to be at home, expecting the duty attack. An excrement changes colorings as a result of breeding of pigment and becomes more light.

Treatment of diarrhea must be complex. Above all things it is needed to recommend a diet with the exception of milk and other provoking products. For the removal of bacterial factor antibiotics are applied. Favourable action in case of the signs of stagnation in a stomach are had weak solutions of organic acids (lemon, apple and others like that).

Among other most distribution was got by the A.A. Kuragin and S.D. Hroismann (1971) suggestion to treat postvagotomy diarrhea by benzohexamethonium (for 1 ml 2,5 % solution

2–3 times per a day). Reported also about successful application of cholesteramine (for 4 g 3 times per a day with the subsequent decline of dose to 4 g per days).

At heavy passing of postvagotomy diarrhea, that does not respond to conservative treatment, it is needed to recommend operative treatment — degastroenterostomy with pyloroplasty. However, the type of drainage operation, as practice shows, does not influence on frequency of diarrhea origin. In this connection, some surgeons with success applied the inversion of the segment of thin bowel, located distal from the area of maximal absorption.

The cancer of stomach is a malignant formation, that develops from epithelium tissue of mucus stomach. Among the tumours of organs of digestion this pathology takes first place and is the most frequent, by the reason of death from malignant formations in many countries of world. Frequency of it at the last 30 years considerably diminished in the countries of Western Europe and North America, but yet remains high in Japan, China, countries of East Europe and South America.

Etiology of cancer of stomach is unknown. It is known that, as other diseases of gastrointestinal tract, a cancer damages a stomach. According to statistical information, it meets approximately in 40 % of all localizations of cancer.

The factors of external environment has the substantial influencing on frequency of this pathology. Above all things, feed, smoke food, salting, freezing of products and their contamination of aflatoxin. Consider that a “food factor” can be: a) by a carcinogen; b) by the solvent of carcinogens; c) to grow into a carcinogen in the process of digestion; d) to be instrumental in action of carcinogens; e) not enough to neutralize carcinogens.

In the USA and countries of Western Europe frequency of cancer of stomach in 2 times more large in the lower socio-economic groups of population. Some professional groups also can it (miners, farmers, works of rubber, woodworking and asbestine industry). High correlation communication is set between frequency of cancer of stomach and use of alcohol and smoking. The value of genetic factors (heredity, blood type) is not led to.

The cancer of stomach arises up mainly in age 60 years and above, more frequent men are ill.

Precancer. The precancer diseases of stomach are: a) chronic metaplastic disregenerator gastritis conditioned by helicobacter pylori; b) villous polypuses of stomach and chronic ulcers; c) nutritional anemia due to vitamin B12 deficiency (pernicious); d) resected stomach concerning an ulcer.

The presence of precancer changes of mucous tunic of stomach has substantial influence for frequency of stomach cancer. In those countries, where morbidity on the cancer of stomach is higher, considerably more frequent chronic gastritises are diagnosed. Lately in etiology of chronic gastritises take the important value helicobacter pylori. In Japan, where the cancer of stomach is in 40 % cases is the reason of death, chronic gastritis appears in 80 % cases of resected stomach, concerning a cancer.

Connection between polypuses, chronic gastric ulcers and possible it malignization comes into question in literature during many decades. Most authors consider that polypuses could be malignant differently. There are three histological types of polypuses: hyperplastic, villous and hamartoma. There are hyperplastic polypuses, but it not malignant.

Hamartoma is accumulation of cells of normal mucous tunic of stomach. They never becomes malignant.

Villous polypuses are potentially malignant in 40 % cases, but it happen in 10 times less, than hyperplastic. The possibility of malignization of chronic gastric ulcers is not proved. The American scientists support a hypothesis, that the cancer of stomach can be ulcerous often, but malignization of ulcers takes place rarely (no more than 3 %). From data of the Japanese scientists, on 50–70th there was higher correlation connection between chronic gastric ulcers and cancer of stomach. The frequent decline of this correlation is lately noticed (70 % on 50–70th and 10 % on 80th).

Frequency of cancer of stomach at patients with pernicious anaemia hesitates within the 5–10 %, that in 20 times higher, compare with control population. In patients with a resected stomach after peptic ulcers is multiplied the risk of origin of stomach cancer in 2–3 times (duration of latent period hesitates from 15 to 40 years). The reason of such dependence is not found out, but there is a version, that this is linked with a gastric epithelium metaplasia by an intestinal type.

From all malignant formations of the stomach in 95 % adenocarcinoma is observed. Epidermoid cancer, adeno-acanthoma and carcinoid tumours do not exceed 1 %. Frequency of leiomyosarcoma hesitates within the limits of 1–3 %. Lymphoma of gastrointestinal tract is localized in a stomach.

The prognosis of localization depends on the degree of invasion, histological variants of tumour.

The macroscopic forms of cancer of stomach in different times were described variously. More than 60 years ago the German pathologist Bermann described 5 macroscopic forms of cancer of stomach: 1) polypoid or mushroom-like; 2) saucer-shaped or with ulcerous and expressly salient edges; 3) with ulcerous and infiltration of walls of stomach; 4) diffuse-infiltrate; 5) unclassified.

American pathopsychologists is selected 4 forms. The tumours of stomach with ulcerous are the most frequent macroscopic form of cancer of stomach and arise up on soil of chronic ulcer. The signs suspicious on malignization are: the sizes of ulcer more than 2 cm in a diameter, appearance of the heightened edges.

The polypoid tumours of stomach observed only in 10 %. These tumours can achieve considerable sizes without an invasion and metastasis. Scirrhus carcinoma is the third macroscopic type. This category of tumours also does not exceed 10 %. The scirrhus carcinoma is the signs of infiltration by anaplastic cancer cells, diffusely developed connecting tissue which results in the bulge and rigidity of wall of stomach. So called “small cancers” belong to the fourth macroscopic type. It meet comparative rarely (no more than 5 %) and is characterized by superficial accumulation of cancer cells which substitute for normal mucus in such kind: a) superficial flat layer which does not rise above the level of mucus; b) salient (bursting) formation; c) erosions.

Mainly (more than 50 %) tumours arise up in a antral part or in distal (lower) third of stomach, rarer (to 15 %) — in a body and in cardia (to 25 %).

However, lately more often observed cardioesophageal cancers and diminishment of

frequency of tumours of distal parts of stomach. In 2 % cases meet the multicentric focuses of growth, but from data of some authors, this percent could be multiplied in 10 times after carefully histological inspection of the resected stomachs. This assertion is based on the theory of the “tumour field” (D.I. Holovin, 1992). Especially this typically for patients which has pernicious anaemia or chronic metaplastic disregenerative gastritis.

Metastasis is carried out by lymphogenic, hematogenic and implantation ways mostly. Three (from data of some authors, four) pools of lymphogenic metastasis are selected: left gastric (knots on passing of small curvature of stomach in a gastro-subgastric ligament and pericardial); splenic (mainly, suprainfrapancreatic knots); hepatic (knots in a hepato-duodenal ligament, right gastric omentum that lower pyloric groups, right gastric and suprapyloric groups, pancreatoduodenal group).

However, the such way of lymphogenic metastasis is conditional and incomplete, as at presence of block lymph flow passes retrograde metastasis, so called “jumping metastases” which predetermine the origin of remote lymphogenic metastases in left supraclavicular lymph nodes (Virhov metastasis) appear, in Lymph nodes of left axillar and inguinal areas, metastases in a umbilicus.

Direct distribution: small and large omentum, esophagus and duodenum; liver and diaphragm; pancreas, spleen, bile ducts.

Front wall of stomach: colon bowel and mesocolon; organs and tissues of retroperitoneal space.

Lymphogenic metastasis: regional lymph nodes, remote lymph nodes, left supraclavicular lymph node (Virhov), lymph node of axillar area (Irish); in a umbilicus (sisters Joseph).

Hematogenic metastasis: liver, lungs, bones, cerebrum.

Peritoneal metastasis: peritoneum, ovarium (the Krukenberg metastasis), Duglas space (the Shnicler metastasis).

All authors which are engaged in the study of problem of cancer of stomach underline absence or vagueness, no specificity of symptoms, especially on the early stages of disease. The displays of cancer of stomach are very various and depend on localization of tumour, character of its growth, morphological structure, distribution on contiguous organs and tissues. At localization of tumour in a cardial part patient complains firstly, as a rule, for appearance of dysphagy.

At careful, purposeful collection of anamnesis it is not succeeded to expose some other, most early symptoms, which precedes to dysphagy and forces a patient to appeal to the doctor. The unpleasant feeling behind a breastbone and feeling of unpassing of hard food on a esophagus appear at the beginning of disease. After some time (as a rule, it is enough quickly, during a few weeks, sometimes even days) a hard food does not pass (it is to wash down by water or other liquid). This period can be during 1–3 months. Patients address a doctor exactly in this period. Other symptoms appear to this time: regurgitation, pain behind a breastbone, loss of mass of body, sometimes even exhaustion, the grey colouring of person, a skin is dry, quickly grows general weakness. Sometimes patients address a doctor, when already with large effort a spoon-meat passes only or complete stenosis came.

At localization of tumour in the antral part of stomach the first complaints, as a rule, are

up to appearance of feeling of weight in epigastric region after the reception of food (even in a two-bit), “feeling of saturation” (after the reception of glass of water), belch (at first it is simple by air, and then with a smell). Feeling of weight grows for a day, patients forced to cause vomiting. In the morning there can be vomiting by mucus with the admixtures of “coffee-grounds” (so called “cancer” water). Patients loses weight (mass of body is lost), a weakness, anaemia grows.

Tumours localized in the body of stomach show up either a pain syndrome or syndrome of so called “small signs” (A.I. Savitsky, 1947), which is characterized by appearance of amotivational general weakness, decline of capacity, rapid fatigueability, depression (by the loss of interest to the environment), proof decline of appetite, gastric discomfort, making progress weight lost.

The carried chronic diseases of stomach, for which typical seasonality, can influence on the clinical sign of cancer of stomach. At appearance of “gastric” complaints out of season or in absent of effect from the got therapy concerning the exacerbation of “gastritis”, “ulcers” must guard a patient and doctor (symptom of “precipice” of gastric anamnesis).

In case of occurring of “gastric” symptoms first in persons in age 50 years and older it is foremost necessary to eliminate the cancer of stomach.

In parts of patients cancer of stomach shows up only the metastatic damage of other organs or complications. More than twenty so called “atypical” forms, which are characterized by “causeless” anaemia, ascites, icterus, fever, edemata, hormonal disturbances, changes of carbohydrate exchange, intestinal symptoms, are distinguished.

During the examination of patients with the cancer of stomach the pallor of skin covers (at anaemia) is observed, in neglected case is “frog” stomach (sign of ascites).

During palpation determined painful in a epigastric area, sometimes possible to palpate the tumour.

During auscultation of patients with pylorostenosis it is possible to define “noise of splash”.

Laboratory information: hypochromic anaemia, neutrophilic leukocytosis, megascopic ESR; during examination of gastric secretion: hypo- and anacidity and achlorhydria.

Gastroduodenoscopy enables to diagnose a tumour even smaller 5 mm and conduct an aiming biopsy with histological examination of the taken material.

Roentgenoscopy and roentgenography examination of stomach. Basic signs: defect of filling, local absence of peristalsis, “malignant” relief of mucous tunic (Pic. 3.2.18).

Ultrasonic examination: presence of metastases in a liver, pancreas.

Computer tomography allows to estimate the basic parameters of tumour, germination in neighbouring organs and presence of metastases.

It is expedient to apply laparoscopy, mainly, for the decision of question about operable of tumour (diagnostics of metastatic defeat of organs of abdominal cavity).

At an early cancer complaints depend on the previous gastric diseases. Therefore, on the basis of clinical information, suspecting a tumour is possible only on occasion, when in patients next to clear pain symptoms an appetite goes down, appear anaemia, general weakness. In practice an early cancer is recognized at purposeful screening, and also in the process of

endoscopic or roentgenologic examination of gastric patients.

A differential diagnosis is conducted with an peptic ulcer, gastritis, polyposis, other gastric and ungastric diseases. For a cancer there is typical firmness of symptoms, instead of their seasonality (typical syndrome of “precipice” of gastric anamnesis) or tendency to their gradual progress.

The row of diseases, with which the cancer of stomach is to differentiate to the doctor, depends from character of complaints of patients.

Five basic clinical syndromes are selected:

- 1) pain;
- 2) gastric discomfort;
- 3) anaemic;
- 4) dysphagic;
- 5) disturbance of evacuation from a stomach.

At patients, at what cancer of stomach shows up a pain syndrome and syndrome of gastric discomfort, a differential diagnosis is conducted with the peptic ulcer, gastritis, cancer of body of pancreas.

It is oriented on features dynamics of development of pain syndrome, ingravescent of the general condition, change of character of complaints.

A question about character of anaemia, source and nature of bleeding decides at an anaemic syndrome. In the process of examination attention is paid to the state of bottom of stomach, where bleeding malignant formations can be.

At a dysphagic syndrome a differential diagnosis is conducted with the cicatrical narrowing, achalasia of esophagus. For malignant formations testify short anamnesis, gradual progress of symptoms, signs of gastric discomfort, general weakness, weight lost.

At disturbance of evacuation from a stomach during stenosis of pyloric part, absence of ulcerous anamnesis, declining years of patients, relatively quick (weeks, months) growth of stenosis testify for tumor.

The presence of cancer of stomach is a indications for surgical treatment. However, counting on success is possible only at presence of the limited tumours (within the limits of the 0–II stages). At the III stage of disease implementation of the widespread combined operations in a radical volume is possible, however most patients die during 1–2 years. A distal or proximal subtotal resection (Pic. 3.2.19) and total gastrectomy (Pic. 3.2.20) is performed with removing of large and small omentumes and regional areas of metastasis with obligatory histological examination of stomach on the lines of resections.

During the combined operations organs which are pulled in to the pathological process are removed.

In case of IV stage of disease and satisfactory state of patient palliative operations which improve quality of life of patient are performed.

In case of presence of complications (mainly stenosis) and grave common condition of patient perform symptomatic operative treatments.

Symptomatic is operations which will liquidate one of symptoms of cancer of stomach. In this group of operations include: 1) roundabout gastrojejunoanastomosis (Pic. 3.2.21) and

jejunosoma (in case of the stenosis tumours of stomach output); 2) gastrostoma (Pic. 3.2.22) in case of the cancer of cardial part of stomach with disturbance of patency; 3) edging of bleedingx vessels in case of complication of cancer by bleeding; 4) tamponade by omentum during the perforation of tumour.

The value of radial therapy and chemotherapy, as independent methods of treatment of cancer of stomach, is limited. Radial therapy is indicated for patients with cardial cancer as preoperative course or as palliative treatment. Adjuvant mono- or polychemotherapy (mainly by 5-phtoruracil) is conducted in a postoperative period as combined therapy and in case of dissemination of the tumours.

Prognosis. The indexes of five-year survival of patients with the cancer of stomach hesitate within the limits of 5–30 %, but, from data of most authors, they do not exceed 10 %.

ABDOMINAL PAIN, EVALUATION OF PAIN CHARACTERISTICS IN THE DIFFERENTIAL DIAGNOSTIC OF ABDOMINAL DISEASES

Abdominal pain (or stomach ache) is a common symptom associated with transient disorders or serious disease. Diagnosing the cause of abdominal pain can be difficult, because many diseases can cause this symptom. Most frequently the cause is benign and/or self-limiting, but more serious causes may require urgent intervention.

DIFFERENTIAL DIAGNOSIS

Gastrointestinal

GI tract

Inflammatory: gastroenteritis, appendicitis, gastritis, esophagitis, diverticulitis, Crohn's disease, ulcerative colitis, microscopic colitis

Obstruction: hernia, intussusception, volvulus, post-surgical adhesions, tumours, superior mesenteric artery syndrome, severe constipation, hemorrhoids

Vascular: embolism, thrombosis, hemorrhage, sickle cell disease, abdominal angina, blood vessel compression (such as celiac artery compression syndrome), Postural orthostatic tachycardia syndrome

digestive: peptic ulcer, lactose intolerance, coeliac disease, food allergies

Glands

Bile system

Inflammatory: cholecystitis, cholangitis

Obstruction: cholelithiasis, tumours

Liver

Inflammatory: hepatitis, liver abscess

Pancreatic

Inflammatory: pancreatitis

Renal and urological

Inflammation: pyelonephritis, bladder infection

Obstruction: kidney stones, urolithiasis, Urinary retention, tumours

Vascular: left renal vein entrapment

Gynaecological or obstetric

Inflammatory: pelvic inflammatory disease

Mechanical: ovarian torsion

Endocrinological: menstruation, Mittelschmerz

Tumors: endometriosis, fibroids, ovarian cyst, ovarian cancer

Pregnancy: ruptured ectopic pregnancy, threatened abortion

Abdominal wall

muscle strain or trauma

muscular infection

neurogenic pain: herpes zoster, radiculitis in Lyme disease, abdominal cutaneous nerve entrapment

syndrome (ACNES), tabes dorsalis

· Referred pain

· from the thorax: pneumonia, pulmonary embolism, ischemic heart disease, pericarditis

· from the spine: radiculitis

· from the genitals: testicular torsion

· Metabolic disturbance

· uremia, diabetic ketoacidosis, porphyria, C1-esterase inhibitor deficiency, adrenal insufficiency, lead poisoning, black widow spider bite, narcotic withdrawal

· Blood vessels

· aortic dissection, abdominal aortic aneurysm

· Immune system

· sarcoidosis

· vasculitis

· familial Mediterranean fever

· Idiopathic

· irritable bowel syndrome (affecting up to 20% of the population, IBS is the most common cause of recurrent, intermittent abdominal pain)

ACUTE ABDOMINAL PAIN

Acute abdomen can be defined as severe, persistent abdominal pain of sudden onset that is likely to require surgical intervention to treat its cause. The pain may frequently be associated with nausea and vomiting, abdominal distention, fever and signs of shock. One of the most common conditions associated with acute abdominal pain is acute appendicitis.

Selected causes of acute abdomen

· Traumatic : blunt or perforating trauma to the stomach, bowel, spleen, liver, or kidney

· Inflammatory :

· Infections such as appendicitis, cholecystitis, pancreatitis, pyelonephritis, pelvic inflammatory disease, hepatitis, mesenteric adenitis, or a subdiaphragmatic abscess

· Perforation of a peptic ulcer, a diverticulum, or the caecum

· Complications of inflammatory bowel disease such as Crohn's disease or ulcerative colitis

· Mechanical :

· Small bowel obstruction secondary to adhesions caused by previous surgeries, intussusception, hernias, benign or malignant neoplasms

· Large bowel obstruction caused by colorectal cancer, inflammatory bowel disease, volvulus, fecal impaction or hernia

· Vascular : occlusive intestinal ischemia, usually caused by thromboembolism of the superior mesenteric artery

BY LOCATION

Location

· Upper middle abdominal pain

· Stomach (gastritis, stomach ulcer, stomach cancer)

· Pancreas pain (pancreatitis or pancreatic cancer, can radiate to the left side of the waist, back, and even

shoulder)

- Duodenal ulcer, diverticulitis
- Appendicitis (starts here, after several times moves to lower right abdomen)
- Upper right abdominal pain
 - Liver (caused by hepatomegaly due to fatty liver, hepatitis, or caused by liver cancer, abscess)
 - Gallbladder and biliary tract (gallstones, inflammation, roundworms)
 - Colon pain (below the area of liver - bowel obstruction, functional disorders, gas accumulation, spasm, inflammation, colon cancer)
- Upper left abdominal pain
 - Spleen pain (splenomegaly)
 - Pancreas
 - Colon pain (below the area of spleen - bowel obstruction, functional disorders, gas accumulation, spasm, inflammation, colon cancer)
- Middle abdominal pain (pain in the area around belly button)
 - Appendicitis (starts here)
 - Small intestine pain (inflammation, intestinal spasm, functional disorders)
- Lower abdominal pain
- Lower right abdominal pain
 - Cecum (intussusception, bowel obstruction)
 - Appendix point (Appendicitis location)
- Lower left abdominal pain
 - Sigmoid colon (polyp), sigmoid volvulus, obstruction or gas accumulation)
- Pelvic pain
 - bladder (cystitis, may secondary to diverticulum and bladder stone, bladder cancer)
 - pain in women (uterus, ovaries, fallopian tubes)
- Right lumbago and back pain
 - liver pain (hepatomegaly)
 - right kidney pain (its location below the area of liver pain)
- Left lumbago and back pain
 - less in spleen pain
 - left kidney pain
- Low back pain
 - kidney pain (kidney stone, kidney cancer, hydronephrosis)
 - Ureteral stone pain

DIAGNOSTIC APPROACH

When a physician assesses a patient to determine the etiology and subsequent treatment for abdominal pain the patient's history of the presenting complaint and physical examination should derive a diagnosis in over 90% of cases.

It is important also for a physician to remember that abdominal pain can be caused by problems outside the abdomen, especially heart attacks and pneumonias which can occasionally present as abdominal pain.

Investigations that would aid diagnosis include

- Blood tests including full blood count, electrolytes, urea, creatinine, liver function tests, pregnancy test, amylase and lipase.
- Urinalysis
- Imaging including erect chest X-ray and plain films of the abdomen
- An electrocardiograph to rule out a heart attack which can occasionally present as abdominal pain

If diagnosis remains unclear after history, examination and basic investigations as above then more advanced investigations may reveal a diagnosis. These as such would include

- Computed Tomography of the abdomen/pelvis
- Abdominal or pelvic ultrasound
- Endoscopy and colonoscopy (not used for diagnosing acute pain)

ACUTE APPENDICITIS

Acute appendicitis is an inflammation of vermiform appendix caused by festering microflora.

Etiology and pathogenesis

Most frequent causes of acute appendicitis are festering microbes: intestinal stick, streptococcus, staphylococcus. Moreover, microflora can be in cavity of appendix or get there by hematogenic way, and for women – by lymphogenic one.

Factors which promote the origin of appendicitis, are the following: a) change of reactivity of organism; b) constipation and atony of intestine; c) twisting or bends of appendix; d) excrement stone in its cavity; e) thrombosis of vessels of appendix and gangrene of wall as a substance of inflammatory process (special cases).

Pathomorphology

Simple (superficial) and destructive (phlegmonous, gangrenous primary and gangrenous secondary) appendicitises which are morphological expressions of phases of acute inflammation that is completed by necrosis can be distinguished.

In simple appendicitis the changes are observed, mainly, in the distant part of appendix. There are stasis in capillaries and venule, edema and hemorrhages. Focus of festering inflammation of mucus membrane with the defect of the epithelium covering is formed in 1–2 hours (primary affect of Ashoff). This characterizes acute superficial appendicitis. The phlegmon of appendix develops to the end of the day. The organ increases, its serous tunic becomes dimmed, sanguineous, stratifications of fibrin appear on its surface, and there is pus in cavity.

In gangrenous appendicitis the appendix is thickened, its serous tunic is covered by dimmed fibrinogenous tape, differentiating of the layer structure through destruction is not succeeded.

Classification (by V.I. Kolesnikov)

1. Appendiceal colic.
2. Simple superficial appendicitis.
3. Destructive appendicitis:
 - a) phlegmonous;
 - б) gangrenous;
 - в) perforated.
4. Complicated appendicitis:
 - a) appendicular infiltrate;

- б) appendicular abscess;
- в) diffuse purulent peritonitis.

5. Other complications of acute appendicitis (pylephlebitis, sepsis, retroperitoneal phlegmon, local abscesses of abdominal cavity).

Simple superficial appendicitis

Destructive phlegmonous appendicitis:

Destructive gangrenous appendicitis:

Symptoms and clinical course

Four phases are distinguished in clinical course of acute appendicitis: 1) epigastric; 2) local symptoms; 3) calming down; 4) complications.

The disease begins with a sudden pain in the abdomen. It is localized in a right iliac area, has moderate intensity, permanent character and not irradiate. With 70 % of patients the pain arises in a epigastric area - it is an epigastric phase of acute appendicitis. In 2–4 hours it moves to the place of appendix existence (the Kocher's symptom). At coughing patients mark strengthening of pain in a right iliac area – it is a positive cough symptom.

Together with it, nausea and vomiting that have reflex character can disturb a patient. Often there is a delay of gases. The temperature of body of most patients rises, but high temperature can occur rarely and, mainly, it is a low grade fever. The general condition of patients gets worse only in case of growth of destructive changes in appendix.

During the examination it is possible to mark, that the right half of stomach falls behind in the act of breathing, and a patient wants to lie down on a right side with bound leg.

Painfulness is the basic and decisive signs of acute appendicitis during the examination by palpation in a right iliac area, tension of muscle of abdominal wall, positive symptoms of peritoneum irritation. About 100 pain symptoms characteristic of acute appendicitis are known, however only some of them have the real practical value.

The Blumberg's symptom. After gradual pressing by fingers on a front abdominal wall from the place of pain quickly, but not acutely, the hand is taken away. Strengthening of pain is considered as a positive symptom in that place. Obligatory here is tension of muscles of front abdominal wall. [Slide](#).

The Voskresensky's symptom. By a left hand the shirt of patient is drawn downward and fixed on pubis. By the taps of 2-4 fingers of right hand epigastric area is pressed and during exhalation of patient quickly and evenly the hand slides in the direction of right iliac area, without taking the hand away. Thus there is an acute strengthening of pain.

The Bartomier's symptom is the increase of pain intensity during the palpation in right iliac area of patient in position on the left side. At such pose an omentum and loops of thin intestine is displaced to the left, and an appendix becomes accessible for palpation.

The Sitkovsky's symptom. A patient, that lies on left, feels the pain which arises or increases in a right iliac area. The mechanism of intensification of pain is explained by displacement of blind gut to the left, by drawing of mesentery of the inflamed appendix.

The Rovsing's symptom. By a left hand a sigmoid bowel is pressed to the back wall of stomach. By a right hand by balloting palpation a descending bowel is pressed. Appearance of pain in a right iliac area is considered as a sign characteristic of appendicitis.

The Obrazcov's symptom. With the position of patient on the back by index and middle fingers the right iliac area of most painful place is pressed and the patient is asked to heave up the straightened right leg. At appendicitis pain increases acutely.

The Rozdolsky's symptom. At percussion there is painfulness in a right iliac area.

The general analysis of blood does not carry specific information, which would specify the presence of acute appendicitis. However, much leukocytosis and change of formula to the left in most cases can point to the present inflammatory process.

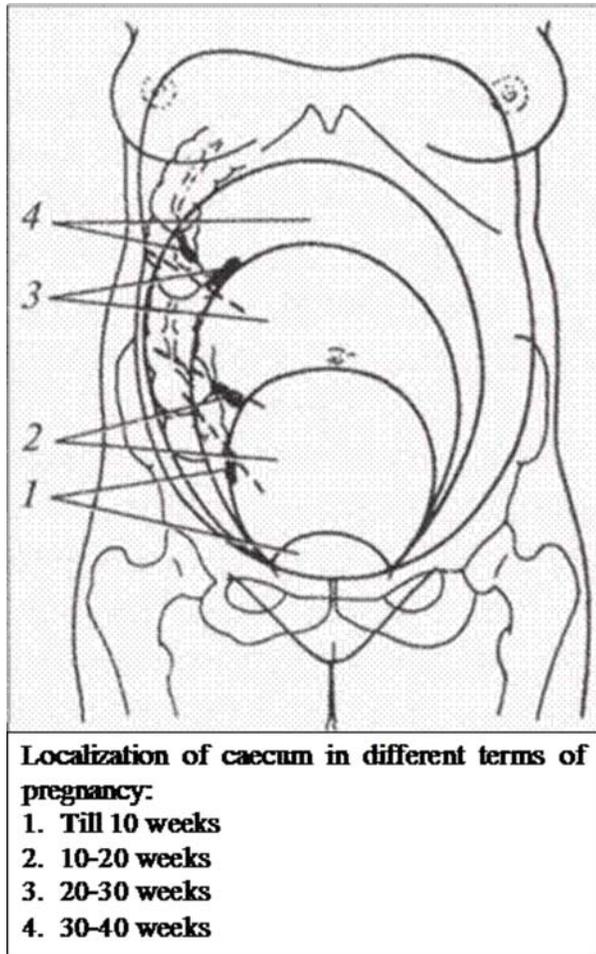

Variants of clinical course and complication

Acute appendicitis in children. With children of infancy acute appendicitis can be seen infrequently, but, quite often carries atypical character. All this is conditioned, mainly, by the features of anatomy of appendix, insufficient of plastic properties of the peritoneum, short omentum and high reactivity of child's organism. The inflammatory process in the appendix of children quickly makes progress and during the first half of days from the beginning of disease there can appear its destruction, even perforation. The child, more frequent than an adult, suffers vomiting. Its general condition gets worse quickly, and already the positive symptoms of irritation of peritoneum can show up during the first hours of a disease. The temperature reaction is also expressed considerably acuter. In the blood test there is high leukocytosis. It is necessary to remember, that during the examination of calmless children it is expedient to use a chloral hydrate enema.

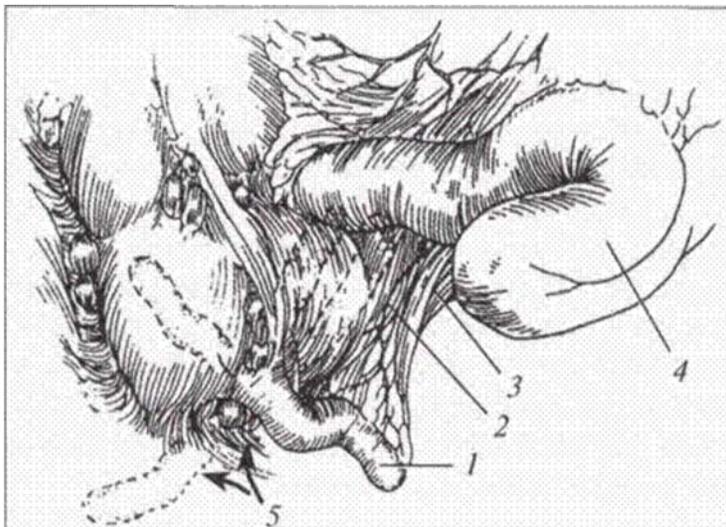

Acute appendicitis of the people of declining and old ages can be met not so often, as of the persons of middle ages and youth. This contingent of patients is hospitalized to hospital rather late: in 2–3 days from the beginning of a disease. Because of the promoted threshold of pain sensitiveness, the intensity of pain in such patients is small, therefore they

almost do not fix attention on the epigastric phase of appendicitis. More frequent are nausea and vomiting, and the temperature reaction is expressed poorly. Tension of muscles of abdominal wall is absent or insignificant through old-age relaxation of muscles. But the symptoms of irritation of peritoneum keep the diagnostic value with this group of patients. Thus, the sclerosis of vessels of appendix results in its rapid numbness, initially-gangrenous appendicitis develops. Because of such reasons the destructive forms of appendicitis prevail, often there is appendiceal infiltrate.

With **pregnant women** both the bend of appendix and violation of its blood flow are causes of the origin of appendicitis. Increased in sizes uterus causes such changes. It, especially in the second half of pregnancy, displaces a blind gut together with an appendix upwards, and an overdistension abdominal wall does not create adequate tension. It is needed also to remember, that pregnant women periodically can have a moderate pain in the abdomen and changes in the blood test. Together with that, *psoas-symptom* and the *Bartomier's* symptom have a diagnostic value at pregnant women.

Clinical course of acute appendicitis at the atypical location (not in a right iliac area) will differ from a classic vermiform appendix .

Variants of appendix localization

1. Appendix
2. Appendicular artery
3. Appendicular mesentery
4. Ilium
5. Caecum

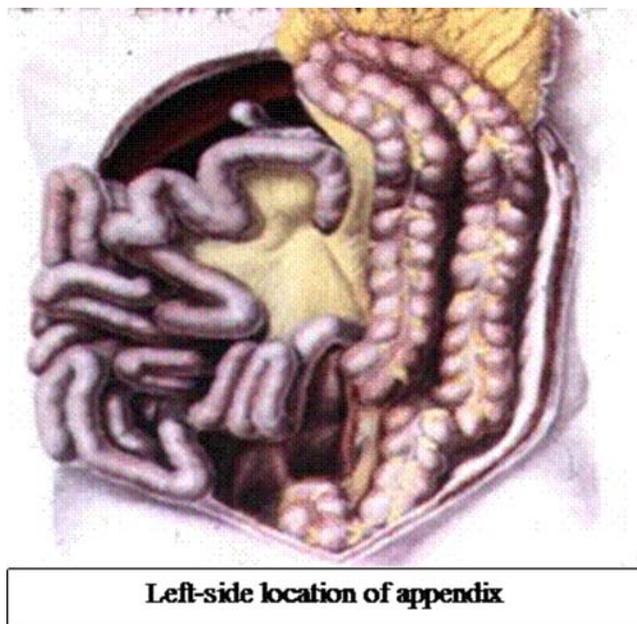

Appendicitis at retrocecal and retroperitoneal location of appendiceal appendix can be with 8–20 % patients. Thus an appendix can be placed both in a free abdominal cavity and retroperitoneal. An atypical clinic arises, as a rule, at the retroperitoneal location. The patients complain at pain in lumbus or above the wing of right ileum. There they mark painfulness during palpation. Sometimes the pain irradiates to the pelvis and in the right thigh. The positive symptom of Rozanov — painfulness during palpation in the right Pti triangle is characteristic. In transition of inflammatory process on an ureter and kidney in the urines analysis red corpuscles can be found.

Appendicitis at the pelvic location of appendix can be met in 11–30 % cases. In such patients the pain is localized above the right Poupart's ligament and above pubis. At the very low placing of appendix at the beginning of disease the reaction of muscles of front abdominal wall on an inflammatory process can be absent. With transition of inflammation on an urinary bladder or rectum either the dysuric signs or diarrhea develops, mucus appears in an excrement. Distribution of process on internal genital organs provokes signs characteristic of their inflammation.

Appendicitis at the *medial placing* of appendix. The appendix in patients with such pathology is located between the loops of intestine, that is the large field of suction and irritation of peritoneum. At these anatomic features mesentery is pulled in the inflammatory process, acute dynamic of the intestinal obstruction develops in such patients. The pain in the abdomen is intensive, widespread, the expressed tension of muscles of abdominal wall develops, that together with symptoms of the irritation of peritoneum specify the substantial threat of peritonitis development.

For the *subhepatic location* of appendix the pain is characteristic in right hypochondrium. During palpation painfulness and tension of muscles can be marked.

Left-side appendicitis appears infrequently and, as a rule, in case of the reverse placing of all organs, however it can occur at a mobile blind gut. In this situation all signs which characterize acute appendicitis will be exposed not on the right, as usually, but on the left.

Among complications of acute appendicitis most value have appendiceal infiltrates and abscesses.

[Appendiceal infiltrate](#) is the conglomerate of organs and tissue not densely accrete round the inflamed vermiform appendix. It develops, certainly, on 3–5th day from the beginning of disease. Acute pain in the stomach calms down thus, the general condition of a patient gets better. Dense, not mobile, painful, with unclear contours, formation is palpated in the right iliac area. There are different sizes of infiltrate, sometimes it occupies all right iliac area. The stomach round infiltrate during palpation is soft and unpainful.

At reverse development of infiltrate (when resorption comes) the general condition of a patient gets better, sleep and appetite recommence, activity grows, the temperature of body and indexes of blood is normalized. Pain in the right iliac area calms down, infiltrate diminishes in size. In this phase of infiltrate physiotherapeutic procedure is appointed, warmth on the iliac area.

In two months after resorption of infiltrate appendectomy is conducted.

At abscessing of infiltrate the condition of a patient gets worse, the symptoms of acute appendicitis become more expressed, the temperature of body, which in most cases gains hectic character, rises, the fever appears. Next to that, pain in the right iliac area increases. Painful formation is felt there. In the blood test high leukocytosis is present with the acutely expressed change of leukocyte formula to the left.

Local abscesses of abdominal cavity, mainly, develops as a result of the atypical placing of appendix or suppuration. More frequent from other there are pelvic abscesses. Thus a patient is disturbed by pain beneath the umbilicus, there are dysuric disorders, diarrhea and tenesmus. The temperature of body rises to 38,0–39,0°C, and rectal — to considerably higher numbers. In the blood test leukocytosis, change of formula of blood is fixed to the left.

During the rectal examination the weakened sphincter of anus is found. The front wall of rectum at first is only painful, and then its overhanging is observed as dense painful infiltrate. [Slide](#).

A *subdiaphragmatic abscess* develops at the high placing of appendix. The pain in the lower parts of thorax and in an upper quarter of umbilicus often to the right, that increases at deep inhalation except for the signs of intoxication, is characteristic of it. A patient, generally, occupies semisitting position. Swelling in an epigastric area is observed in heavy cases, smoothing and painful intercostal intervals. The umbilicus often during palpation is soft, although tension in the area of right hypochondrium is possible. Painfulness at pressure on bottom (9–11) ribs is the early and permanent symptom of subdiaphragmatic abscess (the Krukov's symptom).

Roentgenologically the right half of diaphragm can fall behind from left one while breathing, and there is a present reactive exudate in the right pleura cavity. A gas bubble is considered the roentgenologic sign of subdiaphragmatic abscess with the horizontal level of liquid, which is placed under the diaphragm.

[Interloop abscesses](#) are not frequent complications of acute appendicitis. As well as all abscesses of abdominal cavity, they pass the period of infiltrate and abscess formation with the recreation of the proper clinic.

The poured festering peritonitis develops as a result of the timely unoperated appendicitis. Diagnostics of this pathology does not cause difficulties.

Pylephlebitis is a complication of both appendicitis and after-operative period of appendectomy.

The reason of this pathology is acute retrocecal appendicitis. At its development the thrombophlebitis process from the veins of appendix, passes to the veins of bowels mesentery, and then on to the portal vein. Patients complain at the expressed general weakness, pain in right hypochondrium, high hectic temperature of body, fever and strong sweating. Patients are adynamic, with expressed subicteritiousness of the scleras. During palpation painfulness is observed in the right half of umbilicus often and the symptoms of irritation of peritoneum are not acutely expressed.

In case with rapid passing of disease the icterus appears, the liver is increased, kidney-hepatic insufficiency makes progress, and patients die in 7-10 days from the beginning of disease. At gradual subacute development of pathology the liver and spleen is increased in size, and after the septic state of organism ascites arises.

Diagnostic program

1. Anamnesis information.
2. Information of objective examination.
3. General analysis of blood and urine.
4. Vaginal examination for women.
5. Rectal examination for men.

Differential diagnostics

Acute appendicitis is differentiated with the diseases which are accompanied by pain in the umbilical area.

Food toxicoinfection. Complaints for pain in the epigastric area of the intermittent character, nausea, vomiting and liquid emptying are the first signs of disease. The state of patients progressively gets worse from the beginning. Next to that, it is succeeded to expose that a patient used meal of poor quality. However, here patients do not have phase passing, which is characteristic of acute appendicitis, and clear localization of pain. Defining the symptoms of irritation of peritoneum is not succeeded, the peristalsis of intestine is, as a rule, increased.

Acute pancreatitis. In anamnesis in patients with this pathology there is a gallstone disease, violation of diet and use of alcohol. Their condition from the beginning of a disease is heavy. Pain is considerably more intensive, than during appendicitis, and is concentrated in the upper half of umbilical area. Vomiting is frequent and does not bring to the recovery of patients.

Perforative peptic and duodenum ulcer. Diagnostic difficulties during this pathology arise up only on occasion. They can be in patients with the covered perforation, when portion of gastric juice flows out in an abdominal cavity and stays too long in the right iliac area, or in case of atypical perforations. Taking it into account, it is needed to remember, that the pain in the perforative ulcer is considerably more intensive in epigastric, instead of in the right iliac area. On the survey roentgenogram of organs of abdominal cavity under the right cupula of diaphragms free gases can be found.

The apoplexy of ovary more frequent is with young women and, as a rule, on 10-14 day after menstruation. Pain appears suddenly and irradiate in the thigh and perineum. At the beginning of disease there can be a collapse. However, the general condition of patients suffers insignificantly. When not enough blood was passed in the abdominal cavity, all signs of pathology of abdominal cavity organs calm down after some time. Signs, which are characteristic of acute anemia, appear at considerable hemorrhage. Abdomen more frequent is soft and painful down, (positive Kulenkampff's symptom: acute pain during palpation of stomach and absent tension of muscles of the front abdominal wall).

During paracentesis of back fornix the blood which does not convolve is got.

Extra-uterine pregnancy. A necessity to differentiate acute appendicitis with the interrupted extra-uterine pregnancy arises, when during the examination the patient complains at the pain only down in the stomach, more to the right. Taking it into account, it is needed to remember, that at extra-uterine pregnancy a few days before there can be intermittent pain in the lower part of the abdomen, sometimes excretions of "coffee" colour appear from vagina. In anamnesis often there are the present gynaecological diseases, abortions and pathological passing of pregnancy. For the clinical picture of such patient inherent sudden appearance of intensive pain in lower part of the abdomen. Often there is a brief loss of consciousness. During palpation considerable painfulness is localized lower, than at appendicitis, the abdomen is soft, the positive Kulenkampff's symptom is determined. Violations of menstrual cycle testify for pregnancy, characteristic changes are in milk glands, vagina and uterus. During the vaginal examination it is sometimes possible to palpate increased tube of uterus. The temperature of body more frequently is normal. If hemorrhage is small, the changes in the blood test are not present. The convincing proof of the broken extra-uterine pregnancy is the dark colour of blood, taken at puncture of back fornix of vagina.

Acute cholecystitis. The high placing of vermiform appendix in the right half of abdomen during its inflammation can cause the clinic somewhat similar to acute cholecystitis. But unlike appendicitis, in patients with cholecystitis the pain is more intensive, has cramp-like character, is localized in right hypochondrium and irradiate in the right shoulder and shoulder-blade. Also the epigastric phase is absent. The attack of pain can arise after the reception of spicy food and, is accompanied by nausea and frequent vomiting by bile. In anamnesis patients often have information about a gallstone disease. During examination intensive painfulness is observed in right hypochondrium, increased gall-bladder and positive symptoms Murphy's and Ortner's.

Right-side kidney colic. For this disease termina at the level of kidney and in lumbus is inherent, hematuria and dysuric signs which can take place at the irritation of ureter by the inflamed appendix. Intensity of pain in kidney colic is one of the basic differences from acute appendicitis. Pain at first appears in lumbus and irradiate downward after passing of ureter in genital organs and front surface of the thigh. In diagnostics urogram survey is important, and if necessary — chromocystoscopy. Absence of function of right kidney to some extent allows to eliminate the diagnosis of acute appendicitis.

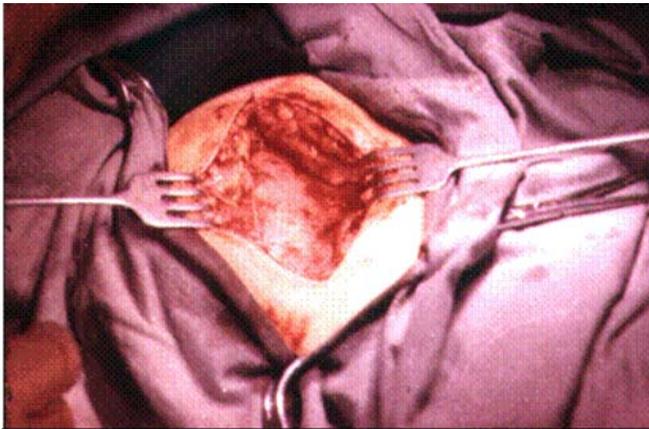

Tactics and choice of treatment method

As experience of surgeons of the whole world testifies, in acute appendicitis timely operation is the unique effective

method of treatment.

Access for appendectomy must provide implementation of operation. [McBurney's incision](#) is typical.

When during operation the appendix without the special difficulties can be shown out [in a wound](#), antegrade *appendectomy* is executed. On clamps its mesentery is cut off and ligated. Near the basis the appendix is [ligated and cut](#). Stump is processed by solution of antiseptic and peritonized by a purse-string suture .

McBurney's incision

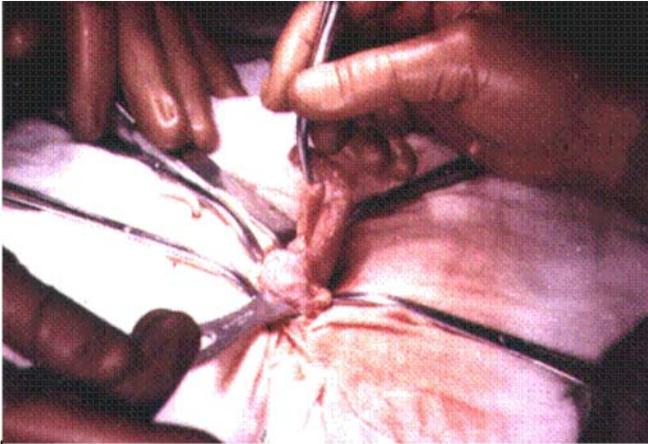

Dissecting of aponeurosis

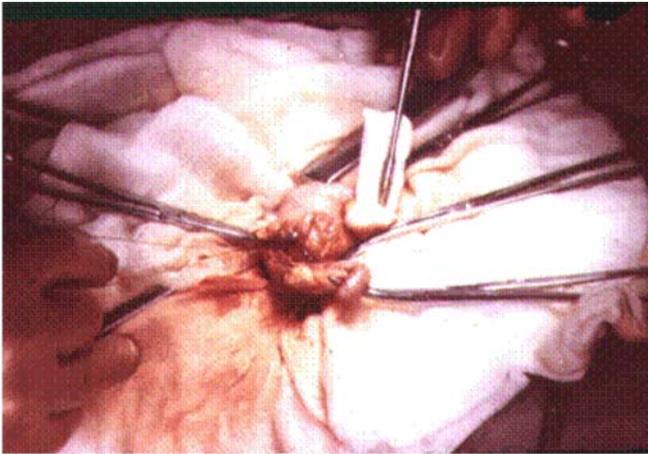

**Deviation of internal oblique and transverse
muscles**

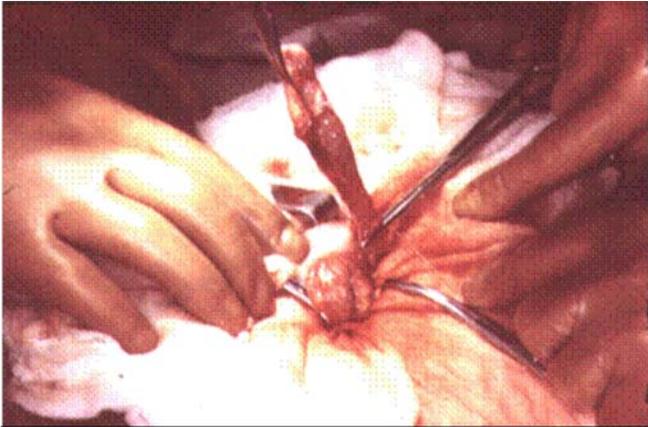

Dissection of the peritoneum

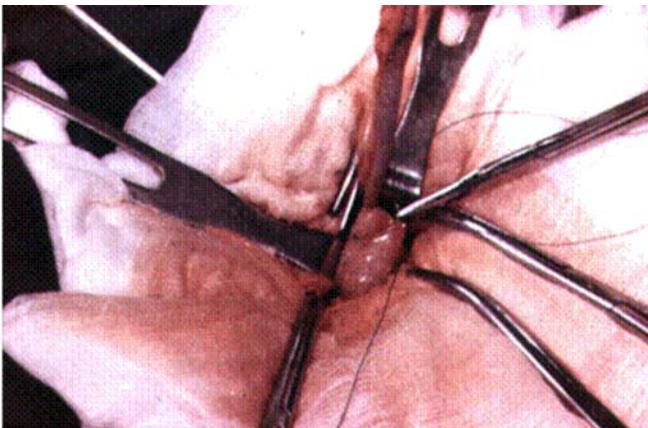

Drawing out the cecum (appendix) into the wound

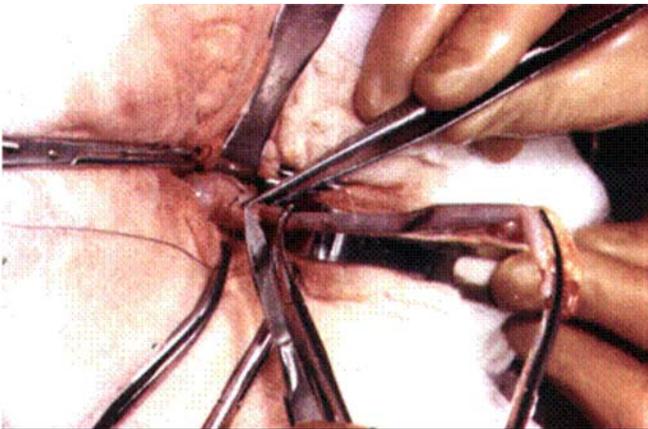

Ligation and cutting off the appendicular mesenterium

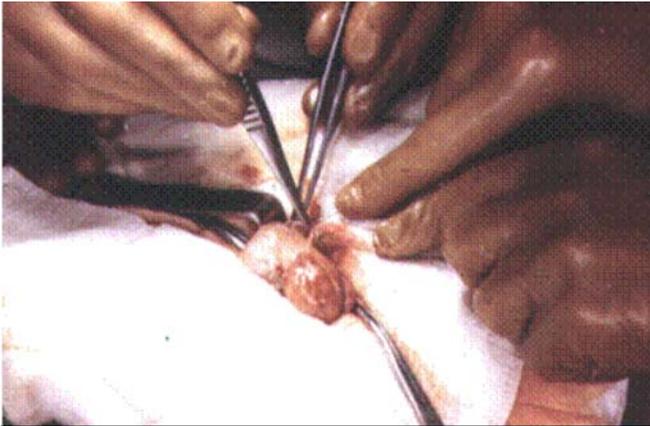

Ligation of appendix near the base

Purse-string suture on the base

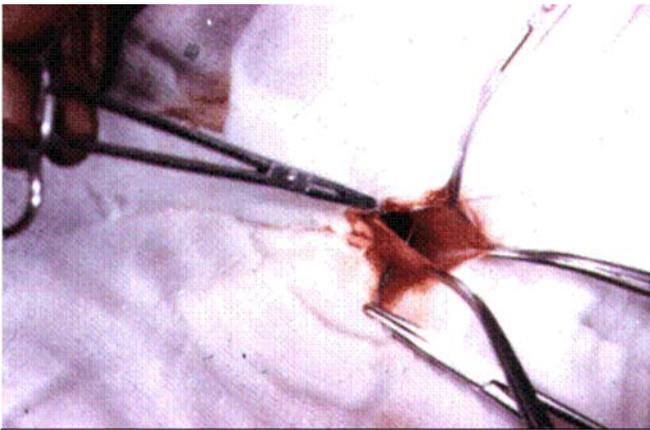

Cutting off the appendix

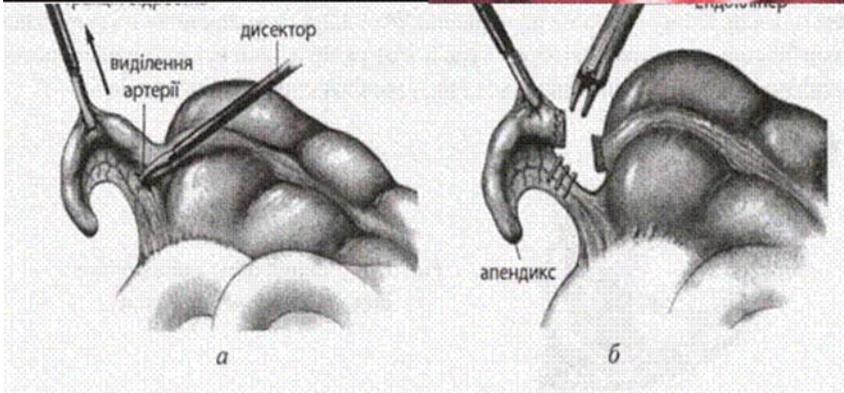

Plunging the appendicular stump

Z-like peritonealization of the appendicular stump

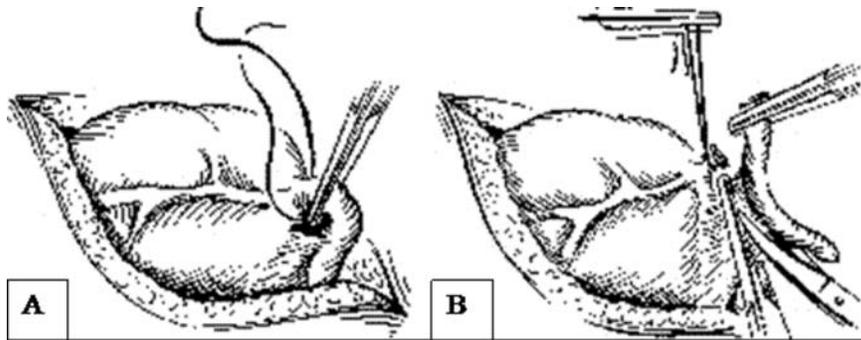

Suturing of peritoneum

Laparoscopic appenectomy

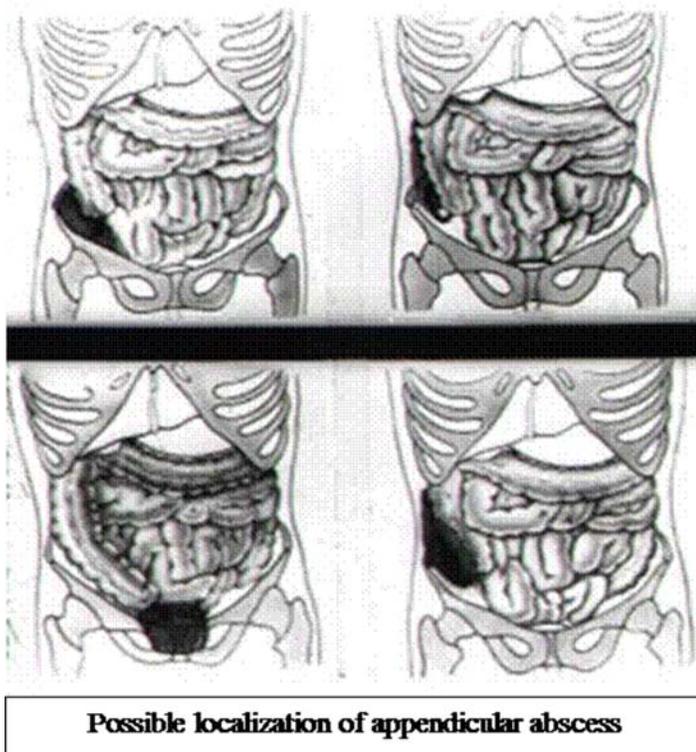

If only the basis of appendix is taken in a wound, and an apex is fixed in an abdominal cavity, more rationally retrograde appendectomy is performed. Thus the appendix near basis is cut between two ligatures. Stump is processed by antiseptic and peritonized. According to it the appendix is removed in the direction from basis to the apex.

**A****B****Retrograde appendectomy****A – ligation of appendicular base****B – mobilization of appendix**

According to indication operation is concluded by draining of abdominal cavity (destructive appendicitis, exudate in an abdominal cavity, capillary hemorrhage from the bed). In recent years the laparoscopy methods of appendectomy are successfully performed.

In patients with appendiceal infiltrate it is necessary to perform conservative-temporizing tactic. Taking it into account, bed rest is appointed, protective diet, cold on the area of infiltrate, antibiotic therapy. According to resorption of infiltrate, in two months, planned appendectomy is executed.

Treatment of appendiceal abscess must be only operative. Opening and drainage of abscess, from [retroperitoneal access](#), is performed. To delete here the appendix is not necessary, and because of danger of bleeding, peritonitis and intestinal fistula — even dangerously.

[video2](#)

[video3](#)

Acute pancreatitis

The basis of disease of pancreas is degenerative-inflammatory processes which are considered to be acute pancreatitis tissue by its own enzymes. In the structure of acute pathology of organs of abdominal cavity this disease takes the appendicitis and cholecystitis. Women suffer from acute pancreatitis 3–3,5 times more frequently than men.

Anatomy(Fig.1;Fig.2; Fig.3.)

Etiology and pathogenesis

Acute pancreatitis is a polyetiology disease. Its secondary forms, which arise on the background of pathologies of bile-excreting system and duodenum are closely associated with anatomic and functionally with pancreas, and are met in clinical practice.

Among the “starting” factors of origin of cholelithiasis disease (biliary pancreatitis) abuse by an alcohol and food overloads (fat and irritating products), traumas of pancreas, operating-room in particular, and also separate infectious

diseases (parotitis, mononucleosis) are most frequent, especially infection of bilious ways. However, in 10–20 % of patients the reason of acute pancreatitis remains unknown (cryptogenic form).

In the basis of such damages of pancreas and enzymic toxemia lies mainly activating of pancreatic, and then the tissue enzymes (trypsin, lipase, amylase). Often the combination of the broken outflow of pancreatic secret and promoted secretion takes place, which provokes intraductal hypertension.

Among explanations of primary mechanisms of activating of pancreatic enzymes the most value belongs to: a) theory of “general duct” with reflux of bile in the ducts of pancreas; b) blockade of outflow of pancreatic juice with development of intraductal hypertension and penetration of secret in interstitial tissue; in) violation of blood flow of pancreas (vasculitis, thrombophlebitis and embolisms, cardiac insufficiency and others like that); g) toxic and allergic damages of gland. The role of alcohol in such situations can be dual: stimulation of secretion of pancreas and direct damaging action on its tissue.

Pathomorphology

The process of acute inflammation of pancreas consistently passes the stages of edema, pancreatonecrosis and festering pancreatitis. In the stage of edema there is pancreas of hyperemic, increased in volume, with the shallow hearths of necrosis or, as it is in swingeing majority of cases, without them.

Pancreatonecrosis can pass with fatty or hemorrhagic character. In the first case, as a rule, pancreas is increased, dense, cut whity-yellow hearths are selected to necrosis. Increase of crimson-black pancreas with darkly-brown infiltrate on a cut is characteristic for hemorrhagic pancreatonecrosis.

Dystrophy of parenchyma is exposed microscopically, up to necrosis, hemorrhages, thromboses of vessels and signs of inflammatory infiltration.

Classification

(V All-russian convention of surgeons, 1978)

I. Clinico-anatomy forms:

1. Arching form.
2. Fatty pancreatonecrosis.
3. Hemorrhagic pancreatonecrosis.

II. Prevalence of necrosis:

1. Local (focus) damage of gland.
2. Subtotal damage of gland.
3. Total damage of gland.

III. Ran across: abortive, progressive.

IV. Periods of disease:

1. Period of hemodynamic violations and pancreatogenic shock.
2. Period of functional insufficiency of parenchymatous organs.
3. Period of degenerative and festering complications.

Symptoms and clinical passing

The disease begins suddenly, after the surplus reception of rich spicy food and use of alcohol. Pain, vomiting and phenomena of dynamic intestinal obstruction are considered the most characteristic signs of acute pancreatitis.

A stomach-ache is permanent and so strong, that can result in shock, localized in an epigastric area and left hypochondrium. Some patients feel pain in right hypochondrium with irradiation in the back, loin or breastbone. (Fig.4)

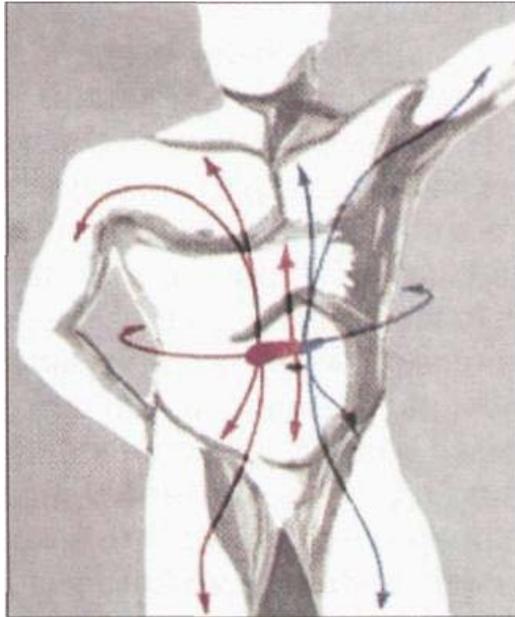

Fig.4.Scheme of pain irradiation at acute pancreatitis

In a short period of time after appearance of pain there is a repeated strong vomiting, that does not facilitate the state of patient.

In general vomiting is considered a frequent and characteristic symptom. It is repeated or continuous and never brings facilitation. Vomit masses contain bile, as admixture, and at the difficult form of acute pancreatitis remind “coffee-grounds”.

Nausea, hiccup, belch and dryness in a mouth are attributed as less characteristic symptoms of this pathology.

During the examination the skin is pale, often subicterus. Some patients have cyanosis with a “marble picture” as a result of violation of microcirculation. Later the component of respiratory insufficiency can join it. At progressive general condition the patient quickly gets worse to passing of acute pancreatitis, intoxication grows. The skin takes shelter with sticky sweat.

The temperature of body of patients at the beginning of disease can be normal. It rises at resorption of products of autolysis tissue and development of inflammatory process in bilious ways.

The pulse in most cases is at first slow, then becomes frequent, notably passing ahead the increase of temperature of body.

Arterial pressure goes down.

The tongue in the first hour of disease is moist, assessed by white and grey raid. At vomiting by bile the raid has yellow or greenish tint.

The abdominal is blown away, peristaltic noises are loosened. The signs of paresis of stomach and intestine demonstrate early. They need to be included in the pathological process of mesentery root of bowel. At palpation painfulness in an epigastric area and in right, and sometimes and in left, hypochondrium is marked. However, in spite of great pain in stomach, it remains soft for a long time. A little later there is moderate tension or resistance of muscles of front abdominal wall.

Poor local symptoms during heavy intoxication are characteristic for the early period of acute pancreatitis. Later there are symptoms of irritation of peritoneum, and at percussion dulling is marked in lateral parts of abdominal as a result of accumulation of liquid, and also the sign of aseptic phlegmon of retroperitoneal cellulose as slurred or edema of lumbar area is seen. For diagnostics of acute pancreatitis there is the row of characteristic symptoms which have different clinical value.

The Mondor's symptom is violet spots on face and trunk.

The Lagermph's symptom is acute cyanosis of person.

The Halsted's Symptom is cyanosis of abdominal skin.

The Gray's symptom is cyanosis of lateral walls of abdomen.

The Kullen's symptom is the yellow colouring of skin near a belly-button.

The Korte's symptom is painful resistance as a lumbar bar in a epigastric area on 6–7 cm higher belly-button.

The Voskresynskyy's symptom is absence of pulsation of abdominal aorta in an epigastric area.

The Mayo-Robson's symptom is feeling of pain at pressure by fingers in the left costal-vertebral corner.

The Rozdolsky's symptom — painfulness at percussion above pancreas.

The Blumberg's symptom — in patients with acute pancreatitis more frequently is low-grade. Such feature of this sign of irritation of peritoneum needs to be explained by character of localization of pathological process, mainly in retroperitoneal spacious.

In clinical passing of pancreatonecrosis it is possible to select three periods (V.S. Saveljev, 1978).

The I period (hemodynamic violations and pancreatogenic shock) lasts during 2–3 days. Violation of central hemodynamics, diminishment of volume of circulatory blood and disorders of microcirculation, which at first arise as a result of angiospasm, are considered the most characteristic signs, and later as a result of joining of the intravascular rolling up and laying of elements of blood.

The II period (insufficiency of parenchymatous organs) lasts from 3rd to the 7th day of disease. Violation of functions of basic organs and systems, sign of cardio-vascular, hepatic and kidney insufficiency and growth of violations of breathing are thus observed. In this period there is possible damaging of the central nervous system, which is erected mainly to disorders of psyche, appearances of delirium and commas which in the eventual result are the main reasons of patients' death.

The III period (postnecrosis dystrophic and festering complications) comes in 1–2 weeks after the beginning of disease. During it, on the background of progress of necrosis processes in pancreas, the regenerative changes develop, there are parapancreatic infiltrate and cysts, cystic fibrosis of pancreas. Aseptic retroperitoneal phlegmon which strengthens intoxication can also develop. There is festering pancreatitis at joining of infection. During this period such complications, as erosive bleeding, internal or external fistula, retroperitoneal phlegmon, can develop in patients. (Fig.5)

Fig.5. Scheme of pyo-inflammatory diffusion at acute pancreatitis

- 1- subhepatic space(6%)
- 2- right lateral flanc(23%)
- 3- subphrenic space(36 %)
- 4- left lateral flanc(40%)
- 5- retroperitoneal space(67%)

From laboratory information leucocytosis which at the necrosis and hemorrhagic forms of pancreatitis sometimes arrives at $25-30 \times 10^9/l$, lymphopenia, change of leukocytic formula to the left and the increased ESR are characteristic. Growth of activity of amylase of blood and urine is very often marked, and is the important sign of pancreatitis. For estimation of the state of other organs maintenance of general albumen and its factions, glucose of blood, bilirubin, urea, electrolytes, acid-base equilibrium (ABE), and also the state of blood coagulation are determined. It is necessary to mark that the exposure of hypocalcemia is considered a bad predictive sign of heavy passing of acute pancreatitis.

Ultrasonic examination of gall-bladder and pancreas often specifies the increase of their sizes, bulge of walls and presence or absence of concrement of gall-bladder and general bilious duct.

Computer tomography enables to describe in details the changes in pancreas and surrounding organs.

At *sciagraphy survey* of organs of abdominal cavity gives a possibility to expose the unfolded “horseshoe” of duodenum, pneumatization, expansion of transverse colon (*the Gobia's symptom*). On the 1st stage of diagnostics in the plan of differential diagnosis of acute destructive pancreatitis with other diseases of abdominal cavity, diagnostics of distribution of destructive damaging of different parts of pancreas and estimation of distribution of parapancreatitis is possible only by the method of computer tomography which depending on clinico-laboratory signs and weight of passing is needed to apply in a different period, and sometimes a few times in dynamics with interval of 4–5 days.

Laparoscopy and laparocentesis are often used for a doubtful diagnosis or necessity of taking away the exudation of abdominal cavity for biochemical or bacteriological examination.

Retrograde endoscopic cholangiopancreatography is used in case of mechanical icterus and suspicion of choledocholithiasis. The last methods are invasive and can if it is necessary transform from diagnostic to manipulation treatments: laparoscopic draining of abdominal cavity at pancreatogenic peritonitis and endoscopic papillotomy at choledocholithiasis and biliary pancreatitis.

Variants of clinical passing and complications

Clinical passing of disease can be abortive, slowly or quickly progressive. At *abortive passing* the process is limited to acute edema of pancreas with convalescence in 7–10 days.

Rapid progress is characteristic for pancreatonecrosis. In patients expressed toxemia, impregnation by exudation of retroperitoneal cellulose and development of fermentative hemorrhagic peritonitis can be seen. Strengthening of stomachache, continuous vomiting, proof paresis of intestine, positive symptoms of irritation of peritoneum and growth of hemodynamic violations are the clinical signs of necrosis of pancreas.

There is a formation of parapancreatic infiltrate at *slow progress*.

Among early complications of acute pancreatitis shock, peritonitis and acute cardiac, pulmonary, hepatic and kidney insufficiency can be distinguished.

Before later complications it is needed to deliver the abscesses of pancreas, subdiaphragmatic, interintestinal abscesses, pyogenic abscess omentum bag, phlegmons of retroperitoneal space and erosive bleeding.

In future formations of pseudocysts, fistula of pancreas, intestinal fistula and development of saccharine diabetes are possible.

Diagnosis program

1. Anamnesis and physical methods of inspection.
2. General analysis of blood and urine.
3. Biochemical blood test (amylase, bilirubin, sugar).
4. Analysis of urine on diastase.
5. Sonography.
6. Computer tomography.
7. Cholecystocholangiography.
8. Endoscopic retrograde cholangiopancreatography.
9. Laparoscopy.
10. Laparocentesis.

Differential diagnostics

Acute pancreatitis needs to be differentiated with the row of acute diseases of organs of abdominal cavity.

Acute mechanical intestinal obstruction. In patients with this pathology pain is of the alternated character and is accompanied by nausea, vomiting, delay of gases and emptying. It is possible to see the Klotz bowls on the sciagram survey of organs of abdominal cavity.

Acute cholecystitis runs with characteristic localization of pain and muscular defense, with presence of increased, painful gall-bladder or infiltrate in right hypochondrium. Often acute (especially lately) pancreatitis develops on the background of gallstone disease (biliary pancreatitis).

Thrombosis or embolism of mesenteric vessels. Both for pancreatitis and for the thrombosis of mesenteric vessels great pain at soft abdomen (absence of defense muscles of front abdominal wall), that precedes to development of peritonitis, is inherent. Yet from the beginning the disease gains heavy character of passing. In anamnesis in such

patients a heart disease or heart attack of myocardium rheumatic is met. As a result of gangrene of intestine, the symptoms of peritonitis appear very quickly and intoxication grows. The fragments of mucus shell are found in flushing waters of intestine at the detailed examination, which have the appearance of "meat flushing".

A perforated gastric and duodenum ulcer is distinguished by the presence of dagger pain, defense of abdominal wall, ulcerous anamnesis.

Tactics and choice of treatment method

The conservative method is considered the basic one for treatment of acute pancreatitis, but in connection with that unsuccessful conservative treatment of patients with acute pancreatitis can often put a question about the necessity of operation, therefore patients must be in permanent surgical establishment. Thus acute pancreatitis with heavy passing is necessary to be treated under the conditions of separation of intensive therapy.

Before conservative treatment hunger, bed rest, fight against pain and enzymic toxemia, conducting of acid-base state, prophylaxis of festering infection and acute ulcers of digestive duct are to be entered.

Patient's stomach is washed by cold soda solution and a cold on an epigastric area and left hypochondrium is used. Medicinal therapy is prescribed also: spasmolytics (papaverine, platyphyllin, no-shparum, baralgine, atropine); inhibitor of protease (contrical, trasilol, gordox, antagosan); cytostatic agent (5-fluorouracil, florafur). Positive action of inhibitor of protease is marked only in the first days of disease which are subject to conditioned application of large doses. Antibiotics of wide spectrum of action: a) tienam, which most effective in the prophylaxis of festering pancreatitis, as is selected by pancreatic juice; b) cephalosporins (kefzol, cefazoline); c) cefamizine (mefoxine).

Disintoxication therapy is conducted also (5 % but 10 % solutions of glucose, hemodes, reopolyhlukine, polyhlukine, plasma of blood, only from 3 to 5 liters on days, in accordance with a necessity).

For the improvement of rheological properties of blood heparine is prescribed (5 000 ODES every 4 hours).

If patients have the expressed pain syndrome and phenomena of general intoxication during all pain period plus 48 hours (by Bakulev), hunger is used. Such mode lasts on the average of 2–4 days. The parenteral feed of albuminous hydrolyzate is thus conducted, by the mixtures of amino acid and fatty emulsion. Alkaline water of to 1–2 l. and albuminous-carbohydrate diet are also appointed. Infusion therapy is complemented by plasma, by albumen, hemodes, reopolyhlukine. The improvements of microcirculation in pancreas are achieved due to introduction of reopolyhlukine, komplamine, trental and heparin 5000 ODES 6 times per days under the control the indexes of the coagulation system of blood. Anticholinergic drug (sulfate of atropine, methacin, platyphyllin), H₂-histamin blocker (cimetidine, ranisan, ranitidine, famotidine, omeprazol) are also applied. For the removal of pain: 1) sulfate of the atropine 0,1 % — 1 ml + promedol 2 % — 1 ml + papaverine 2 % — 2 ml + analgin 50 % — 2 ml; 2) isotonic solution of chloride of sodium — 500 ml + baralgine — 5 ml + diphenhydramine hydrochloride 1 % — 1 ml + papaverine 2 % — 2 ml + magnesium the sulfate 25 % — 5 ml + ascorbic acid — 5 ml + lipoic acid 0,5 % — 2 ml + novocaine 0,5 % — 10 ml. are used. From the first days by a nasogastral probe the permanent aspiration of gastric maintenance is conducted also. The Motility function of gastro-intestinal highway gets better at application of cerucal or primperane. With the same purpose forced diuresis (maninil, furosemide, aminophylline) is used on the background of intravenous introduction of plenty of liquid.

At uneffective conservative treatment of patients with acute pancreatitis of middle weight and heavy form it is expedient to apply surgical treatment.

Surgical treatment is carried out for patients with biliary pancreatitis (for a day long from the beginning of disease) in combination with the destructive forms of cholecystitis, at complications of acute pancreatitis by peritonitis, abscess of omentum bag or phlegmon of retroperitoneal cellulose.

Overhead-middle laparotomy, which allows to estimate the state of pancreas, bilious ways and other organs of abdominal cavity, is the best access in this situation. In case of destructive pancreatitis the possible use of lumbar laparotomy from left to right hypochondrium through a mesogastric area is useful.

Cholecystectomy is executed at calculous cholecystitis, phlegmonous inflammation of walls of gall-bladder and biliary pancreatitis. If there are more than 0,9 cm at expansion of choledochus, presence of concrement, ointment-like bile in it, increase of concentration of bilirubin in the whey of blood over 21 mmol/L, choledocholithotomy is complemented by external draining of choledochus. Information of lithiasis of general bilious duct is absent, cholecystectomy in patients with acute pancreatitis is complemented by external draining of choledochus, better by Pikovskyy method (through stump of cystic duct).

Transduodenal sphincteroplasty (Fig.6) is shown at fixed concrement of large duodenal papilla, if they are diagnosed intraoperative, and also in the cases of papillotomy with extraction of concrement when there is no possibility to execute endoscopic operation.

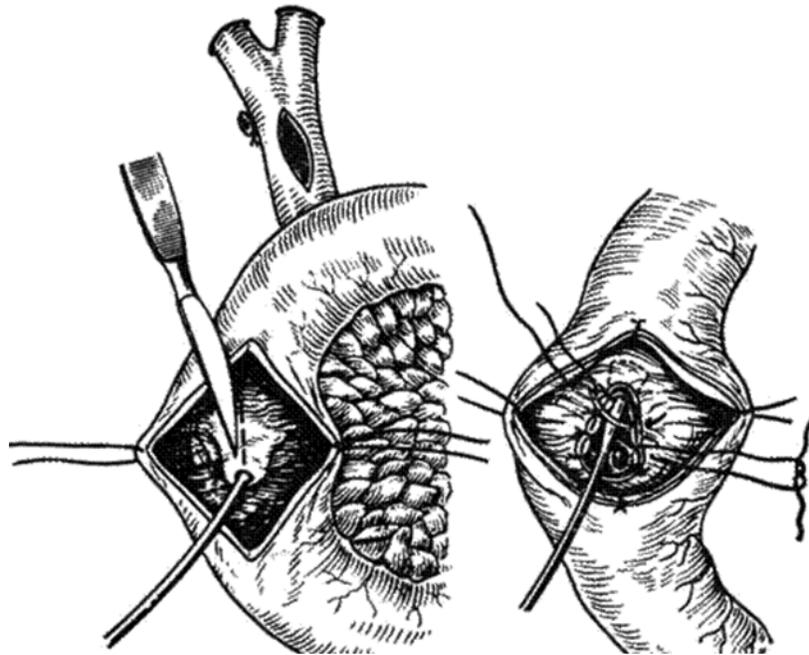

Fig.6. Transduodenal papillotomy with sphincteroplasty

Omentopancreatopexy. After laparotomy and cutting of gastro-colon and gastro-pancreatic ligament mobile part of large omentum through opening in gastro-colon ligament is conducted and fixed by separate stitches to the peritoneum along the overhead and lower edges of pancreas. Such operation needs to be considered rational at the expressed edema of pancreas and presence of necrosis in it.

Abdominisation of pancreas. A cellulose round pancreas (along the lower and overhead edges of body and tail) is infiltrated by solution of novocaine, after it parietal peritoneum is cut. Under the body and tail glands free end of omentum is conducted and is bundled by a gland. This operation is able to warn the hit of enzymes and products of disintegration in retroperitoneal space.

Sequestrectomy is deleting of necrosis part of gland within the limits of nonviable tissue. Operation is executed in a dull way.

Necrectomy (deleting of necrosis part of gland within the limits of healthy tissue) is executed by an acute way: tissue of gland is cut on verge of necrosis and bleeding vessels are carefully banded.

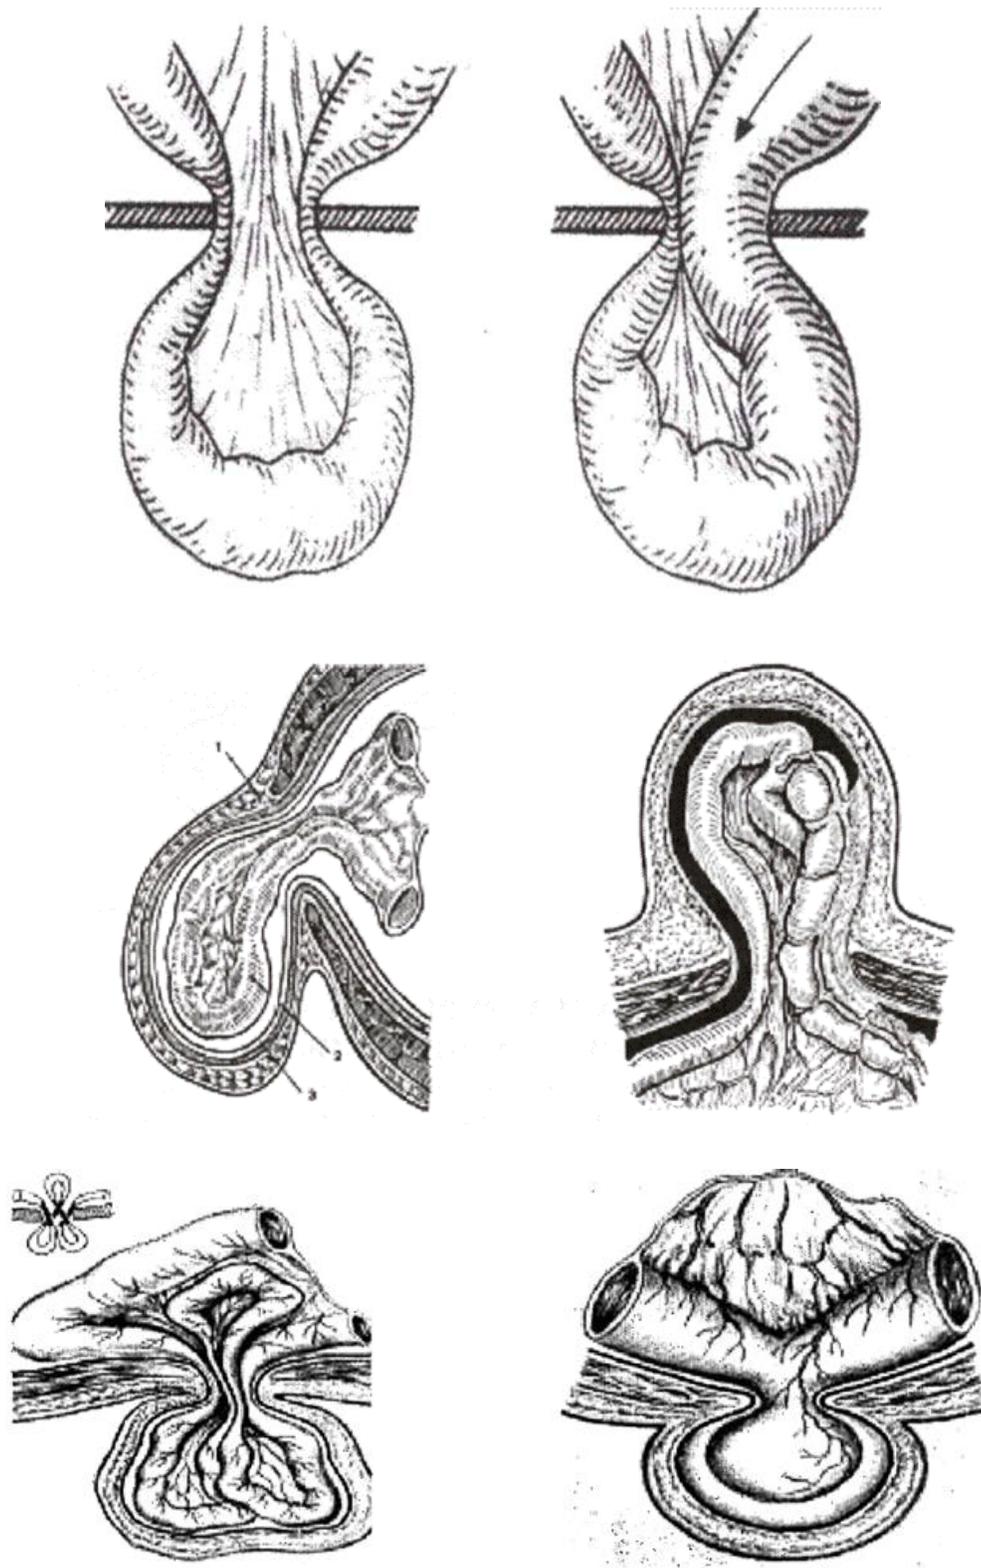

The resection of pancreas is deleting the part of organ with its transversal cutting within the limits of the unchanged (ad oculus) tissue of gland. The resections of tail and body of pancreas are distinguished.

Pancreatectomy is a complete deleting of pancreas. Operative treatment is applied infrequently. After the resection of pancreas adequate draining of its bed is very responsible.

The prognosis of disease depends on character of morphological changes of parapancreatic to the cellulose in pancreas. The more difficult destructive changes, the worst the prognosis.

INCARCERATED HERNIA

Incarcerated hernia is sudden pressing of hernia contents in a hernia orifice. Incarceration is the most frequent and most dangerous complication of hernia diseases.

Pic. Types of incarcerations

Etiology and pathogenesis

Depending on mechanism, the elastic and fecal incarceration is distinguished. At the *elastic incarceration*, after increasing intraabdominal pressure, one or a few organs relocated from an abdominal cavity to the hernia sack, where it is compressed with following ischemia and necrosis in the area of hernia gate. At the fecal incarceration in the intestinal loop which is in a hernia sack, plenty of excrement passed quickly. Proximal part of loop is

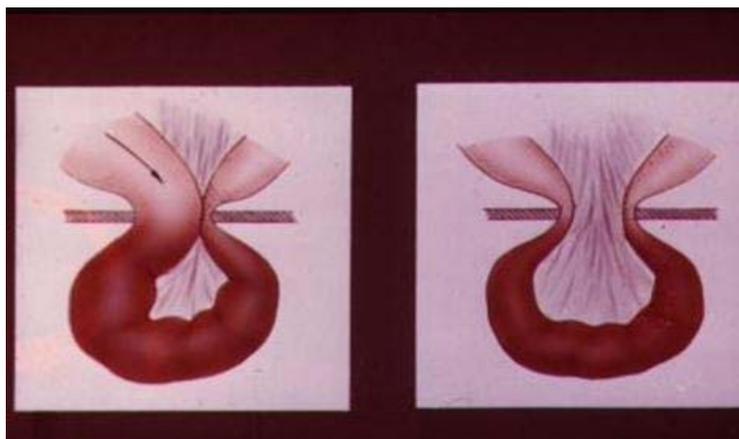

overfilled, and distal is compressed in a hernia gate. So, arose its strangulation, as well as at the elastic incarceration.

Most often the loop of bowel is incarcerated. Thus three parts are distinguished in it: proximal, distal loop, central part. The heaviest pathological changes during incarceration takes place in a strangulated furrow in the central part of the incarcerated bowel.

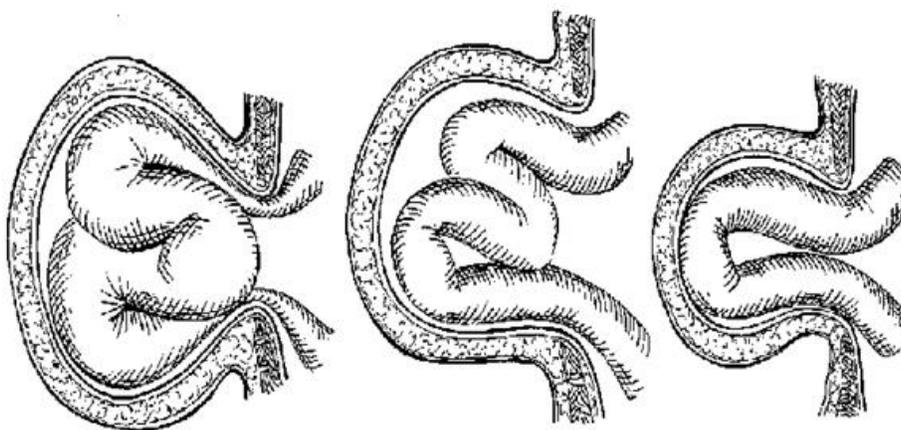

Pathomorphology

At incarcerated hernia an important role has all internal rings: inguinal, umbilical, “weak places” in a diaphragm, orifice of the omental bursa, numeral and “variant” folds of peritoneum.

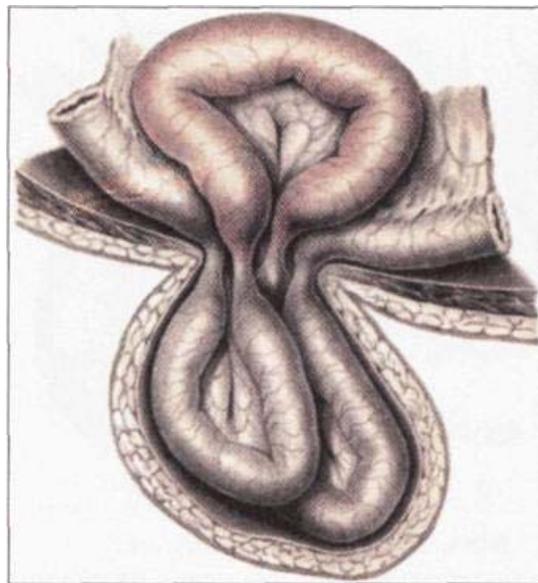

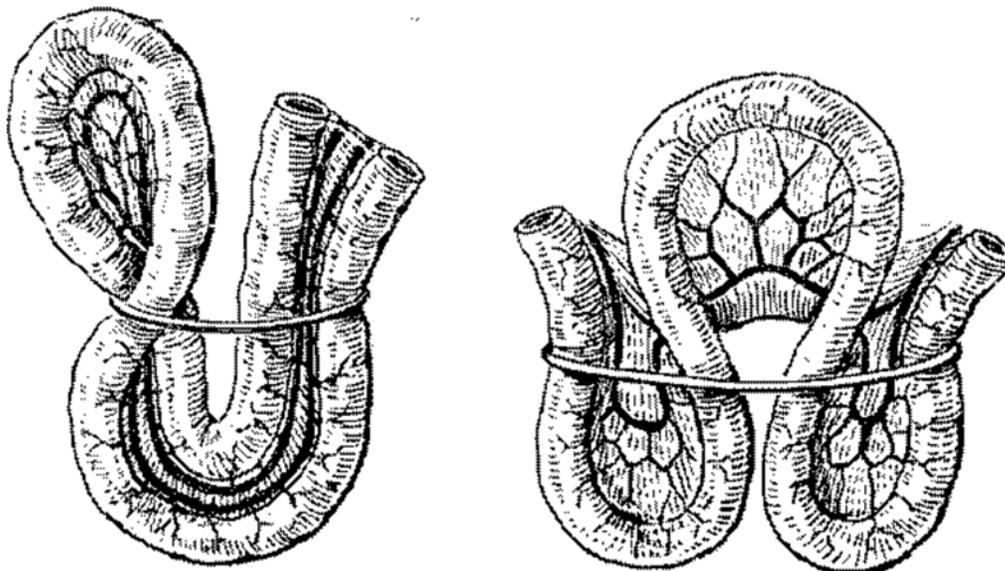

In the place of compressing of the bowels and mesentery, as a rule, it is possible to find a strangulation furrow. If circulation of blood changes, the wall of bowel cyanotic, with hemorrhages and necrosis of a different size. The loop of bowel which is located proximally the places of strangulation are extended, and distal loop mainly without changes.

Pic. Mechanizm of the incarceration.

Pic. Scheme of the incarceration.

Pic. Retrograde incarceration.

Classification of the incarcerated hernia

The incarcerated hernia is divided into the complete and incomplete. The other types of incarceration is partial (the Richter's hernia) and retrograde. The incarcerated hernia can be without the destructive changes of hernia contents and with the phlegmon of hernia sack.

Clinical management

The clinic of the incarcerated hernia depends on pulling in organ, character and duration of jamming. The clinical signs of the incarcerated hernia can be divided into three groups: 1) local changes; 2) common signs; 3) complication. From the most characteristic signs of local changes the most common is sharp pain, irreducible hernia, tension of hernia sack that and negative symptom of the "cough push".

Pain sometimes is so intensive that causes pain shock. In the case of intestinal obstruction a pain is attack-like. In case of occurring of peritonitis pain changes the character and becomes permanent.

It is necessary to mean that tensions of hernia sack and incarceration of the hernia, as signs of jamming, lose it value, if hernia was irreducible.

From other side, the isolation of hernia sack from an abdominal region during jamming is the reason of the *negative symptom of the "cough push"*.

The common signs at the incarcerated hernia has phase character. *Nausea* and *vomits* during first hours of disease has reflex reason, and on 2nd and 3rd days has toxic reason, that is consequence of antiperistaltic and reflux of intestinal contents to the stomach.

The *temperature of body* at first time is normal, and than rises, but usually low grade fever.

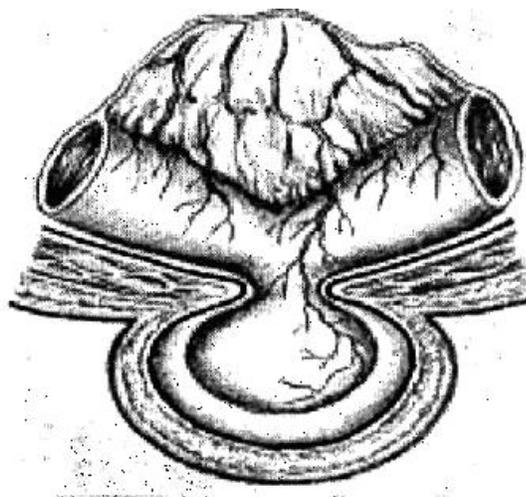

The clinic of acute intestinal obstruction and peritonitis develops at the protracted jamming of intestine. The phlegmon of hernia sack can develop in the area of the hernia swelling.

Clinical variants and complications

There are different forms of incarceration of internal organs, and accordingly — different clinical variants.

Retrograde incarceration. In such cases a hernia sack contains no less than two loops of intestine. But these loops are damaged less, than loop which is in an abdominal cavity. At this variant of jamming peritonitis arose quicker. So, surgeon during operation must always remember about the necessity of careful revision of the incarcerated loops of bowel.

Parietal incarceration (the Richter's hernia). Unlike retrograde, which has wide hernia gate, a similar pathology arises in case of narrow hernia gate. In a hernia sack in such patients located part of bowel wall, opposite it mesentery edge.

Thus, as a rule, patency of bowel is not broken. Such variant of jamming is dangerous, because there are no evident clinical signs or some of them are quite absent and intestinal patency almost is always present. Necrosis of bowel wall comes quickly and in 2-3 days the perforation with subsequent development of peritonitis begins after jamming.

The Littre's hernia. Jamming of Meckel's diverticulum can come at oblique inguinal hernia. Clinical signs of this pathology reminds the parietal incarceration. Sometimes is possible to palpate dense, short, thick tension bar in a hernia sack.

Incarceration at sliding hernia. It is observed at patients with inguinal hernia. At sliding hernia of colon, as a rule, there is the fecal incarceration. A bowel is the external wall of hernia sack in such cases. About it is necessary to remember during opening of hernia sack. Jammings of urinary bladder meet enough rarely, mainly at older-men at oblique sliding hernia of inguinal channel. It is necessary to ask before the operation, whether a patient had disorders of urination before jamming. Frequent urges, or, opposite, the reflex delay of urination is arose at the beginning of jamming already, and in urine expose macro- or microhematuria. If during operation at opening of hernia sack it medial wall has dense, doughy consistency, it is an urinary bladder.

At the incarcerated hernia the contents of hernia sack can be also omentum, appendages of colon, internal female genital organs. Sometimes combination of the incarcerated inguinal hernia with different pathological changes of testicle and deferent duct can take place.

Rough manual reduction of the incarcerated hernia can bring to pseudoreduction. Then the local signs of the incarcerated hernia disappear, and jamming of organs and its consequences is kept. There are five variants of the pseudoreduction: 1) at multicompartiment hernia sacks there is the possible moving of strangulated organs from one chamber in other, that located more deep or in a preperitoneal adipose tissue; 2) separation and reduction of hernia sack together with it content in an abdominal cavity or in a preperitoneal adipose tissue; 3) abruption of the neck from other part of hernia sack and reduction it together with content in an abdominal cavity or in a preperitoneal adipose tissue; 4) abruption of the neck from a hernia sack and from a parietal peritoneum with reduction of the incarcerated organs in an abdominal cavity; 5) break of the incarcerated bowel at the rough reduction of hernia.

Untimely operative at the incarcerated hernia, usually, is complicated by the gangrene of bowel, peritonitis or phlegmon of hernia sack. Such complications considerably worsen clinical status of patient and require other surgical tactic.

Diagnosis program

1. Anamnesis examination.
2. Physical examination.
3. Blood analysis and urine analysis.
4. Digital investigation of the rectum.
5. Survey X-Ray of abdominal cavity organs.

Differential diagnostics

As experience shows, the incarcerated hernia we should differentiate with irreducible, which as a rule, is not tense, positive symptom of the "cough push", painful on palpation. A patient complained for long duration of the disease. The incarcerated hernia needs to be differentiated with coprostasis. In such patients disorder of bowel loop patency, that is in a hernia sack, creates accumulation of excrement. Coprostasis mostly found at fecal hernia in older people, that suffer from intractable constipation. Clinically it develops gradually and slowly. The hernia swelling almost not painfully, some tense, a positive symptom of the "cough push". Beginning of coprostasis is unconnected with physical tension. Application of cleansing siphon enema washed of excrement and liquidated coprostasis.

Unreal jamming of hernia. In clinical practice there are often such situation, when during the acute surgical diseases of organs of abdominal cavity free external abdominal hernia becomes irreducible, painfully and tense, and looks like incarcerated. This is the unreal jamming of hernia, which can be observed at the acute surgical diseases of organs of abdominal cavity, ascites. During examination of such patients it is necessary to remember, that at the unreal jamming abdominal pain, vomiting, worsening of the general condition and signs of the intestine obstruction come earlier, than changes in a hernia sack.

In addition, during the operation in patients with incarcerated hernia, it is needed to make sure, whether there

is a strangulation furrow, or organ, that is in a hernia sack, fixed in a hernia gate. When these signs are absent, it is possible to consider that jamming is unreal.

The incarcerated femoral hernia must be differentiated with inguinal lymphadenitis, by varicose expansion of large hypodermic vein, varicose knot and their thrombophlebitis, tumor and abscess.

From such pathology without surgical procedure it is possible to differentiate only varicose expansion of veins (varicose knot), for which the positive Valsalv test — at horizontal position of patient with the leg heaved up a knot is empty.

The incarcerated inguinal hernia needs to be differentiated also with hydrocele and orchiepididymitis, cyst of deferent duct, cyst of round ligamentum of uterus, bartholinitis. Patients, who have with such diseases, a process usually does not spread higher external ring of inguinal channel. Also, absence of testicle in scrotum can be cryptorchism sign.

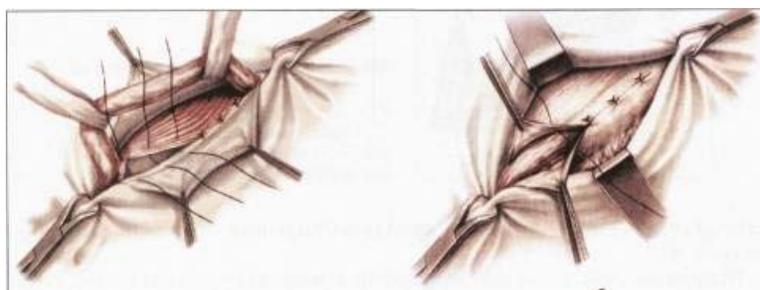

The common clinical signs of the internal incarcerated hernia is abdominal pain and symptoms of the intestinal obstruction. A final diagnosis is set during the operation.

Tactics and choice of treatment method

The incarcerated hernia, regardless of time of its origin, localization and age of patient, must be operated on. However, if a patient is hospitalized already with the expressed symptoms of intestinal obstruction, than should be preoperative treatment. Such conservative therapy must be brief (1–1,5 hours), but always actively directed for correction of violations of metabolism and prophylaxis of possible pulmonary and cardiovascular complications. It is necessary also to conduct evacuation of the gastric contents and other preparatory procedures.

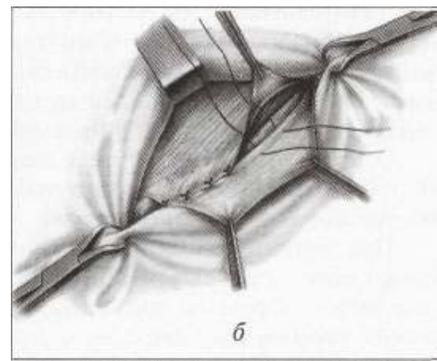

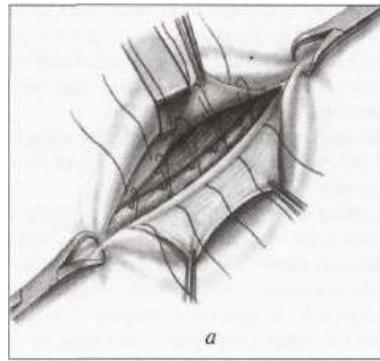

Patient with reduced hernia must be hospitalized and observed during 1–2 days. If a abdominal pain is contained or is growing, the signs of peritonitis and intoxication appear, than performed urgent laparotomy and necessary operation. If the symptoms of “acute” abdomen are not present, a patient examined and prepared for elective operation. On oblique inguinal hernias, we should strengthen anterior wall of the inguinal channel. On direct inguinal hernias, we should strengthen posterior wall of the inguinal channel. On recurrence hernias - we should strengthen anterior and posterior wall of the inguinal channel.

Bassini repair. After extraction of the hernia sac, we are taking spermatic duct on holders. Between the borders of transverse muscle, internal oblique muscle, transverse fascia and inguinal ligament interrupted sutures placed. Except that, couples sutures placed between border of abdominal rectus muscle sheath and pubic bone periosteum.

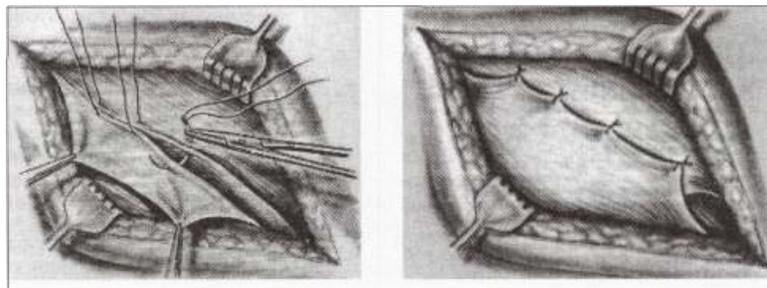

In such way, inguinal space closed and posterior wall strengthened. Spermatic duct placed on the new-formed posterior wall of the inguinal channel. Over the spermatic duct aponeurosis restored by interrupted sutures.

Girard in such kind of the operations propose to attach the edges of the internal oblique muscle and transversal muscle to the inguinal ligament over the spermatic duct. The aponeurosis of the external oblique muscle sutured by second layer of the suture. Excess of the aponeurosis is fixed to the muscle in the form of duplication.

Spasokukotskyy proposed to catch the edges of the internal oblique muscle and transversal muscle with aponeurosis of the external oblique muscles by single-layer interrupted suture.

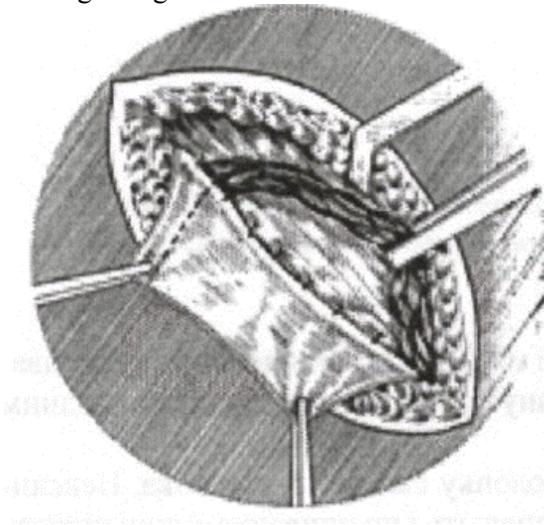

Martynov proposed the fixation to the Poupart's ligament only internal edge of the external oblique muscle aponeurosis without muscles. External edge of the aponeurosis sutured over internal in the form of duplication.

Kimbarovskyy, based on the principles of joining similar tissues, proposed special suture: Sutures placed on 1 cm from the edge of the external oblique abdominal muscle aponeurosis, grasped the part of the internal oblique and transversal muscle. After that, aponeurosis is sutured one more time from behind to the front and attached to the Poupart's ligament.

Kukudganov proposed to restore back wall of inguinal interval. Sutures are placed between the Couper's ligamentum, vagina of direct abdominal muscle and aponeurosis of the transversal muscle.

Postempyskyy proposed the deaf closing of inguinal interval with the lateral moving of spermatic duct.

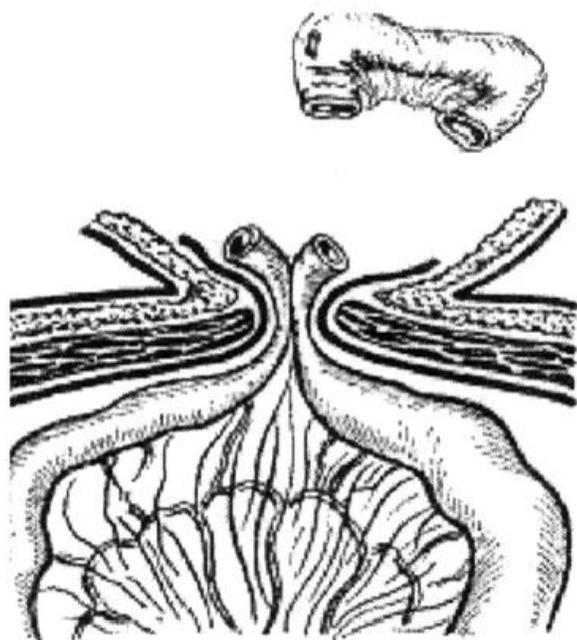

The plastic narrowing of internal inguinal ring of to 0,8 cm is the important moment of this modification. On occasion, when internal and external inguinal rings are in one plane, a spermatic duct is displaced inlateral direction by transversal incision of the oblique and transversal muscles. Then edge of the vagina of direct muscle and aponeurosis of the internal and transversal muscles is fixed to the Couper's ligament.

Operation at the incarcerated hernia is executed under the general anesthesia. A hernia sack is selected from surrounding tissue, cut it in the area of bottom and remove hernia water, defining its character and sending to

bacterial inoculation. Retaining the damaged organs, a strangulated ring is cut. It is necessary to remember, that at the incarcerated femoral hernia ring cut up and some medially, because a femoral vein passes from a lateral side.

If a bowel is contents of hernia sack, we must estimate its viability. Remembering about possibility of the retrograde jamming, special attention must be paid to the state of strangulation furrow. About viability of the bowels testify: 1) renewal of its normal color; 2) presence or renewal of peristalsis; 3) renewal of pulsation of vessels of mesentery and bowel. If there are the certain doubting, a bowel is dipped on a holder in an abdominal cavity and in 15–20 minutes it is examined repeatedly. If one of the resulted signs of viability is absent even, it is necessary to conduct the resection of bowel. The resection is executed, receded from the strangulation furrow on a proximal loop 30–40 cm and distal — 15–20 cm. Anastomosis between proximal and distal loops it is better to impose “end-to-end”. The plastic of hernia gate are conducted depending on indications after one of the surgical methods.

When the necrosis elements of omentum or fatty pendants of colon are contents of hernia sack, they must be removed within the limits of healthy tissue.

There can be necrosis of wall of colon or urinary bladder at sliding hernia. In such cases it is needed to be limited to the minimum surgical procedure: to dip a necrosis area by sutures inside the bowel or use it for forming of colostomy or epicystostomy. These are the best to conclude operation.

In similar situations at the incarcerated parietal hernia in most patients it is possible to be limited to peritonization of displaced area of wall of bowel. If after the peritonization there is the threat of narrowing of bowel or necrosis goes outside of the strangulation furrow, it is needed to conduct the resection of bowel.

Because of insufficient blood flow of Meckel's diverticulum and, permanent threat of it necrosis, at patients with Littre's hernia it resection must be performed.

At the phlegmon of hernia sack operation is begun with herniotomy. If the incarcerated organ is damaged by necrosis, and in a hernia sack present pus, than there is a necessity for surgeon to perform laparotomy. After that incarcerated organ resected within the limits of healthy tissue (in the generally accepted limits — 40 cm of proximal loop and 20 cm distal) and impose anastomosis. An abdominal cavity is sewn up. Incarcerated loops of bowel, together with it blind ends which located in an abdominal cavity, removed through a hernia sack, a peritoneum is sutured, the hernia sack is drained, the plastic of hernia gate are not performed. Skin is sewn up by widely spaced sutures.

HEMORRHOIDS. RECTAL FISSURES. PARAPROCTITIS. RECTAL FISTULAS. EPITHELIAL PARACOCCIDIOIDAL CANALS

EMBRYOLOGY AND ANATOMY

Embryology

The embryonic gastrointestinal tract begins developing during the fourth week of gestation. The primitive gut is derived from the endoderm and divided into three segments: *foregut*, *midgut*, and *hindgut*. Both *midgut* and *hindgut* contribute to the colon, rectum, and anus.

The *midgut* develops into the small intestine, ascending colon, and proximal transverse colon, and receives blood supply from the superior mesenteric artery. During the sixth week of gestation, the midgut herniates out of the abdominal cavity, and then rotates 270 degrees counterclockwise around the superior mesenteric artery to return to its final position inside the abdominal cavity during the tenth week of gestation.

The *hindgut* develops into the distal transverse colon, descending colon, rectum, and proximal anus, all of which receive their blood supply from the inferior mesenteric artery. During the sixth week of gestation, the distal-most end of the hindgut, the *cloaca*, is divided by the urorectal septum into the urogenital sinus and the rectum.

The distal anal canal is derived from ectoderm and receives its blood supply from the internal pudendal artery. The dentate line divides the endodermal hindgut from the ectodermal distal anal canal.

Anatomy

The large intestine extends from the ileocecal valve to the anus. It is divided anatomically and functionally into the *colon*, *rectum*, and *anal canal*. The wall of the colon and rectum comprise five distinct layers: mucosa, submucosa, inner circular muscle, outer longitudinal muscle, and serosa. In the colon, the outer longitudinal muscle is separated into three *teniae coli*, which converge proximally at the appendix and distally at the rectum, where the outer longitudinal muscle layer is circumferential. In the distal rectum, the inner smooth-muscle layer coalesces to form the internal anal sphincter. The intraperitoneal colon and proximal one third of the rectum are covered by serosa; the mid and lower rectum lack serosa.

Colon Landmarks

The colon begins at the junction of the terminal ileum and cecum and extends 3 to 5 feet to the

rectum. The rectosigmoid junction is found at approximately the level of the sacral promontory and is arbitrarily described as the point at which the three *teniae coli* coalesce to form the outer longitudinal smooth muscle layer of the rectum. The *cecum* is the widest diameter portion of the colon (normally 7.5 to 8.5 cm) and has the thinnest muscular wall. As a result, the cecum is most vulnerable to perforation and least vulnerable to obstruction. The ascending colon is usually fixed to the retroperitoneum. The hepatic flexure marks the transition to the transverse colon. The intraperitoneal transverse colon is relatively mobile, but is tethered by the gastrocolic ligament and colonic mesentery. The greater omentum is attached to the anterior/superior edge of the transverse colon. These attachments explain the characteristic triangular appearance of the transverse colon observed during colonoscopy. The splenic flexure marks the transition from the transverse colon to the descending colon. The attachments between the splenic flexure and the spleen (the lienocolic ligament) can be short and dense, making mobilization of this flexure during colectomy challenging. The descending colon is relatively fixed to the retroperitoneum. The sigmoid colon is the narrowest part of the large intestine and is extremely mobile. Although the sigmoid colon is usually located in the left lower quadrant, redundancy and mobility can result in a portion of the sigmoid colon residing in the right lower quadrant. This mobility explains why volvulus is most common in the sigmoid colon and why diseases affecting the sigmoid colon, such as diverticulitis, may occasionally present as right-sided abdominal pain. The narrow caliber of the sigmoid colon makes this segment of the large intestine the most vulnerable to obstruction.

Colon Vascular Supply

The arterial supply to the colon is highly variable (Fig. 28-1). In general, the *superior mesenteric artery* branches into the *ileocolic artery* (absent in up to 20% of people), which supplies blood flow to the terminal ileum and proximal ascending colon, the *right colic artery*, which supplies the ascending colon, and the *middle colic artery*, which supplies the transverse colon. The *inferior mesenteric artery* branches into the *left colic artery*, which supplies the descending colon, several *sigmoidal branches*, which supply the sigmoid colon, and the *superior rectal artery*, which supplies the proximal rectum. The terminal branches of each artery form anastomoses with the terminal branches of the adjacent artery and communicate via the *marginal artery of Drummond*. This arcade is complete in only 15 to 20% of people.

Colon Lymphatic Drainage

The lymphatic drainage of the colon originates in a network of lymphatics in the muscularis mucosa. Lymphatic vessels and lymph nodes follow the regional arteries. Lymph nodes are found on the bowel wall (epicolic), along the inner margin of the bowel adjacent to the arterial arcades (paracolic), around the named mesenteric vessels (intermediate), and at the origin of the superior and inferior mesenteric arteries (main). The *sentinel lymph nodes* are the first one to four lymph nodes to drain a specific segment of the colon, and are thought to be the first site of metastasis in colon cancer. The utility of sentinel lymph node dissection and analysis in colon cancer remains controversial.

Colon Nerve Supply

The colon is innervated by both *sympathetic* (inhibitory) and *parasympathetic* (stimulatory) nerves, which parallel the course of the arteries. Sympathetic nerves arise from T6-T12 and L1-L3. The parasympathetic innervation to the right and transverse colon is from the vagus nerve; the parasympathetic nerves to the left colon arise from sacral nerves S2-S4 to form the *nervi erigentes*.

Anorectal Landmarks

The rectum is approximately 12 to 15 cm in length. Three distinct submucosal folds, the *valves of Houston*, extend into the rectal lumen. Posteriorly, the *preseccal fascia* separates the rectum from the presacral venous plexus and the pelvic nerves. At S4, the *rectosacral fascia (Waldeyer's fascia)* extends forward and downward and attaches to the fascia propria at the anorectal junction. Anteriorly, *Denonvilliers' fascia* separates the rectum from the prostate and seminal vesicles in men and from the vagina in women. The *lateral ligaments* support the lower rectum. The surgical anal canal measures 2 to 4 cm in length and is generally longer in men than in women. It begins at the anorectal junction and terminates at the anal verge. The *dentate* or *pectinate line* marks the transition point between columnar rectal mucosa and squamous anoderm. The 1 to 2 cm of mucosa just proximal to the dentate line shares histologic characteristics of columnar, cuboidal, and squamous epithelium and is referred to as the *anal transition zone*. The dentate line is surrounded by longitudinal mucosal folds, known as the *columns of Morgagni*, into which the anal crypts empty. These crypts are the source of cryptoglandular abscesses

In the distal rectum, the inner smooth muscle is thickened and comprises the *internal anal sphincter* that is surrounded by the *subcutaneous, superficial, and deep external sphincter*. The *deep external anal sphincter* is an extension of the *puborectalis muscle*. The *puborectalis, iliococcygeus, and pubococcygeus muscles* form the *levator ani muscle* of the pelvic floor.

Anorectal Vascular Supply

The *superior rectal artery* arises from the terminal branch of the inferior mesenteric artery and supplies the upper rectum. The *middle rectal artery* arises from the internal iliac; the presence and size of these arteries are highly variable. The *inferior rectal artery* arises from the internal pudendal artery, which is a branch of the internal iliac artery. A rich network of collaterals connects the terminal arterioles of each of these arteries, thus making the rectum relatively resistant to ischemia

The venous drainage of the rectum parallels the arterial supply. The *superior rectal vein* drains into the portal system via the inferior mesenteric vein. The *middle rectal vein* drains into the internal iliac vein. The *inferior rectal vein* drains into the internal pudendal vein, and subsequently into the internal iliac vein. A submucosal plexus deep to the columns of Morgagni forms the *hemorrhoidal plexus* and drains into all three veins.

Anorectal Lymphatic Drainage

Lymphatic drainage of the rectum parallels the vascular supply. Lymphatic channels in the upper and middle rectum drain superiorly into the inferior mesenteric lymph nodes. Lymphatic channels in the lower rectum drain both superiorly into the inferior mesenteric lymph nodes and laterally into the internal iliac lymph nodes. The anal canal has a more complex pattern of lymphatic drainage. Proximal to the dentate line, lymph drains into both the inferior mesenteric lymph nodes and the internal iliac lymph nodes. Distal to the dentate line, lymph primarily drains into the inguinal lymph nodes, but can also drain into the inferior mesenteric lymph nodes and internal iliac lymph nodes.

Anorectal Nerve Supply

Both sympathetic and parasympathetic nerves innervate the anorectum. Sympathetic nerve fibers are derived from L1-L3 and join the preaortic plexus. The preaortic nerve fibers then extend below the aorta to form the *hypogastric plexus*, which subsequently joins the parasympathetic fibers to form the pelvic plexus. Parasympathetic nerve fibers are known as the *nervi erigentes* and originate from S2-S4. These fibers join the sympathetic fibers to form the pelvic plexus. Sympathetic and parasympathetic fibers then supply the anorectum and adjacent urogenital organs.

The internal anal sphincter is innervated by sympathetic and parasympathetic nerve fibers; both types of fibers inhibit sphincter contraction. The external anal sphincter and puborectalis muscles are innervated by the *inferior rectal branch* of the *internal pudendal nerve*. The levator ani receives innervation from both the *internal pudendal nerve* and direct branches of S3 to S5. Sensory innervation to the anal canal is provided by the *inferior rectal branch* of the *pudendal nerve*. While the rectum is relatively insensate, the anal canal below the dentate line is sensate.

Congenital Anomalies

Perturbation of the embryologic development of the midgut and hindgut may result in anatomic abnormalities of the colon, rectum, and anus. Failure of the midgut to rotate and return to the abdominal cavity during the tenth week of gestation results in varying degrees of intestinal malrotation and colonic nonfixation. Failure of canalization of the primitive gut can result in colonic duplication. Incomplete descent of the urogenital septum may result in imperforate anus and associated fistulas to the genitourinary tract. Many infants with congenital anomalies of the hindgut have associated abnormalities in the genitourinary tract.

Normal Physiology

Fluid and Electrolyte Exchanges

Water, Sodium, Potassium, Chloride, Bicarbonate, and Ammonia

The colon is a major site for water absorption and electrolyte exchange. Approximately 90% of the water contained in ileal fluid is absorbed in the colon (1000 to 2000 mL/d), and up to 5000 mL of fluid can be absorbed daily. Sodium is absorbed actively via a Na-K ATPase. The colon can absorb up to 400 mEq of sodium per day. Water accompanies the transported sodium and is absorbed passively along an osmotic gradient. Potassium is actively secreted into the colonic lumen and absorbed by passive diffusion. Chloride is absorbed actively via a chloride–bicarbonate exchange.

Bacterial degradation of protein and urea produces ammonia. Ammonia is subsequently absorbed and transported to the liver. Absorption of ammonia depends in part upon intraluminal pH. A decrease in colonic bacteria (e.g., broad spectrum antibiotic usage) and/or a decrease in intraluminal pH (e.g., lactulose administration) will decrease ammonia absorption.

Short-Chain Fatty Acids

Short-chain fatty acids (acetate, butyrate, and propionate) are produced by bacterial fermentation of dietary carbohydrates. Short-chain fatty acids are an important source of energy for the colonic mucosa, and metabolism by colonocytes provides energy for processes such as active transport of sodium. Lack of a dietary source for production of short-chain fatty acids, or diversion of the fecal stream by an ileostomy or colostomy, may result in mucosal atrophy and "diversion colitis."

Colonic Microflora and Intestinal Gas

Approximately 30% of fecal dry weight is composed of bacteria (10^{11} to 10^{12} bacteria/g of feces). Anaerobes are the predominant class of microorganism, and *Bacteroides* species are the most common (10^{11} to 10^{12} organisms/mL). *Escherichia coli* are the most numerous aerobes (10^8 to 10^{10} organisms/mL). Endogenous microflora are crucial for the breakdown of carbohydrates and proteins in the colon and participate in the metabolism of bilirubin, bile acids, estrogen, and cholesterol. Colonic bacteria also are necessary for production of vitamin K. Endogenous bacteria also are thought to suppress the emergence of pathogenic microorganisms, such as *Clostridium difficile*. However, the high bacterial load of the large intestine may contribute to sepsis in critically ill patients and may contribute to intra-abdominal sepsis, abscess, and wound infection following colectomy.

Intestinal gas arises from swallowed air, diffusion from the blood, and intraluminal production. Nitrogen, oxygen, carbon dioxide, hydrogen, and methane are the major components of intestinal gas. Nitrogen and oxygen are largely derived from swallowed air. Carbon dioxide is produced by the reaction of bicarbonate and hydrogen ions, and by the digestion of triglycerides to fatty acids. Hydrogen and methane are produced by colonic bacteria. The production of methane is highly variable. The gastrointestinal tract usually contains between 100 and 200 mL of gas and 400 to 1200 mL per day are released as flatus, depending upon the type of food ingested.

Motility, Defecation, and Continence

Motility

Unlike the small intestine, the large intestine does not demonstrate cyclic motor activity characteristic of the migratory motor complex. Instead, the colon displays intermittent contractions of either low or high amplitude. Low-amplitude, short-duration contractions occur in bursts and appear to move the colonic contents both antegrade and retrograde. It is thought that these bursts of motor activity delay colonic transit and thus increase the time available for absorption of water and exchange of electrolytes. High-amplitude contractions occur in a more coordinated fashion and create "mass movements." Bursts of "rectal motor complexes" also have been described. In general, cholinergic activation increases colonic motility.

Defecation

Defecation is a complex, coordinated mechanism involving colonic mass movement, increased intra-abdominal and rectal pressure, and relaxation of the pelvic floor. Distention of the rectum causes a reflex relaxation of the internal anal sphincter (the rectoanal inhibitory reflex) that allows the contents to make contact with the anal canal. This "sampling reflex" allows the sensory epithelium to distinguish solid stool from liquid stool and gas. If defecation does not occur, the rectum relaxes and the urge to defecate passes (the *accommodation response*). Defecation proceeds by coordination of increasing intra-abdominal pressure via the Valsalva maneuver, increased rectal contraction, relaxation of the puborectalis muscle, and opening of the anal canal.

Continence

The maintenance of fecal continence is at least as complex as the mechanism of defecation. Continence requires adequate rectal wall compliance to accommodate the fecal bolus, appropriate neurogenic control of the pelvic floor and sphincter mechanism, and functional internal and external sphincter muscles. At rest, the puborectalis muscle creates a "sling" around the distal rectum, forming a relatively acute angle that distributes intraabdominal forces onto the pelvic floor. With defecation, this angle straightens, allowing downward force to be applied along the axis of the rectum and anal canal. The internal and external sphincters are tonically active at rest. The internal sphincter is responsible for most of the resting, involuntary sphincter tone (resting pressure). The external sphincter is responsible for most of the voluntary sphincter tone (squeeze pressure). Branches of the pudendal nerve innervate both the internal and external sphincter. Finally, the hemorrhoidal cushions may contribute to continence by mechanically blocking the anal canal. Thus, impaired continence may result from poor rectal compliance, injury to the internal and/or external sphincter or puborectalis, or nerve damage or neuropathy.

Clinical Evaluation

Clinical Assessment

A complete history and physical examination is the starting point for evaluating any patient with suspected disease of the colon and rectum. Special attention should be paid to the patient's past medical and surgical history to detect underlying conditions that might contribute to a gastrointestinal problem. If patients have had prior intestinal surgery, it is essential that one understand the resultant gastrointestinal anatomy. In addition, family history of colorectal disease, especially inflammatory bowel disease, polyps, and colorectal cancer, is crucial. Medication use must be detailed as many drugs cause gastrointestinal symptoms. Before recommending operative intervention, the adequacy of medical treatment must be ascertained. In addition to examining the abdomen, visual inspection of the anus and perineum and careful digital rectal exam are essential.

Endoscopy

Anoscopy

The anoscope is a useful instrument for examination of the anal canal. Anoscopes are made in a variety of sizes and measure approximately 8 cm in length. A larger anoscope provides better exposure for anal procedures such as rubber band ligation or sclerotherapy of hemorrhoids. The anoscope, with obturator in place, should be adequately lubricated and gently inserted into the anal canal. The obturator is withdrawn, inspection of the visualized anal canal is done, and the anoscope should then be withdrawn. It is rotated 90 degrees and reinserted to allow visualization of all four quadrants of the canal. If the patient complains of severe perianal pain and cannot tolerate a digital rectal examination, anoscopy should not be attempted without anesthesia.

Proctoscopy

The rigid proctoscope is useful for examination of the rectum and distal sigmoid colon and is occasionally used therapeutically. The standard proctoscope is 25 cm in length and available in various diameters. Most often, a 15- or 19-mm diameter proctoscope is used for diagnostic examinations. The large (25-mm diameter) proctoscope is useful for procedures such as polypectomy, electrocoagulation, or detorsion of a sigmoid volvulus. A smaller "pediatric" proctoscope (11-mm diameter) is better tolerated by patients with anal stricture. Suction is necessary for an adequate proctoscopic examination.

Flexible Sigmoidoscopy and Colonoscopy

Video or fiberoptic flexible sigmoidoscopy and colonoscopy provide excellent visualization of the colon and rectum. Sigmoidoscopes measure 60 cm in length. Full depth of insertion may allow visualization as high as the splenic flexure, although the mobility and redundancy of the sigmoid colon often limit the extent of the examination. Partial preparation with enemas is usually adequate for sigmoidoscopy and most patients can tolerate this procedure without

sedation. Colonoscopes measure 100 to 160 cm in length and are capable of examining the entire colon and terminal ileum. A complete oral bowel preparation is usually necessary for colonoscopy and the duration and discomfort of the procedure usually require conscious sedation. Both sigmoidoscopy and colonoscopy can be used diagnostically and therapeutically. Electrocautery should generally not be used in the absence of a complete bowel preparation because of the risk of explosion of intestinal methane or hydrogen gases. Diagnostic colonoscopes possess a single channel through which instruments such as snares, biopsy forceps, or electrocautery can be passed; this channel also provides suction and irrigation capability. Therapeutic colonoscopes possess two channels to allow simultaneous suction/irrigation and the use of snares, biopsy forceps, or electrocautery.

Imaging

Plain X-Rays and Contrast Studies

Despite advanced radiologic techniques, plain x-rays and contrast studies continue to play an important role in the evaluation of patients with suspected colon and rectal diseases. Plain x-rays of the abdomen (supine, upright, and diaphragmatic views) are useful for detecting free intra-abdominal air, bowel gas patterns suggestive of small or large bowel obstruction, and volvulus. Contrast studies are useful for evaluating obstructive symptoms, delineating fistulous tracts, and diagnosing small perforations or anastomotic leaks. While Gastrografin cannot provide the mucosal detail provided by barium, this water-soluble contrast agent is recommended if perforation or leak is suspected. Double-contrast barium enema has been reported to be 70 to 90% sensitive for the detection of mass lesions greater than 1 cm in diameter. 1 Detection of small lesions can be extremely difficult, especially in a patient with extensive diverticulosis. For this reason, a colonoscopy is preferred for evaluating nonobstructing mass lesions in the colon. Double-contrast barium enema has been used as a back-up examination if colonoscopy is incomplete.

Computed Tomography

Computed tomography (CT) is commonly employed in the evaluation of patients with abdominal complaints. Its utility is primarily in the detection of extraluminal disease, such as intra-abdominal abscesses and pericolic inflammation, and in staging colorectal carcinoma, because of its sensitivity in detection of hepatic metastases. 2 Extravasation of oral or rectal contrast may also confirm the diagnosis of perforation or anastomotic leak. Nonspecific findings such as bowel wall thickening or mesenteric stranding may suggest inflammatory bowel disease, enteritis/colitis, or ischemia. A standard CT scan is relatively insensitive for the detection of intraluminal lesions.

Virtual Colonoscopy

Virtual colonoscopy is a new radiologic technique that is designed to overcome some of the limitations of traditional CT scanning. This technology uses helical CT and three-dimensional

reconstruction to detect intraluminal colonic lesions. Oral bowel preparation, oral and rectal contrast, and colon insufflation are used to maximize sensitivity. Early evaluation of virtual colonoscopy suggests that accuracy may approach that of colonoscopy for detection of lesions 1 cm in diameter or greater.

Magnetic Resonance Imaging

The main use of magnetic resonance imaging (MRI) in colorectal disorders is in evaluation of pelvic lesions. MRI is more sensitive than CT for detecting bony involvement or pelvic sidewall extension of rectal tumors. MRI also can be helpful in the detection and delineation of complex fistulas in ano. The use of an endorectal coil may increase sensitivity.

Positron Emission Tomography

Positron emission tomography (PET) is used for imaging tissues with high levels of anaerobic glycolysis, such as malignant tumors. 18 F-fluorodeoxyglucose (FDG) is injected as a tracer; metabolism of this molecule then results in positron emission. PET has been used as an adjunct to CT in the staging of colorectal cancer and may prove useful in discriminating recurrent cancer from fibrosis. At present, the efficacy and utility of PET in the detection of recurrent and/or metastatic colorectal cancer remains unproven.

Angiography

Angiography is occasionally used for the detection of bleeding within the colon or small bowel. To visualize hemorrhage angiographically, bleeding must be relatively brisk (approximately 0.5 to 1.0 mL per minute). If extravasation of contrast is identified, infusion of vasopressin or angiographic embolization can be therapeutic.

Endorectal and Endoanal Ultrasound

Endorectal ultrasound is primarily used to evaluate the depth of invasion of neoplastic lesions in the rectum. The normal rectal wall appears as a five-layer structure (Fig. 28-6). Ultrasound can reliably differentiate most benign polyps from invasive tumors based upon the integrity of the submucosal layer. Ultrasound can also differentiate superficial T1-T2 from deeper T3-T4 tumors. Overall, the accuracy of ultrasound in detecting depth of mural invasion ranges between 81 and 94%.³ This modality also can detect enlarged perirectal lymph nodes, which may suggest nodal metastases; accuracy of detection of pathologically positive lymph nodes is 58 to 83%. Ultrasound may also prove useful for early detection of local recurrence after surgery.

Endoanal ultrasound is used to evaluate the layers of the anal canal. Internal anal sphincter, external anal sphincter, and puborectalis muscle can be differentiated. Endoanal ultrasound is particularly useful for detecting sphincter defects and for outlining complex anal fistulas.

Physiologic and Pelvic Floor Investigations

Anorectal physiologic testing uses a variety of techniques to investigate the function of the pelvic floor. These techniques are useful in the evaluation of patients with incontinence, constipation, rectal prolapse, obstructed defecation, and other disorders of the pelvic floor.

Manometry

Anorectal manometry is performed by placing a pressure-sensitive catheter in the lower rectum. The catheter is then withdrawn through the anal canal and pressures recorded. A balloon attached to the tip of the catheter also can be used to test anorectal sensation. The *resting pressure* in the anal canal reflects the function of the internal anal sphincter (normal: 40 to 80 mm Hg), while the *squeeze pressure*, defined as the maximum voluntary contraction pressure minus the resting pressure, reflects function of the external anal sphincter (normal: 40 to 80 mm Hg above resting pressure). The *high-pressure zone* estimates the length of the anal canal (normal: 2.0 to 4.0 cm). The *rectoanal inhibitory reflex* can be detected by inflating a balloon in the distal rectum; absence of this reflex is characteristic of Hirschsprung's disease.

Neurophysiology

Neurophysiologic testing assesses function of the pudendal nerves and recruitment of puborectalis muscle fibers. Pudendal nerve terminal motor latency measures the speed of transmission of a nerve impulse through the distal pudendal nerve fibers (normal: 1.8 to 2.2 msec); prolonged latency suggests the presence of neuropathy. EMG recruitment assesses the contraction and relaxation of the puborectalis muscle during attempted defecation. Normally, recruitment increases when a patient is instructed to "squeeze," and decreases when a patient is instructed to "push." Inappropriate recruitment is an indication of paradoxical contraction (nonrelaxation of the puborectalis). Needle EMG has been used to map both the pudendal nerves and the anatomy of the internal and external sphincters. However, this examination is painful and poorly tolerated by most patients. Needle EMG has largely been replaced by pudendal nerve motor-latency testing to assess pudendal nerve function and endoanal ultrasound to map the sphincters.

Rectal Evacuation Studies

Rectal evacuation studies include the balloon expulsion test and video defecography. Balloon expulsion assesses a patient's ability to expel an intrarectal balloon. Video defecography provides a more detailed assessment of defecation. In this test, barium paste is placed in the rectum and defecation is then recorded fluoroscopically. Defecography is used to differentiate nonrelaxation of the puborectalis, obstructed defecation, increased perineal descent, rectal prolapse and intussusception, rectocele, and enterocele. The addition of vaginal contrast and intraperitoneal contrast is useful in delineating complex disorders of the pelvic floor.

Laboratory Studies

Fecal Occult Blood Testing

Fecal occult blood testing (FOBT) is used as a screening test for colonic neoplasms in asymptomatic, average-risk individuals. The efficacy of this test is based upon serial testing because the majority of colorectal malignancies will bleed intermittently. FOBT has been a nonspecific test for peroxidase contained in hemoglobin; consequently, occult bleeding from any gastrointestinal source will produce a positive result. Similarly, many foods (red meat, some fruits and vegetables, and vitamin C) will produce a false-positive result. Patients were counseled to eat a restricted diet for 2 to 3 days prior to the test. Increased specificity is now possible by using immunochemical FOBT. These tests rely on monoclonal or polyclonal antibodies to react with the intact globin portion of human hemoglobin. Because globin does not survive in the upper gastrointestinal tract, the immunochemical tests are more specific for identifying occult bleeding from the colon or rectum. Dietary restrictions are not necessary. Any positive FOBT mandates further investigation, usually by colonoscopy.

Stool Studies

Stool studies are often helpful in evaluating the etiology of diarrhea. Wet-mount examination reveals the presence of fecal leukocytes, which may suggest colonic inflammation or the presence of an invasive organism such as invasive *E. coli* or *Shigella*. Stool cultures can detect pathogenic bacteria, ova, and parasites. *C. difficile* colitis is diagnosed by detecting bacterial toxin in the stool. 4 Steatorrhea may be diagnosed by adding Sudan red stain to a stool sample.

Serum Tests

Specific laboratory tests that should be performed will be dictated by the clinical scenario. Preoperative studies generally include a complete blood count and electrolyte panel. The addition of coagulation studies, liver function tests, and blood typing/cross-matching depends upon the patient's medical condition and the proposed surgical procedure.

Tumor Markers

Carcinoembryonic antigen (CEA) may be elevated in 60 to 90% of patients with colorectal cancer. Despite this, CEA is not an effective screening tool for this malignancy. Many practitioners follow serial CEA levels after curative-intent surgery in order to detect early recurrence of colorectal cancer. However, this tumor marker is nonspecific, and no survival benefit has yet been proven. Other biochemical markers (ornithine decarboxylase, urokinase) have been proposed, but none has yet proven sensitive or specific for detection, staging, or predicting prognosis of colorectal carcinoma. 5

Genetic Testing

Although familial colorectal cancer syndromes, such as familial adenomatous polyposis (FAP) and hereditary nonpolyposis colon cancer (HNPCC) are rare, information about the specific genetic abnormalities underlying these disorders has led to significant interest in the role of genetic testing for colorectal cancer. 6 Tests for mutations in the adenomatous polyposis coli

(APC) gene responsible for FAP, and in mismatch repair genes responsible for HNPCC, are commercially available and extremely accurate in families with known mutations. Although many of these mutations are also present in sporadic colorectal cancer, the accuracy of genetic testing in average-risk individuals is considerably lower and these tests are not recommended for screening. Because of the potential psychosocial implications of genetic testing, it is strongly recommended that professional genetic counselors be involved in the care of any patient considering these tests.

Evaluation of Common Symptoms

Pain

Abdominal Pain

Abdominal pain is a nonspecific symptom with a myriad of causes. Abdominal pain related to the colon and rectum can result from obstruction (either inflammatory or neoplastic), inflammation, perforation, or ischemia. Plain x-rays and judicious use of contrast studies and/or a CT scan can often confirm the diagnosis. Gentle retrograde contrast studies (barium or Gastrografin enema) may be useful in delineating the degree of colonic obstruction. Sigmoidoscopy and/or colonoscopy performed by an experienced endoscopist can assist in the diagnosis of ischemic colitis, infectious colitis, and inflammatory bowel disease. However, if perforation is suspected, colonoscopy and/or sigmoidoscopy are generally contraindicated. Evaluation and treatment of abdominal pain from a colorectal source should follow the usual surgical principles of a thorough history and physical examination, appropriate diagnostic tests, resuscitation, and appropriately timed surgical intervention.

Pelvic Pain

Pelvic pain can originate from the distal colon and rectum or from adjacent urogenital structures. Tenesmus may result from proctitis or from a rectal or retrorectal mass. Cyclical pain associated with menses, especially when accompanied by rectal bleeding, suggests a diagnosis of endometriosis. Pelvic inflammatory disease also can produce significant abdominal and pelvic pain. The extension of a peridiverticular abscess or periappendiceal abscess into the pelvis may also cause pain. CT scan and/or MRI may be useful in differentiating these diseases. Proctoscopy (if tolerated) also can be helpful. Occasionally, laparoscopy will yield a diagnosis.

Anorectal Pain

Anorectal pain is most often secondary to an anal fissure or perirectal abscess and/or fistula. Physical examination can usually differentiate these conditions. Other, less common causes of anorectal pain include anal canal neoplasms, perianal skin infection, and dermatologic conditions. Proctalgia fugax results from levator spasm and may present without any other anorectal findings. Physical exam is critical in evaluating patients with anorectal pain. If a

patient is too tender to examine in the office, an examination under anesthesia is necessary. MRI may be helpful in select cases where the etiology of pain is elusive.

Lower Gastrointestinal Bleeding

The first goal in evaluating and treating a patient with gastrointestinal hemorrhage is adequate resuscitation. The principles of ensuring a patent airway, supporting ventilation, and optimizing hemodynamic parameters apply and coagulopathy and/or thrombocytopenia should be corrected. The second goal is to identify the source of hemorrhage. Because the most common source of gastrointestinal hemorrhage is esophageal, gastric, or duodenal, nasogastric aspiration should always be performed; return of bile suggests that the source of bleeding is distal to the ligament of Treitz. If aspiration reveals blood or nonbile secretions, or if symptoms suggest an upper intestinal source, esophagogastroduodenoscopy is performed. Anoscopy and/or limited proctoscopy can identify hemorrhoidal bleeding. A technetium-99 (^{99m}Tc)-tagged red blood cell (RBC) scan is extremely sensitive and is able to detect as little as 0.1 mL/h of bleeding; however, localization is imprecise. If the ^{99m}Tc -tagged RBC scan is positive, angiography can then be employed to localize bleeding. Infusion of vasopressin or angioembolization may be therapeutic. Alternatively, a catheter can be left in the bleeding vessel to allow localization at the time of laparotomy. If the patient is hemodynamically stable, a rapid bowel preparation (over 4 to 6 hours) can be performed to allow colonoscopy. Colonoscopy may identify the cause of the bleeding, and cautery or injection of epinephrine into the bleeding site may be used to control hemorrhage. Colectomy may be required if bleeding persists despite these interventions. Intraoperative colonoscopy and/or enteroscopy may assist in localizing bleeding. If colectomy is required, a segmental resection is preferred if the bleeding source can be localized. "Blind" subtotal colectomy may very rarely be required in a patient who is hemodynamically unstable with ongoing colonic hemorrhage of an unknown source. In this setting, it is crucial to irrigate the rectum and examine the mucosa by proctoscopy to ensure that the source of bleeding is not distal to the resection margin

Occult blood loss from the gastrointestinal tract may manifest as iron-deficiency anemia or may be detected with fecal occult blood testing. Because colon neoplasms bleed intermittently and rarely present with rapid hemorrhage, the presence of occult fecal blood should always prompt a colonoscopy. Unexplained iron-deficiency anemia is also an indication for colonoscopy.

Hematochezia is commonly caused by hemorrhoids or fissure. Sharp, knife-like pain and bright-red rectal bleeding with bowel movements suggest the diagnosis of fissure. Painless, bright-red rectal bleeding with bowel movements is often secondary to a friable internal hemorrhoid that is easily detected by anoscopy. In the absence of a painful, obvious fissure, any patient with rectal bleeding should undergo a careful digital rectal examination, anoscopy, and proctosigmoidoscopy. Failure to diagnose a source in the distal anorectum should prompt colonoscopy.

Constipation and Obstructed Defecation

Constipation is an extremely common complaint, affecting more than 4 million people in the United States. Despite the prevalence of this problem, there is lack of agreement about an appropriate definition of constipation. Patients may describe infrequent bowel movements, hard stools, or excessive straining. A careful history of these symptoms often clarifies the nature of the problem.

Constipation has a myriad of causes. Underlying metabolic, pharmacologic, endocrine, psychologic, and neurologic causes often contribute to the problem. A stricture or mass lesion should be excluded by colonoscopy or barium enema. After these causes have been excluded, evaluation focuses upon differentiating *slow-transit constipation* from *outlet obstruction*. Transit studies, in which radiopaque markers are swallowed and then followed radiographically, are useful for diagnosing slow-transit constipation. Anorectal manometry and electromyography can detect nonrelaxation of the puborectalis, which contributes to outlet obstruction. The absence of an anorectal inhibitory reflex suggests Hirschsprung's disease and may prompt a rectal mucosal biopsy. Defecography can identify rectal prolapse, intussusception, rectocele, or enterocele.

Medical management is the mainstay of therapy for constipation and includes fiber, increased fluid intake, and laxatives. Outlet obstruction from nonrelaxation of the puborectalis often responds to biofeedback. 7 Surgery to correct rectocele and rectal prolapse has a variable effect on symptoms of constipation, but can be successful in selected patients. Subtotal colectomy is considered only for patients with severe slow-transit constipation (colonic inertia) refractory to maximal medical interventions. While this operation almost always increases bowel movement frequency, complaints of diarrhea, incontinence, and abdominal pain are not infrequent, and patients should be carefully selected. 8

Diarrhea and Irritable Bowel Syndrome

Diarrhea is also a common complaint and is usually a self-limited symptom of infectious gastroenteritis. If diarrhea is chronic or is accompanied by bleeding or abdominal pain, further investigation is warranted. Bloody diarrhea and pain are characteristic of colitis; etiology can be an infection (invasive *E. coli*, *Shigella*, *Salmonella*, *Campylobacter*, *Entamoeba histolytica*, or *C. difficile*), inflammatory bowel disease (ulcerative colitis or Crohn's colitis), or ischemia. Stool wet-mount and culture can often diagnose infection. Sigmoidoscopy or colonoscopy can be helpful in diagnosing inflammatory bowel disease or ischemia. However, if the patient has abdominal tenderness, particularly with peritoneal signs, or any other evidence of perforation, endoscopy is contraindicated.

Chronic diarrhea may present a more difficult diagnostic dilemma. Chronic ulcerative colitis, Crohn's colitis, infection, malabsorption, and short gut syndrome can cause chronic diarrhea. Rarely, carcinoid syndrome and islet cell tumors (vasoactive intestinal peptide-secreting tumor [VIPoma], somatostatinoma, gastrinoma) present with this symptom. Large villous lesions may cause secretory diarrhea. Collagenous colitis can cause diarrhea without any obvious mucosal

abnormality. Along with stool cultures, tests for malabsorption, and metabolic investigations, colonoscopy can be invaluable in differentiating these causes. Biopsies should be taken even if the colonic mucosa appears grossly normal.

Irritable bowel syndrome is a particularly troubling constellation of symptoms consisting of crampy abdominal pain, bloating, constipation, and urgent diarrhea. Work-up reveals no underlying anatomic or physiologic abnormality. Once other disorders have been excluded, dietary restrictions and avoidance of caffeine, alcohol, and tobacco may help to alleviate symptoms. Antispasmodics and bulking agents may be helpful.

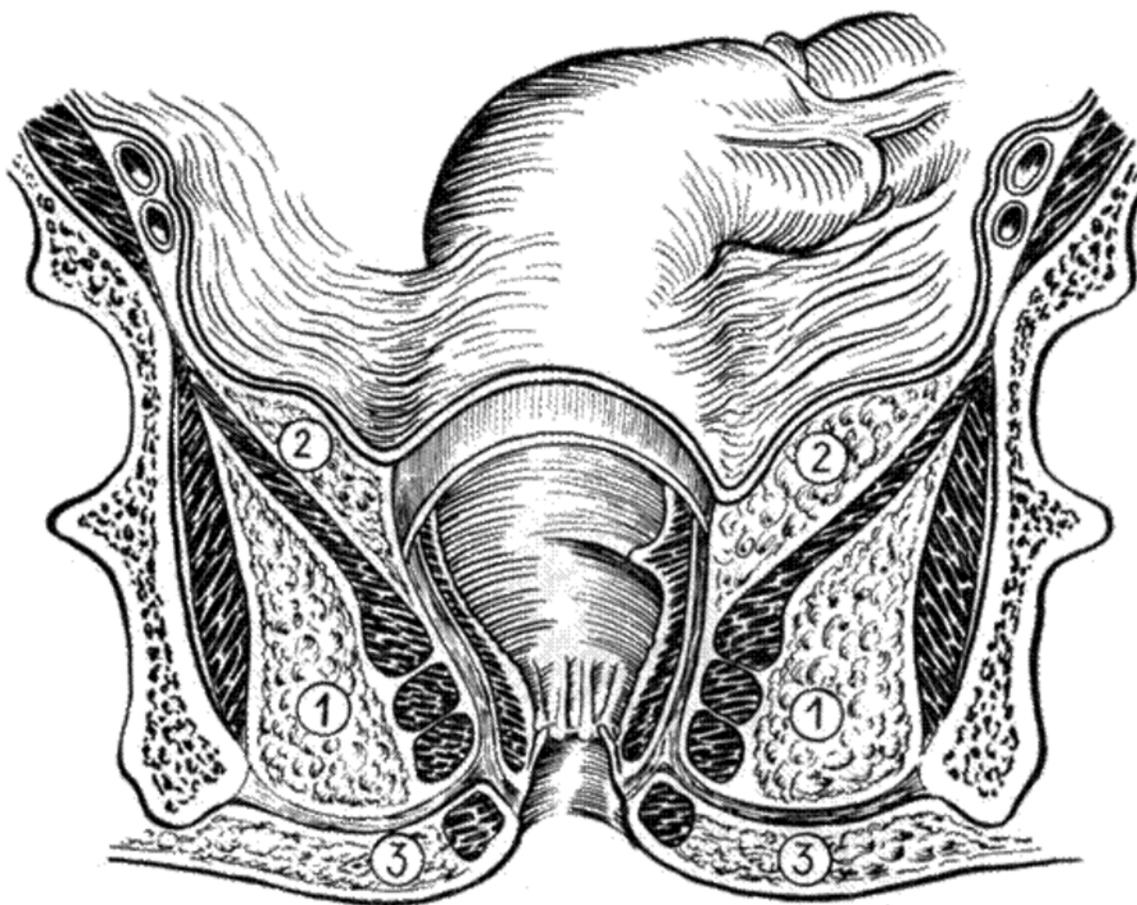

Incontinence

The incidence of fecal incontinence has been estimated to occur in 10 to 13 individuals per 1000 people older than age 65 years. Incontinence ranges in severity from occasional leakage of gas and liquid stool to daily loss of solid stool. The underlying cause of incontinence is often multifactorial and diarrhea is often contributory. In general, causes of incontinence can be classified as *neurogenic* or *anatomic*. Neurogenic causes include diseases of the central nervous system and spinal cord along with pudendal nerve injury. Anatomic causes include congenital abnormalities, procidentia, overflow incontinence secondary to impaction or neoplasm, and trauma. The most common traumatic cause of incontinence is injury to the anal sphincter during vaginal delivery. Other causes include anorectal surgery, impalement, and pelvic fracture.

After a thorough medical evaluation to detect underlying conditions that might contribute to incontinence, evaluation focuses on assessment of the anal sphincter and pudendal nerves. Pudendal nerve terminal motor latency testing may detect neuropathy. Anal manometry can detect low resting and squeeze pressures. Defecography can detect rectal prolapse. Endoanal ultrasound is invaluable in diagnosing sphincter defects.

HEMORRHOIDS

Hemorrhoids from Greek mean bleeding. Nowadays hemorrhoids are volume increase or dilation of cavernous bodies in rectum.

Ishioanal space (1), perirectal space (2), perianal space (3).

Etiology and Pathogenesis

Appearance of hemorrhoids is connected with such factors as functional insufficiency of connective tissue, increase of venous pressure at constipation, hard physical work, low-active life style, pregnancy, alcoholism, spicy food. Mechanism of hemorrhoids' development is connected with disorder of blood outflow by venules from cavernous bodies and their hyperplasia in distal part of rectum. Cavernous bodies are usually situated in basal part of anal columns (Morgagni's). Presence of direct arteriovenous anastomoses conditions in hemorrhoids bleeding of arterial character.

Pathomorphology

External hemorrhoids have their origin from veins of lower hemorrhoidal plexus, internal – from upper. External hemorrhoids are soft, of bluish color, they have not smooth surface and are filled with blood. Sometimes they are dense and filled with thrombs. Sometimes external hemorrhoids are prolapsed internal nodes. They have long leg deeply in anal canal.

Histologically they observe wall atrophy, anomalies of development, often – signs of thrombophlebitis.

Hemorrhoids are cushions of submucosal tissue containing venules, arterioles, and smooth-muscle fibers that are located in the anal canal (see Fig. 28-4). Three hemorrhoidal cushions are found in the left lateral, right anterior, and right posterior positions. Hemorrhoids are thought to function as part of the continence mechanism and aid in complete closure of the anal canal at rest. Because hemorrhoids are a normal part of anorectal anatomy, treatment is only indicated if they become symptomatic. Excessive straining, increased abdominal pressure, and hard stools increase venous engorgement of the hemorrhoidal plexus and cause prolapse of hemorrhoidal tissue. Outlet bleeding, thrombosis, and symptomatic hemorrhoidal prolapse may result.

External hemorrhoids are located distal to the dentate line and are covered with anoderm. Because the anoderm is richly innervated, thrombosis of an external hemorrhoid may cause significant pain. It is for this reason that external hemorrhoids should not be ligated or excised without adequate local anesthetic. A skin tag is redundant fibrotic skin at the anal verge, often persisting as the residual of a thrombosed external hemorrhoid. Skin tags are often confused with symptomatic hemorrhoids. External hemorrhoids and skin tags may cause itching and difficulty with hygiene if they are large. Treatment of external hemorrhoids and skin tags are only indicated for symptomatic relief.

Internal hemorrhoids are located proximal to the dentate line and covered by insensate anorectal mucosa. Internal hemorrhoids may prolapse or bleed, but rarely become painful unless they develop thrombosis and necrosis (usually related to severe prolapse, incarceration, and/or strangulation). Internal hemorrhoids are graded according to the extent of prolapse. First-degree hemorrhoids bulge into the anal canal and may prolapse beyond the dentate line on straining. Second-degree hemorrhoids prolapse through the anus but reduce spontaneously. Third-degree hemorrhoids prolapse through the anal canal and require manual reduction. Fourth-degree hemorrhoids prolapse but cannot be reduced and are at risk for strangulation.

Combined internal and external hemorrhoids straddle the dentate line and have characteristics of both internal and external hemorrhoids. Hemorrhoidectomy is often required for large, symptomatic, combined hemorrhoids. Postpartum hemorrhoids result from straining during labor, which results in edema, thrombosis, and/or strangulation. Hemorrhoidectomy is often the treatment of choice, especially if the patient has had chronic hemorrhoidal symptoms. Portal hypertension was long thought to increase the risk of hemorrhoidal bleeding because of the anastomoses between the portal venous system (middle and upper hemorrhoidal plexuses) and the systemic venous system (inferior rectal plexuses). It is now understood that hemorrhoidal disease is no more common in patients with portal hypertension than in the normal population. Rectal varices, however, may occur and may cause hemorrhage in these patients. In general, rectal varices are best treated by lowering portal venous pressure. Rarely, suture ligation may be necessary if massive bleeding persists. Surgical hemorrhoidectomy should be avoided in these patients because of the risk of massive, difficult-to-control variceal bleeding.

Classification

Hemorrhoids by etiological signs are divided onto innate and acquired, by localization – internal (submucosal), external and mixed (combined).

By clinical course hemorrhoids are: acute and chronic, not complicated and complicated (thrombosis, strangulation of hemorrhoids). There also define primary and secondary hemorrhoids (at liver cirrhosis, diseases of circulatory system, tumors).

Symptoms and clinical course

Early signs of hemorrhoids are rush feeling in anal region that appears due to skin maceration by mucous excretions from rectum. This sign is increased in diet violations that may be a consequence of constipation or diarrhea.

There define three degrees of hemorrhoids. At I degree nodes prolapse from anus during defecation, but they replace independently and are painful during palpation. At II degree there is a need to replace nodes. There is edema in perianal region and pain. At III degree nodes prolapse at very low physical loading, edema and pain are severe. The speciality of chronic hemorrhoids is that there are conditions for appearance of mucosal fissures, polyps and paraproctitis.

Variants of clinical course and complications

Initial part of hemorrhoids is characterized by gradual beginning and low reflected clinical signs – presence of hemorrhoidal nodes. Duration of this period may be different – from several months to years. Chronic course of hemorrhoids is characterized by periodical acute conditions and remissions. Difference of clinical course of hemorrhoids is only in complications.

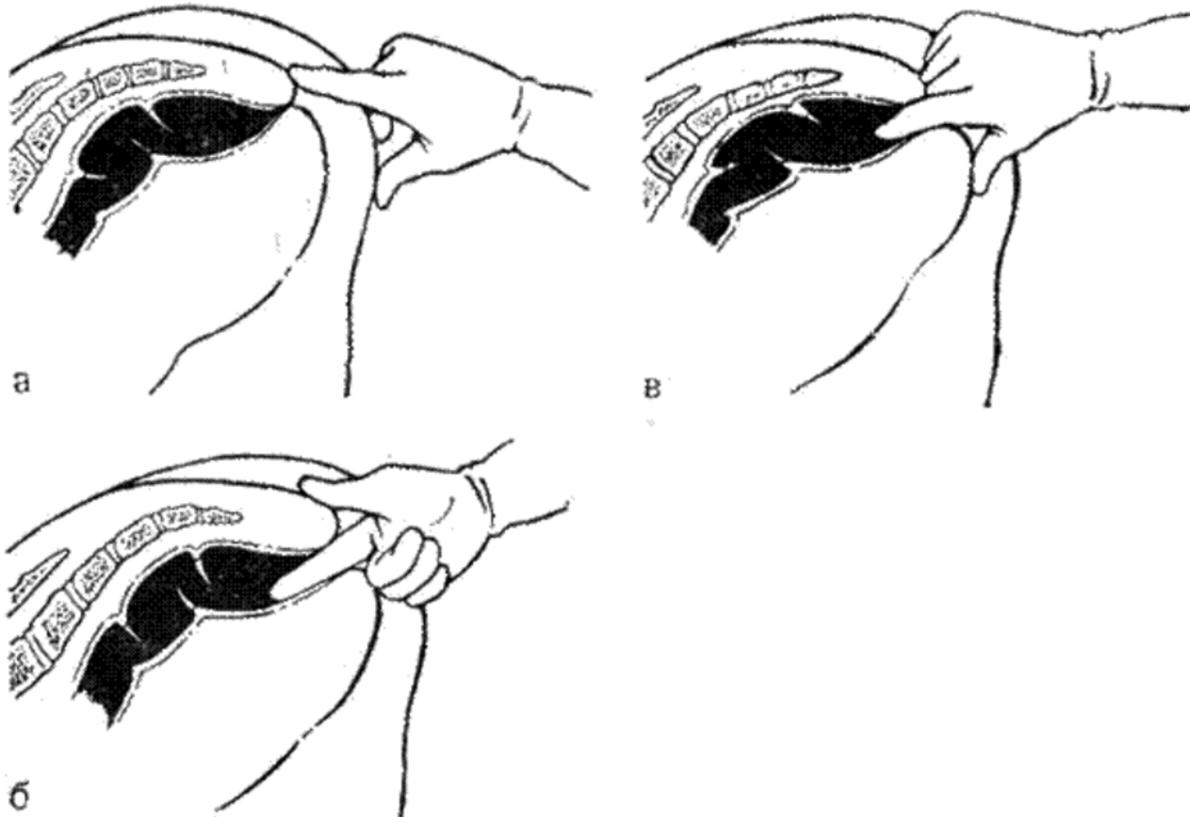

Bleeding from hemorrhoids appears mostly during or after defecation and may be as profuse as moderate. Blood is bright red (arterial).

Acute thrombosis of hemorrhoidal nodes is mostly seen in III degree of hemorrhoids. Thrombosis is a complication of as external as internal nodes. At this there appear edema of bluish color, severe pain. Progress of disease course sometimes may be conditioned by thrombosis of inferior vena cava.

Such complication as prolapse and strangulation in anal sphincter of internal hemorrhoidal nodes appear not so often. Nodes swell, become bluish, sometimes there occur necrosis that spreads on external nodes. Edema of anal region spreads to 10 cm. Body temperature increases to 39 degrees centigrade, defecation and diuresis are disordered, patients cannot sleep due to severe pain, they lose appetite, general status incredibly worsens.

Diagnostic program

1. Anamnesis and physical data.
2. Examination of anal region.
3. Finger investigation of rectum.
4. Examination of rectum by rectal mirror.
5. Rectoromanoscopy.
6. General analysis of blood and urine.
7. Coagulogram.
8. Sedimentation reactions (Reaction of Wassermann).

Digital examination of the rectum:

- a) examination of the perianal region; b) examination of the anus; c) examination of the ampula.**

Digital examination of the rectum

Differential diagnostics

Anal fissure is characterized by severe pain during of after defecation, spasm of sphincter and small bleeding during defecation.

The cancer of rectum at the beginning of disease, usually, is painless, a blood in the first portions of excrement appears. At the examination of rectum hard formation or ulcers with a dense bottom is observed. Histological examination of biopsy specifies a diagnosis.

Single or multiple polyps of rectum may be combined with polyposis of colon. Revealed symptoms are disorder of defecation and blood in feces. Examination of rectum lets us verify the diagnosis.

Incomplete prolapse or *prolapse of rectal mucosa* differs from hemorrhoids of III degree by combination with low reflected incontinention.

Tactics and choice of treating method

Conservative treatment is provided in patients with not complicated hemorrhoids (I degree of disease). Treatment must be complex and include diet therapy, remedies and physioprocedures.

For treatment of such patients they use massage through Diet therapy means excluding from ration spicy and salty food. rectum, recommend carrying of bandages. They also prescribe enemas (micro enemas with warm water, oils, antiseptics), warm as sitting bath, perineal shower, warming compresses.

In acute period they use bandages with cold water, cooling bandages with plumbum water or furacilinum.

Medicamentous therapy includes prescription of anti bleeding remedies and analgetics, antiseptics, anti-inflammatory remedies (orally, intravenously and locally as rectal suppositoria).

They also use physiotherapeutic methods (UHF, darsonvalization), treating physical training for strengthening of abdominal muscles and diaphragm, pelvis, spa treatment (H₂S baths, mud and radon sanatoria).

Indications for surgical treatment are frequent bleedings from hemorrhoidal nodes that are accompanied with anemia, big nodes that worsen defecationm inflammation, prolapse and strangulation of nodes.

There are known more than 30 methods of hemorrhoids' extraction. The main moments of operation are divulsion of sphincter, extraction and ligation of hemorrhoidal nodes situated in zones on 3, 7, and 11 hours at position of patient on back. Hemorrhoidal nodes are cut from external area to internal, leg is ligated by silk ligature and extracted. The most wide spread method is by Milligan-Morgan – extraction of nodes with renewal of mucosa in anus (Pic. 4.1.1).

In patients with complication of secondary hemorrhoids by bleeding that may not be treated by conservative therapy as a rule there is provided only ligation of bleeding areas.

Medical Therapy

Bleeding from first- and second-degree hemorrhoids often improves with the addition of dietary fiber, stool softeners, increased fluid intake, and avoidance of straining. Associated pruritus may often improve with improved hygiene. Many over-the-counter topical medications are desiccants and are relatively ineffective for treating hemorrhoidal symptoms.

Rubber Band Ligation

Persistent bleeding from first-, second-, and selected third-degree hemorrhoids may be treated by rubber band ligation.

Mucosa located 1 to 2 cm proximal to the dentate line is grasped and pulled into a rubber band applicator. After firing the ligator, the rubber band strangulates the underlying tissue, causing scarring and preventing further bleeding or prolapse (Fig. 28-30). In general, only one or two quadrants are banded per visit. Severe pain will occur if the rubber band is placed at or distal to the dentate line where sensory nerves are located. Other complications of rubber band ligation include urinary retention, infection, and

bleeding. Urinary retention occurs in approximately 1% of patients and is more likely if the ligation has inadvertently included a portion of the internal sphincter. Necrotizing infection is an uncommon, but life-threatening complication. Severe pain, fever, and urinary retention are early signs of infection and should prompt immediate evaluation of the patient usually with an exam under anesthesia. Treatment includes débridement of necrotic tissue, drainage of associated abscesses, and broad-spectrum antibiotics. Bleeding may occur approximately 7 to 10 days after rubber band ligation, at the time when the ligated pedicle necroses and sloughs. Bleeding is usually self-limited, but persistent hemorrhage may require exam under anesthesia and suture ligation of the pedicle.

Infrared Photocoagulation

Infrared photocoagulation is an effective office treatment for small first- and second-degree hemorrhoids. The instrument is applied to the apex of each hemorrhoid to coagulate the underlying plexus. All three quadrants may be treated during the same visit. Larger hemorrhoids and hemorrhoids with a significant amount of prolapse are not effectively treated with this technique.

Sclerotherapy

The injection of bleeding internal hemorrhoids with sclerosing agents is another effective office technique for treatment of first-, second-, and some third-degree hemorrhoids. One to 3 mL of a sclerosing solution (5-phenol in olive oil, sodium morrhuate, or quinine urea) are injected into the submucosa of each hemorrhoid. Few complications are associated with sclerotherapy, but infection and fibrosis have been reported.

Excision of Thrombosed External Hemorrhoids

Acutely thrombosed external hemorrhoids generally cause intense pain and a palpable perianal mass during the first 24 to 72 hours after thrombosis. The thrombosis can be effectively treated with an elliptical excision performed in the office under local anesthesia. Because the clot is usually loculated, simple incision and drainage is rarely effective. After 72 hours, the clot begins to resorb, and the pain resolves spontaneously. Excision is unnecessary, but sitz baths and analgesics are often helpful.

Operative Hemorrhoidectomy

A number of surgical procedures have been described for elective resection of symptomatic hemorrhoids. All are based on decreasing blood flow to the hemorrhoidal plexuses and excising redundant anoderm and mucosa.

Closed Submucosal Hemorrhoidectomy

The Parks or Ferguson hemorrhoidectomy involves resection of hemorrhoidal tissue and closure of the wounds with absorbable suture. The procedure may be performed in the prone or lithotomy position under local, regional, or general anesthesia. The anal canal is examined and an anal speculum inserted. The hemorrhoid cushions and associated redundant mucosa are identified and excised using an elliptical incision starting just distal to the anal verge and extending proximally to the anorectal ring. It is crucial to identify the fibers of the internal sphincter and carefully brush these away from the dissection in order to avoid injury to the sphincter. The apex of the hemorrhoidal plexus is then ligated and the hemorrhoid excised. The wound is then closed with a running absorbable suture. All three hemorrhoidal cushions may be removed using this technique; however, care should be taken to avoid resecting a large area of perianal skin in order to avoid postoperative anal stenosis.

Open Hemorrhoidectomy

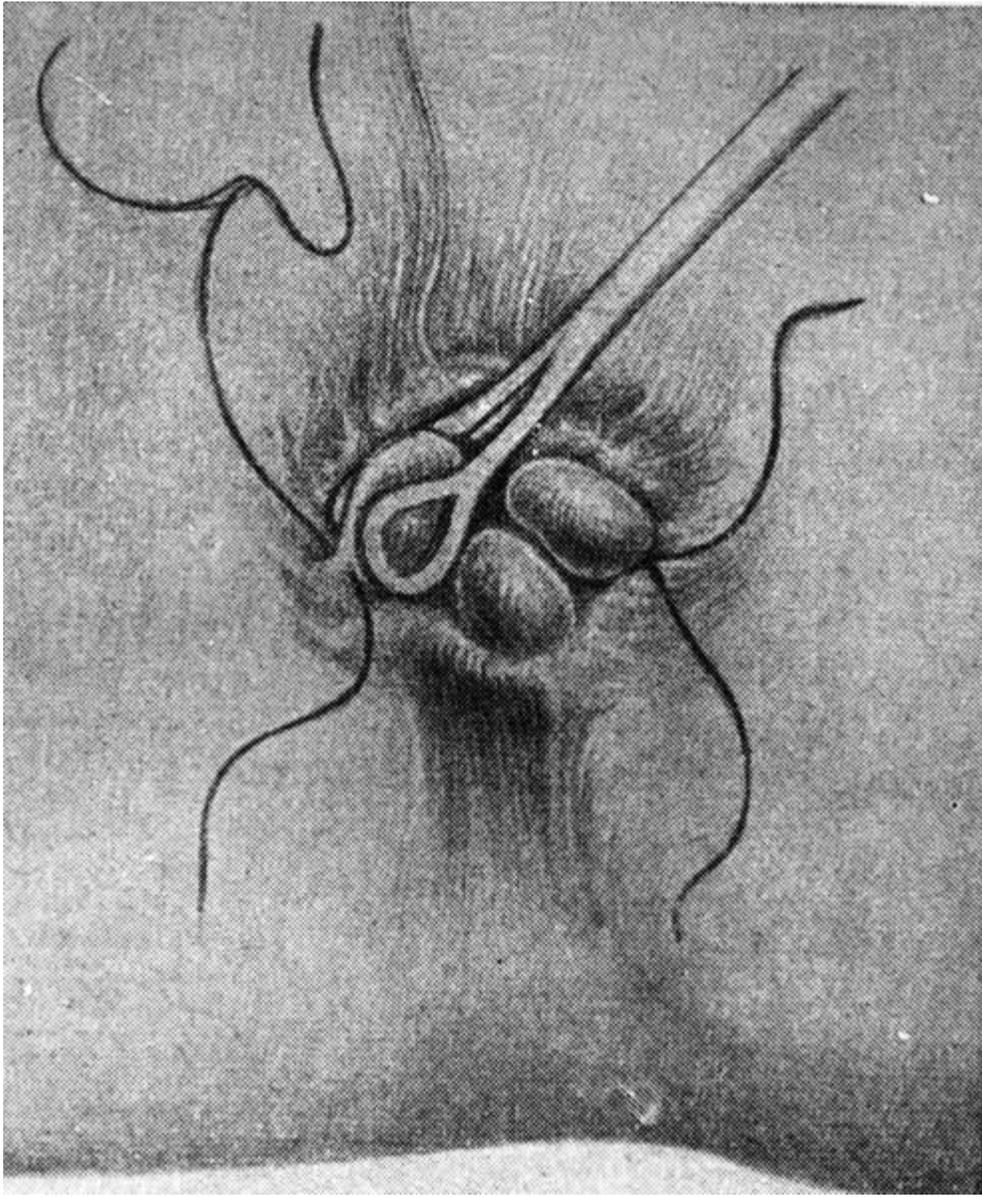

This technique, often called the Milligan and Morgan hemorrhoidectomy, follows the same principles of excision described above, but the wounds are left open and allowed to heal by secondary intention.

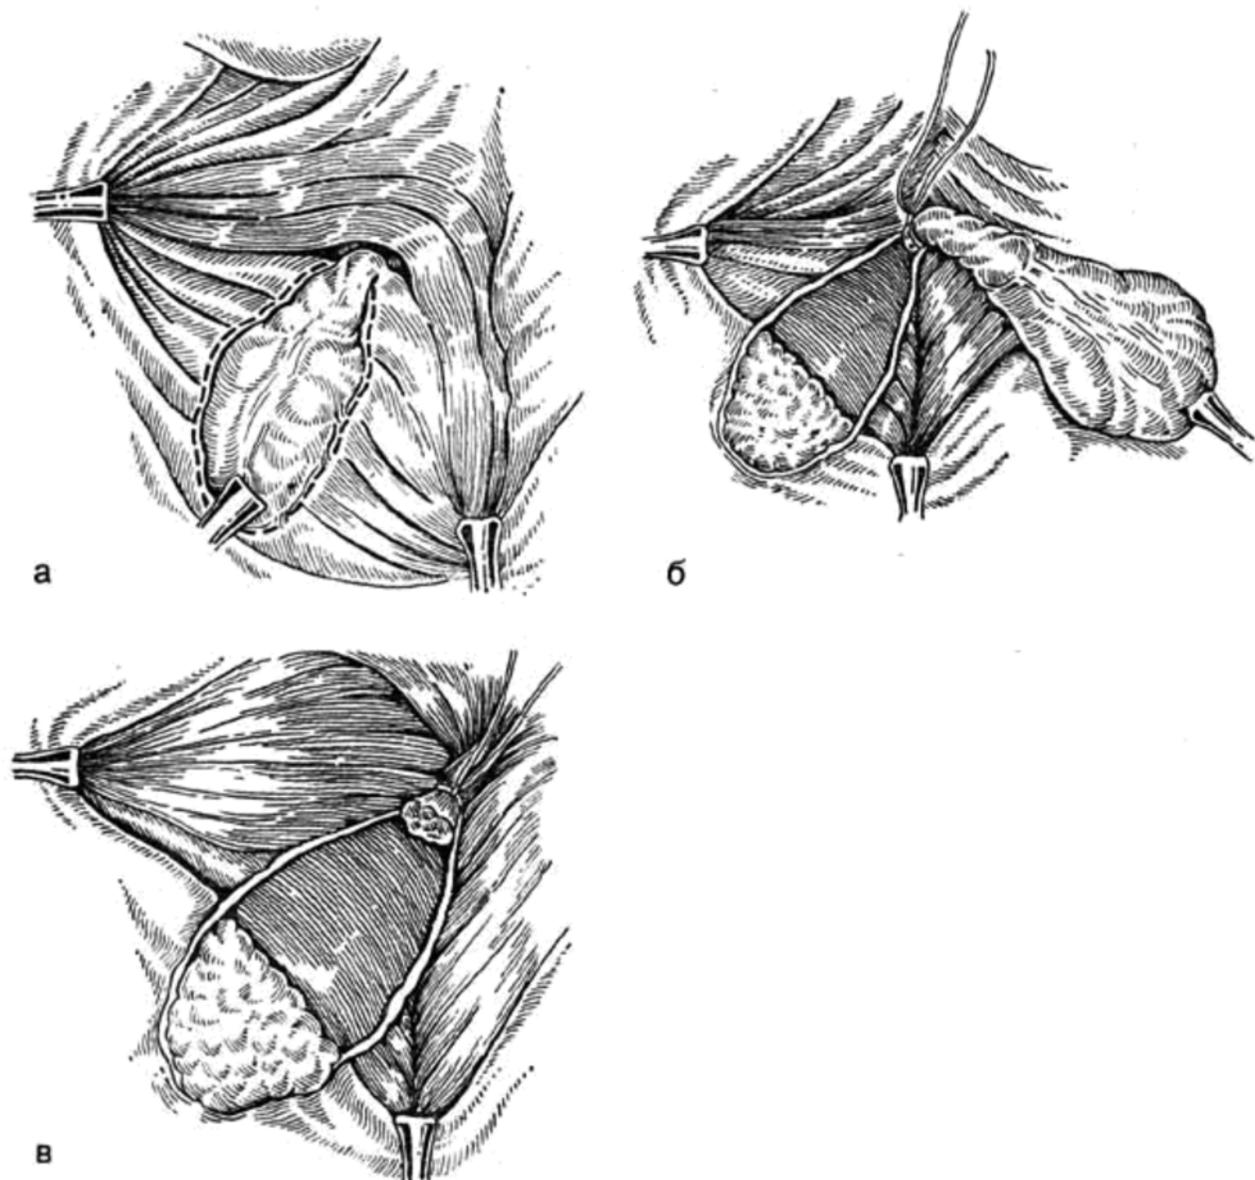

Whitehead's Hemorrhoidectomy

Whitehead's hemorrhoidectomy involves circumferential excision of the hemorrhoidal cushions just proximal to the dentate line. After excision, the rectal mucosa is then advanced and sutured to the dentate line. While some surgeons still use the Whitehead hemorrhoidectomy technique, most have abandoned this approach because of the risk of ectropion (Whitehead's deformity).

Stapled Hemorrhoidectomy

Stapled hemorrhoidectomy has been proposed as an alternative surgical approach. 81–83 Unlike excisional hemorrhoidectomy, stapled hemorrhoidectomy does not aim to excise redundant hemorrhoidal tissue. Instead, stapled hemorrhoidectomy removes a short circumferential segment of rectal mucosa proximal to the dentate line using a circular stapler. This effectively ligates the venules feeding the hemorrhoidal plexus and fixes redundant mucosa higher in the anal canal. Critics suggest that this technique is only appropriate for patients with large, bleeding, internal hemorrhoids, and is ineffective in management of external or combined hemorrhoids. Although stapled hemorrhoidectomy has not been widely accepted at this time, it remains a promising new technique.

Milligan-Morgan operation

After operation hemorrhoidectomy may appear early (bleeding from the wound) and later (stricture of anal canal) complications. With the aim of prevention of bleeding at hemorrhoidectomy leg is ligated with silk ligation, and the wound – by node ligations to bottom. For prevention of stricture of anal canal there makes sense to extract nodes not more than in 4 places. During this between extracted nodes there must stay not injured mucosa. When indicated, if after operation surgeon revealed the stricture of entrance into anal canal, hemorrhoidectomy is finished by dosed sphincterectomy.

During appearance of stricture of anal canal by posterior commissure scar in extracted, there is provided dosed sphincterectomy, and then mucosa is connected with perianal skin with further fixation by separate ligations.

Complications of Hemorrhoidectomy

Postoperative pain following excisional hemorrhoidectomy requires analgesia usually with oral narcotics. Nonsteroidal anti-inflammatory drugs, muscle relaxants, topical analgesics, and comfort measures, including sitz baths, are often useful as well. Several studies show that stapled hemorrhoidectomy is associated with a significant decrease in postoperative pain. Other complications are similar to those seen with excisional hemorrhoidectomy. Urinary retention is a common complication following hemorrhoidectomy and occurs in 10 to 50% of patients. The risk of urinary retention can be minimized by limiting intraoperative and perioperative intravenous fluids, and by providing adequate analgesia. Pain can also lead to fecal impaction. Risk of impaction may be decreased by preoperative enemas or a limited mechanical bowel preparation, liberal use of laxatives postoperatively, and adequate pain control. While a small amount of bleeding, especially with bowel movements, is to be expected, massive hemorrhage can occur after hemorrhoidectomy. Bleeding may occur in the immediate postoperative period (often in the recovery room) as a result of inadequate ligation of the vascular pedicle. This type of hemorrhage mandates an urgent return to the operating room where suture ligation of the bleeding vessel will often solve the problem. Bleeding may also occur 7 to 10 days after hemorrhoidectomy when the necrotic mucosa overlying the vascular pedicle sloughs. While some of these patients may be safely observed, others will require an exam under anesthesia to ligate the bleeding vessel or to oversee the wounds if no specific site of bleeding is identified. Infection is uncommon after hemorrhoidectomy; however, necrotizing soft-tissue infection can occur with devastating consequences. Severe pain, fever, and urinary retention may be early signs of infection. If infection is suspected, an emergent examination under anesthesia, drainage of abscess, and/or débridement of all necrotic tissue are required.

Long-term sequelae of hemorrhoidectomy include incontinence, anal stenosis, and ectropion (Whitehead's deformity). Many patients experience transient incontinence to flatus, but these symptoms are usually short-lived and few patients have permanent fecal incontinence. Anal stenosis may result from scarring after extensive resection of perianal skin. Ectropion may occur after a Whitehead's hemorrhoidectomy. This complication is usually the result of suturing the rectal mucosa too far distally in the anal canal and can be avoided by ensuring that the mucosa is sutured at or just above the dentate line.

RECTAL FISSURES

Rectal fissures are linear or triangle shaped defects of anal mucosa. This disease takes 3rd place after hemorrhoids and paraproctitis by frequency.

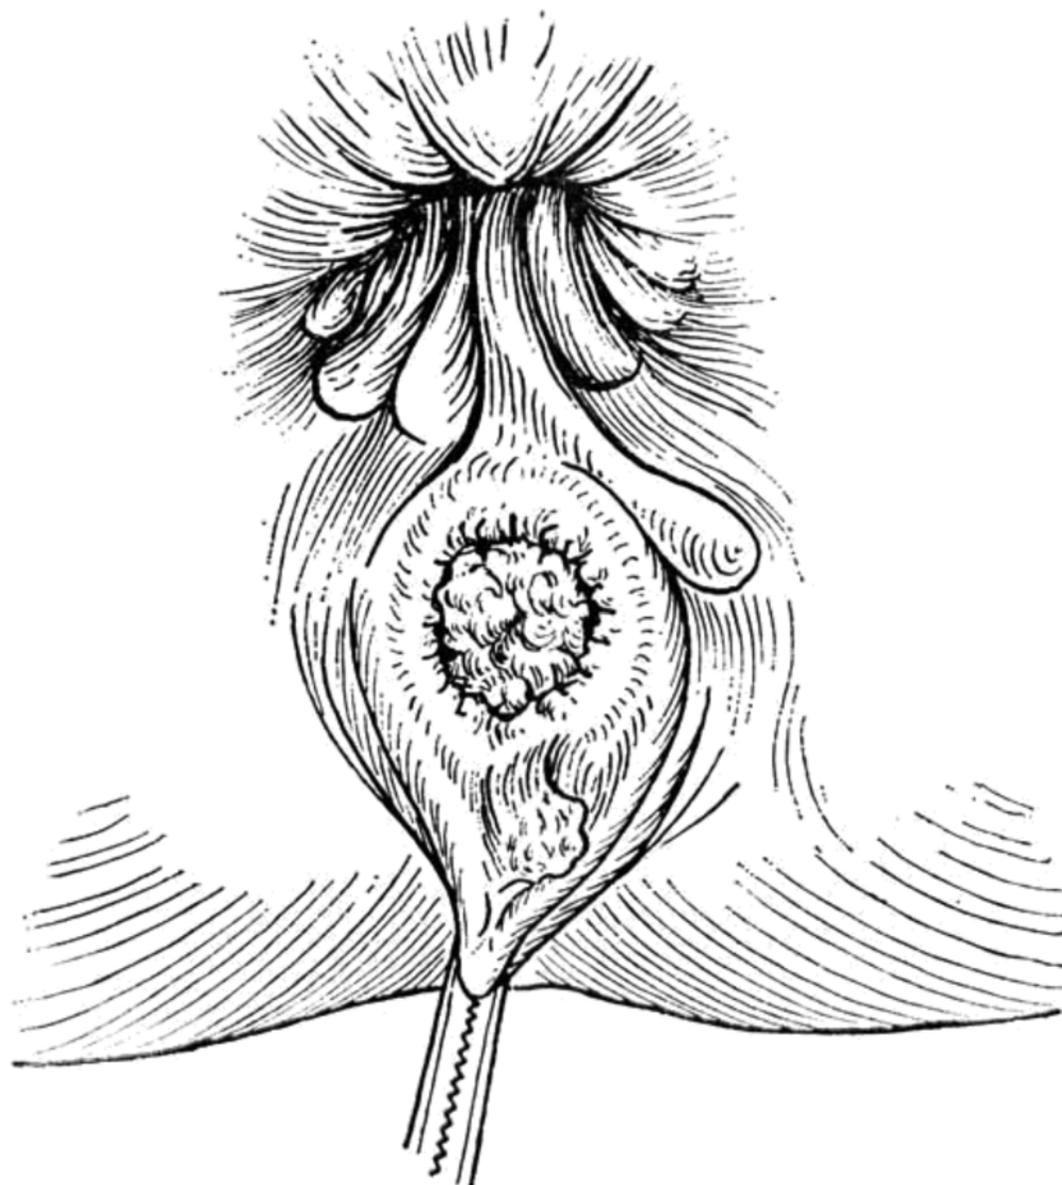

Etiology and pathogenesis

The most wide spread theories of appearance of fissures are mechanic and infectious. Due to the first, appearance of fissures is conditioned by injury of anal mucosa by dense feces in combination with constipation and diarrhea. Diseases that promote formation of fissures are proctosigmoiditis, enterocolitis and hemorrhoids. Often fissures accompany gastritis, gastric and duodenal ulcers.

By infectious theory fissures appear at inflammation of anal glands (criptitis) that lead to tissue fibrosis and decrease of their elasticity. Appearance of disease also may be promoted by syphilis, tuberculosis, homosexuality.

Classification

Rectal fissures by clinical course are divided onto acute and chronic. They may be complicated (paraproctitis, malignization, bleeding, pectenosis) and combined with other diseases of anal canal (hemorrhoids, criptitis, polypus).

Rectal fissures

Symptoms and clinical course

Such disease is seen mostly in women of middle age. Fissures are mostly situated in area of posterior commissure on 6 hours by clock dial in patient's position laying on back. More rarely fissures are situated on anterior and lateral walls. On posterior wall of anal canal conditions of bleeding are worse, that's why there is more danger of mucosal injury during defecation, it is connected with pressure of feces during their motion onto posterior and anterior commissures. Fissure mostly has longitudinal direction and hides between skin folds in anal area. In chronic course near external edge of fissure there appear skin fold with undermined edges, so called terminal tuberculum. On internal edge of fissure there is tuberculum of smaller size. In rare cases there are seen two fissures at the same time.

Clinical picture of anal fissure includes *triad of symptoms*: pain during or after

defecation, spasm of sphincter, and low bleeding during defecation.

Pain in patients with rectal fissures has burning character connected with moving of volumatic dense feces through anal canal. It depends also on degree of reflection of sphincter spasm, irradiates into perineum, genitalia, urinary bladder, back, and conditions disuric signs in males and dysmenorrhea in females.

Sphincter spasm during the onset of the disease may be small. In chronic course it may lead to proliferation of connective tissue.

Blood in feces appears during or after defecation, it has bright red color and is excreted mostly in small quantity.

After examination of patient with such pathology you should ask him to exert himself in relaxed sphincter, it is like defecation. In such conditions anus lowers and deep areas of skin, terminal fold and mucosa become visible. It lets us examine external area of fissure. In incredible spasm of sphincter patient is moved onto table in position on side with legs near abdomen or in "knee-elbow" position, with the help of napkins they carefully move tissues of anus toward different sides. During this in that region of anal ring where is predicted localization of fissure they examine deep skin folds. In careful investigation there may be found fissure without severe pain for patient.

Variants of clinical course and complications

Acute fissure is characterized by acute onset, presence in anal area of linear longitudinal wound with soft bottom and length 1-2 cm, width 0.3-0.5 cm, depth to 0.3 cm. Disease may have duration to two months. As a rule, acute fissures don't cause complications.

Chronic fissures may disturb patients from two months to 1 year and more. In prolonged existence fissure transforms into chronic ulcer with dense sclerozing bottom. In patients with chronic fissures there may appear complications.

Bleeding at rectal fissures is mostly low. There is observed excretion of bright red blood during or after defecation. In extraordinary cases even low but frequent bleeding from rectal fissures leads to revealed anemia.

Pectenosis is revealed in chronic fissures. At this pathology sphincter muscles are replaced by connective tissue and the patient gets coprostasis. Any examination of rectum is impossible because of narrowing of rigid anal ring.

At paraproctitis as a complication of fissure the entrance for infection is crypt through which inflammatory process is spreaded. The patient suffers from pain of pulsing character in area of rectum and perineum, fever. During palpation of perianal region there appear severe pain. Punction lets reveal purulent focus.

Malignization is characteric for prolonged fissure. In such cases pain decreases, there is observed ulcer with dense bottom with grey covering. In first portions of feces there appears blood with bad smell. Excisional biopsia with further histological investigation helps to find out the malignization of fissure.

Diagnostic program

1. Anamnesis and physical data.
2. Examination of canal by stretching of anal tissues.
3. Finger examination of rectum.
4. investigation of rectum by rectal mirror.
5. Rectoromanoscopia (contraindicated in pectenosis).
6. General analysis of blood and urine.
7. Coagulogram.
8. Sedimentation reactions (reaction of Wassermann).

Differential diagnostics

Chronic fissures of rectum should be often differentiated with other diseases that may have the same local signs.

Proctalgia. Pain is localized in the area of rectum. Consider, that the reason of proctalgia is pathology of the higher nervous system (neuroses, hysteria). At objective examination the visible organic changes are not exposed.

The anal form of non specific ulcerous colitis is characterized by the superficial damage of rectum – hyperemia and edema of mucus, formation of shallow ulcers and erosions. As a rule, non specific ulcerous colitis with all its signs begins from the distal part of rectum.

Kron's disease of rectum begins from submucosal layer, ulcers do not spread much, they mostly are like fissures that penetrate onto all depth of intestinal wall, have longitudinal and transversal directions, and may cause formation of fistules and abscesses. At histological investigation during Kron's disease there is revealed granuloma.

Cancer of rectum. Presence in anal canal of formation with not smooth edges and additions of blood in feces gives a possibility to suspect malignization of fissure. Morphological investigation of bioptates with presence of atypical cells proves malignant process.

Tactics and choice of treating method

Acute fissures are treated conservatively.

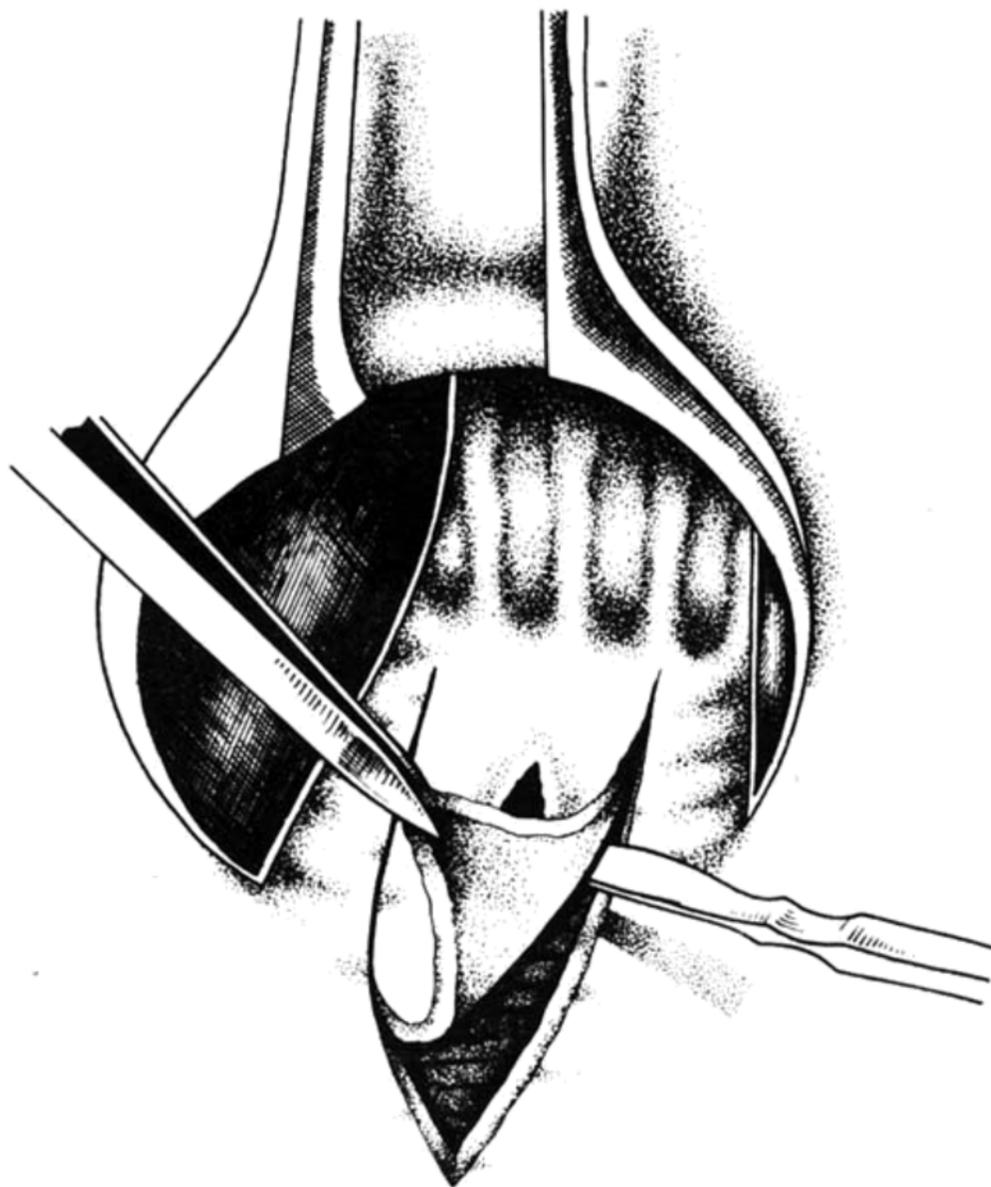

Treatment includes diet therapy, prescription of remedies and physiotherapeutic procedures.

Diet therapy means excluding from ration spicy and salty food, introduction of oral-oil substances that regulate feces.

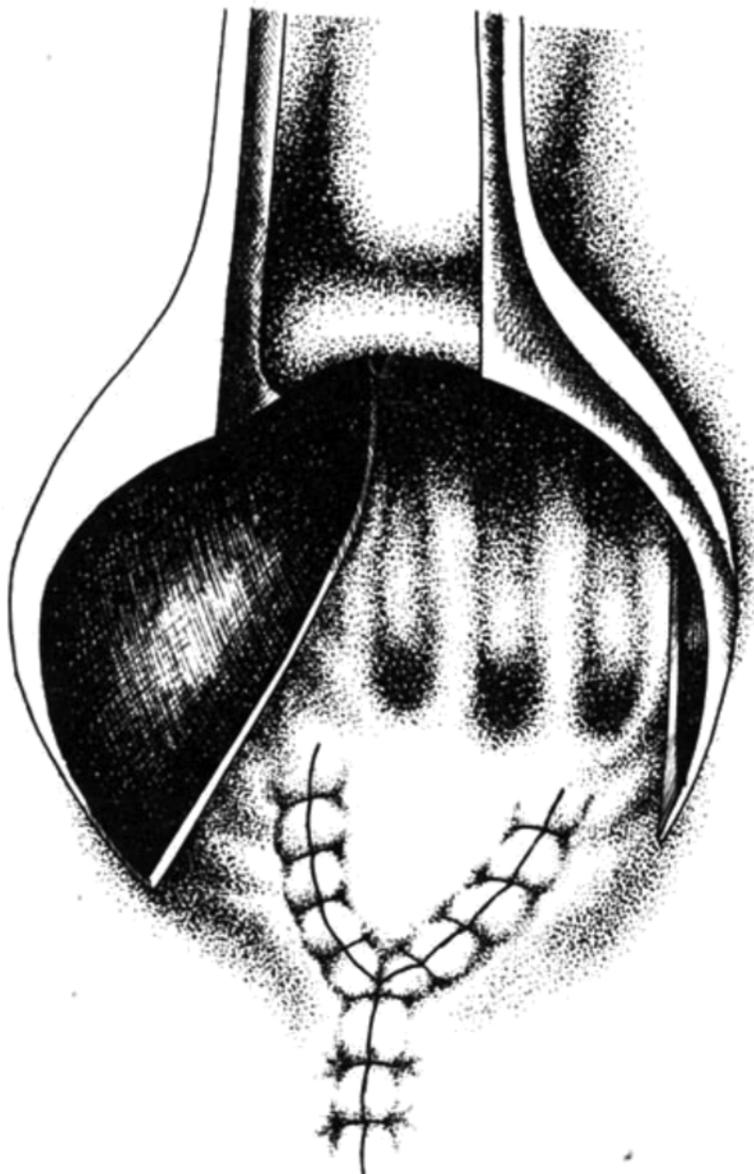

They use warm procedures (baths, hot water bottles), physiotherapeutic measures (darsonvalization, UHF, diathermia).

Medicamentous therapy means prescription of anti-spasmodic (spasmalginum, no-spa, spasmolytinum) and analgetics (promedolum, baralginum).

Rectally they use micro enemas (oily, antiseptic), rectal suppositories (with belladonna, anaesthesinum and their standard forms – proctosedylum, G preparation). Under the fissure by injection they introduce hydrocortizonum with novocainum.

Transverse cut of the mucosa above the upper merge of the Rectal fissures

End view of the operation

Indications for surgical treatment are chronic ulcer complicated by pectenosis, fistule, bleeding, and also non effective conservative treatment. From radical methods we recommend cutting of fissure in longitudinal direction including all the fissure into deleted part. Operation is added by dosed sphincterectomy. Defect of mucosa is closed in transversal direction by ligation of rectal mucosa to perianal skin.

POLYPS OF COLON AND RECTUM

Polyps are non malignant tumors on legs that grow from mucosa.

Etiology and pathogenesis

Reasons of polyp's appearance are disorders in embryonal development , inflammatory processes of mucosa and also viral infection.

Pathomorphology

Polypus of inflammatory origin differ from adenomatous ones by their incorrect form and size variety. They are soft, filled with blood, often with ulceration and hematomas. Such polypus usually combine with other signs of inflammation in intestine.

Adenomatous polypus are often part of syndromes. Thus, combination with non malignant tumors of bones, skin and soft tissues is characteristic for Gardner's syndrome, combination with focal melanosis of mucosa – for Peitz-Eggers' syndrome, combination with brain tumors – for Turco's syndrome.

Classification

By etiology:

- Innate (hereditary, family)
- Acquired (at inflammatory processes)

Separately they define also children (juvenile, innate and acquired).

By process' spreading:

- Single
- Multiple
- Total (injury of all intestines).

By external appearance and microscopic structure:

- True (glandular, fleesy, from multi layer epithelium)
- False (hypertrophic at ulceric colitis, fibrose).

Symptoms and clinical course

Men get this disease in 2-3 times more than women. Single polypus of colon and rectum have usually latent course and are often revealed accidentally.

Multiple polypus may lead to diarrhea, bleeding, changes in morphological and biochemical blood composition. At this children do not develop properly. At distal localization in some patients polypus prolapse and strangulate in anal ring causing pain. Low situated polypus irritate rectum and cause tenesmas, sometimes they cause prolapse of intestinal wall.

Among disease's symptoms first place belongs to disorders of defecation and blood in feces with further anemia, hypoproteinemia, decrease of workability. Fleesy polypus leads to disorders of water-salt and protein metabolism, because mucus' excretion at defecation may achieve 1.5 liters,

At multiple polyposis they define triad of symptoms:

1. Pigment spots (on the face, lips, mucosal membranes of cheeks, fingers, and other areas of covering epithelium).
2. Polyposis of digestive tract.
3. Hereditary character of disease.

Finger examination of rectum and observation with rectal mirror give a possibility to investigate its lower part. During this procedures you can reveal polypus of different size situated on jucosa of rectum and also polypus prolapsed with invaginate of sygmoid colon.

Irigography reveals single and multiple defects of filling (Pic. 4.1.13), so called symptom of “shooted aim” that may be seen in different parts of colon. At presence of invaginate as complication of polypus there is charactering defect of filling.

With the help of rectoromanoscope you can examine rectum and sigmoid colon on average height 30 cm, and fibrocolonoscope is to examine all parts of colon. This investigation method gives a possibility to reveal exact place of polypus’ localization, its appearance including leg width, to provide excisional byopsia and also electrocoagulation.

Variants of clinical course and complications

Polypus of small size at the onset have latent course. With their growth during moving of feces may occur disorder of their completeness with further possible complications. More often is bleeding that in most cases occur defecation. Depending on the height of polypus’ localization in intestine blood may be dark red to bright red color. Blood loss may be from small, light to severe, with signs of small and incredible anemia.

In most patients polypus have a tendense to malignization. Provided biopsia in pre operation period with morphological investigation reveals malignant transformation of tissues and proves this diagnosis not in all cases. It depends on that in what part polypus becomes malignant. Final diagnosis may be put after the operation during histological investigation of all polypus.

Polypus of big size situated in rectum usually strangulate. During this strangulation takes place on the level of anal ring and is accompanied with severe pain. Not reducible polypus may necrotize.

Polypus are situated in caecum, colon and sigmoid colon. In the most motile areas they may lead to intestinal invagination. In this case there appear spastic pain, blood excretion with feces. During abdominal palpation they reveal painful infiltrate. Invagination may prolapse into rectal lumen.

Diagnostic program

1. Anamnesis and physical data.
2. Finger investigation of rectum.
3. Investigation by rectal mirror.

4. Rectoromanoscopy.
5. Irigography.
6. Fibrocolonoscopy.
7. General analysis of blood and urine.
8. Coagulogram

Differential diagnosis

Polypus of colon and rectum should be differentiated with malignant and non epithelial tumors, non specific ulcer colitis and rectal fissures.

Cancer of right part of colon has a course with incredible anemia (toxicoanemic form) due to absorption of tumor's toxic products, their action on hemopoetic organs.

Cancer of left part of colon is usually accompanied with signs of obturative intestinal impassability. Additional examination (finger rectal examination, irigography, endoscopic methods) give a possibility to prove the diagnosis.

At chronic course of non specific ulcer colitis there is injured mucosa of intestine, and little islands of not injured mucosa between multiple big ulcers look like polypus, so called pseudopolyposis. Detailed anamnesis, specialities of clinical course of the disease, irigography and colonoscopy exclude presence of true polypus.

Not epithelial tumors (leiomyoma, lipoma) are situated under intestinal mucosa and at their small size do not cause any symptoms. With their growth mucosa is injured, there occurs bleeding with its signs. X-ray and endoscopic methods of investigation, and also histological investigation prove the final diagnosis.

Chronic fissure of rectum with not smooth edges and terminal tuberculum often simulates true polypus. Removal of this formation both with fissure and provided histological investigation help in proving of diagnosis.

Tactics and choice of treating method

Conservative method of treatment is rarely used. For this is used solution of green greater celandine for its introduction in enemas (3-4 grams of green mass for 1 kg of patient weight, on the average 50 g for adults). A celandine is ground down on a meat grinder, conduct in hot water in the ratio 1:10. A medical cycle includes 15-30 enemas. Per treatments course is conducted three cycles at intervals in one month. The low located polypuses from a stratified epithelium, pseudopolypuses and malignant polypuses are not treated by celandine.

Because of polypuses of small intestine and rectums are inclined to malignization, the basic method of its treatment is surgical .

Methods of operative treatment at polypus are divided into two groups:

1. Local operations (endoscopic electrocoagulation, polypus's removal). Indication for electrocoagulation is presence of single polypus on narrow leg, rarely – multiple polypus. Depending on the localization polypus on wide leg are removed through rectum or by laparotomy with further colotomy.
2. Radical operations as resection of separate segments of colon, right-side, left-side, subtotal colectomy or proctectomy are provided at multiple polypus.

PARAPROCTITIS

Acute paraproctitis is acute inflammation of pararectal cellular tissue. They take near 30% of all diseases of rectum.

Etiology and pathogenesis

In most cases paraproctitis is caused by polymicrobial flora. During inoculation of purulent content there are usually revealed staphylococci, E. coli, Gram positive and Gram negative rods. Causative agents of tuberculosis, actinomycosis, syphilis are rare causative agents of paraproctitis. Clostridial infection causes occurrence of gas gangrene of pelvic cellular tissue. In etiology of paraproctitis the great role belongs to penetration of infection into pararectal cellular tissue, status of organism's immunity, presence of additional diseases (diabetes mellitus). Infection may penetrate through anal glands, injured rectal mucosa, and also by hematogenic and lymphogenic way from neighbour organs injured by inflammatory process. Every anal crypt collects openings from 6-8 anal glands. Thus, anal crypt is opened gate for infection. After that follow swelling and obturation of duct connecting anal gland with anal crypt. Due to that there forms purulent cyst that opens and infection gets into perianal and perirectal spaces.

Pathomorphology

Morphologically there is defined purulent inflammation of crypts with further spreading to perirectal, ischiorectal and pelvic cellular tissue. Purulent inflammation usually is as phlegmone or (rarely) abscess.

Classification

1. By etiology – usual, anaerobic (gangrenous-putrefactive, ascendent anaerobic lymphangitis, anaerobic sepsis), specific, traumatic paraproctitis.
2. By localization – submucosal, subcutaneous, oschiorectal, pelviorectal, retrorectal paraproctitis

Separately there is defined secondary paraproctitis at which inflammatory process

spreads to pararectal cellular tissue from prostate gland or female genitalia.

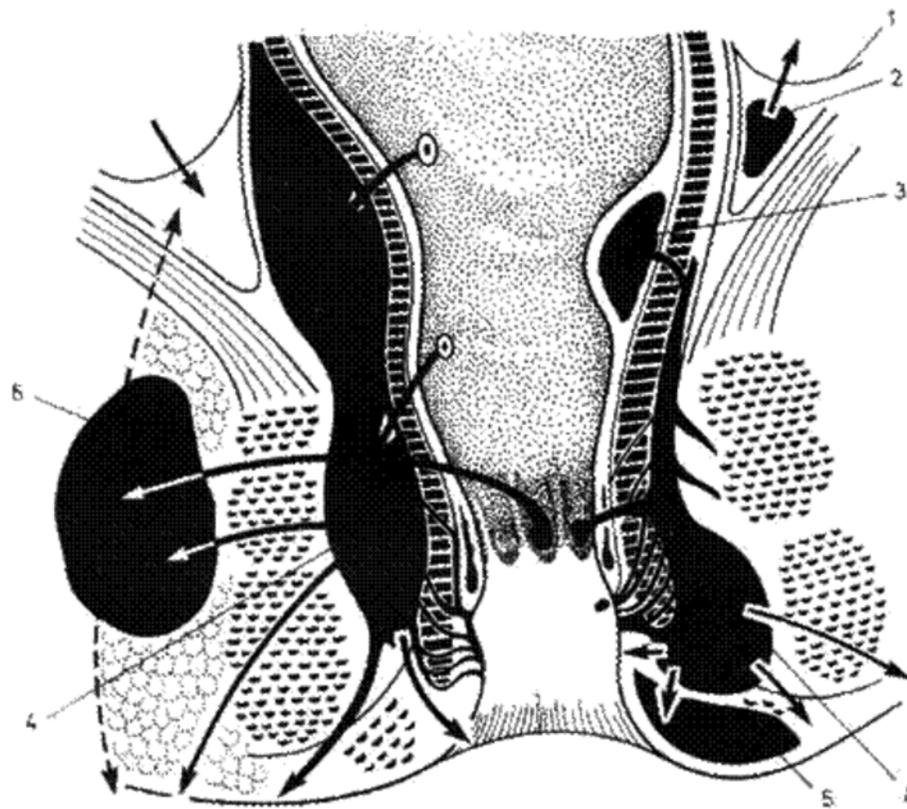

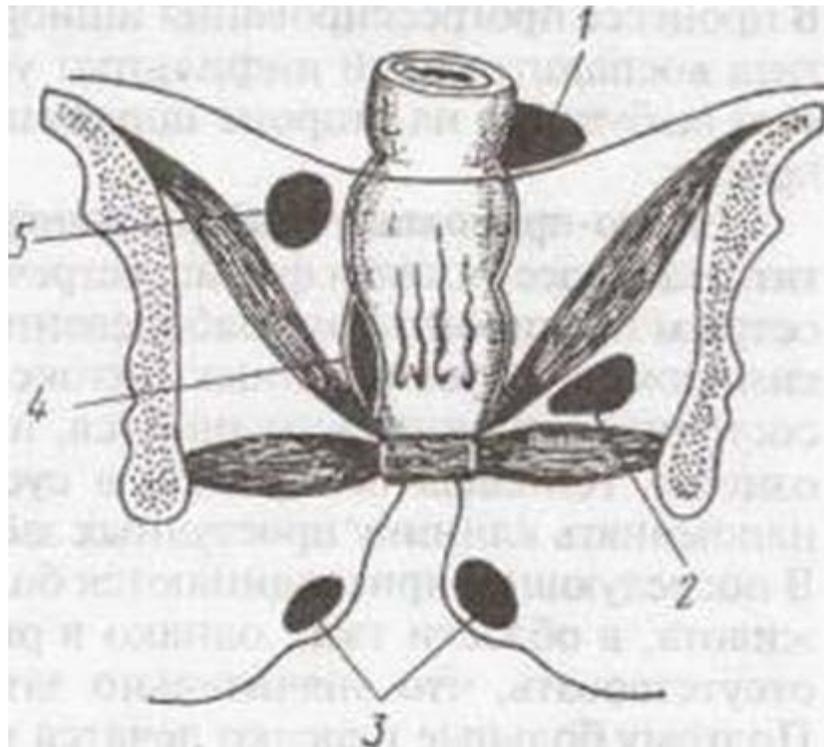

Symptoms and clinical course

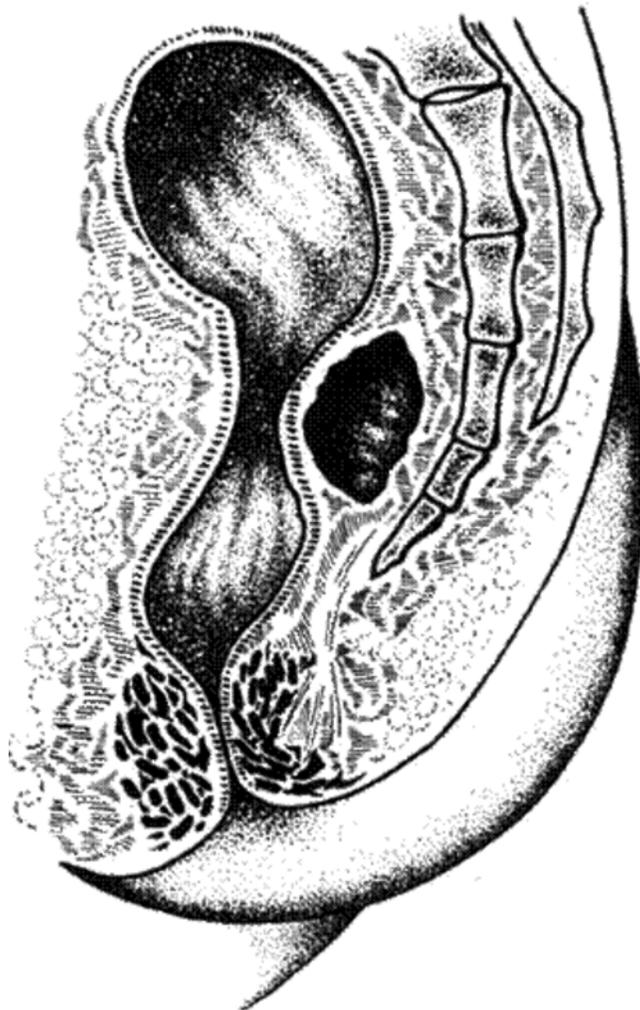

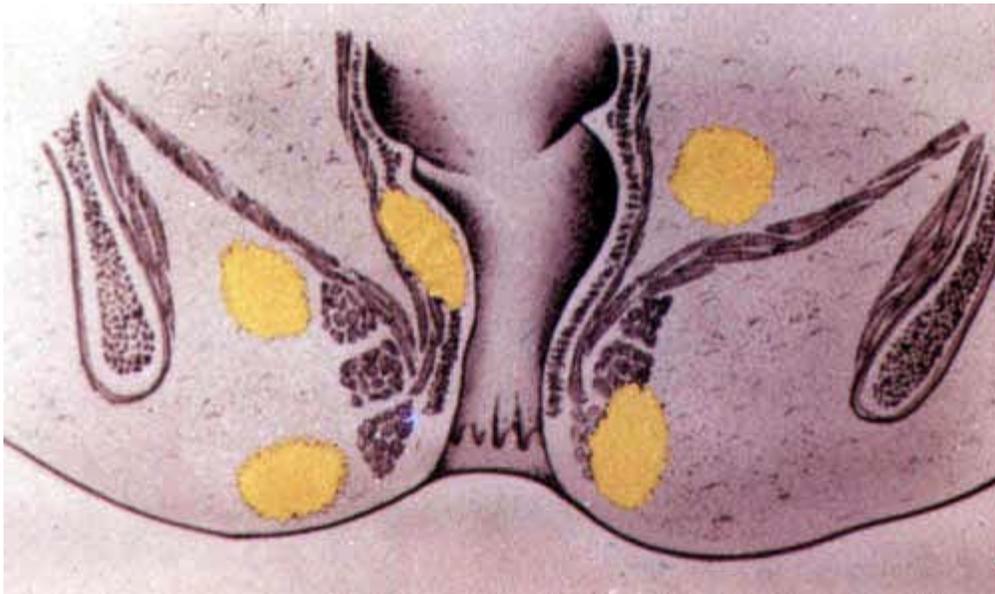

Paraproctitis has as local as general symptoms. The most often are pain in anal region of rectum, swelling, hyperemia, fluctuation, constipation, sometimes - disuria, increase of body temperature, loss of appetite and workability.

During general blood analysis there are leukocytosis with left disposition of leukocyte formula, SES increase. If in-time operative treatment shouldn't be provided, period of disease may increase to 10 days and more. After that there comes independent opening of abscess into rectum (chronic paraproctitis), formation of recurrent paraproctitis or reconvalescense.

Variants of clinical course and complications

Subcutaneous, submucoal and ischiorectal paraproctitis ar characterized mostly by typical course, there usually are no difficulties in putting of diagnosis. Pelviorectal paraproctitis as the most severe form is not revealed exactly. At first pain in inflammated area is not felt, disease starts from headache, fever, increase of body temperature. Sometimes on this stage of disease there is put such diagnosis as influenza. After that appears pain in lower part of pelvis that irradiates into uterus, urinary bladder causing disorders of urination. Patients get treatment in urologist, gynecologist and therapist for a long time. If inflammatory infiltrate of pelviorectal cellular tissue transforms into abscess, disease becomes acute. External signs are revealed at spreading of purulent process onto ischiorectal and subcutaneous cellular tissue. It lasts in limits of one place. At the same time, processes may spread onto other pelvis part and form horseshoe shaped paraproctitis. Retrorectal paraproctitis as a kind of pelviorectal from the very beginning is accompanied with pain. During this pain is concentrated in rectum, coccygeal area, it is increased in sitting position of patient and during defecation. At this localization of abscess there may be two-side horseshoe shaped injury. Paraproctitis with clostridial infection is characterized from the beginning with sever intoxicaton, high temperature.

Palpatory in this regions there is felt crepitation. Acute paraproctitis may be complicated by fistulas, phlegmones, lymphangitis, sepsis. At clostridial infection not in time and incomplete treatment may lead to death.

Diagnostic program

1. Anamnesis and physical data.
2. Examination of anal area and anal canal.
3. Finger examination.

Differential diagnosis

Paraproctitis is differentiated with hemorrhoids, purulent dermoid cysts, suppuration of epithelial paracoccygeal canals, cancer of rectum, tumors and inflammatory diseases of sacral bone.

Acute hemorrhoids are accompanied with severe pain, swelling of perianal area, formation of thrombs in nodes, nodes' necrosis.

Suppurated presacral dermoid cyst has no connection with rectum, and paraproctitis usually does. Pararectal abscess is always connected with rectum in area of anal crypts. If suppurated cyst empties into intestine, then fistula's direction is beyond the linea dentate.

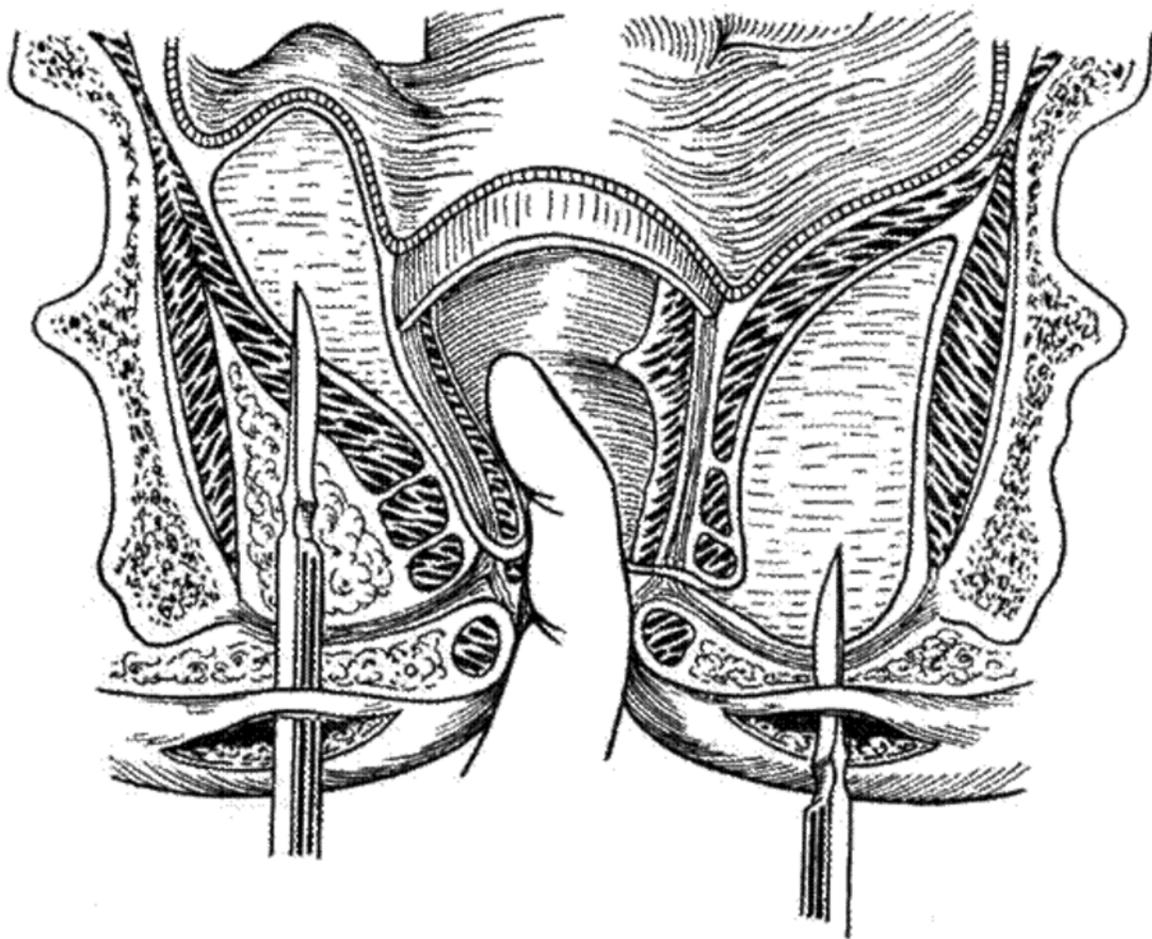

Suppurated epithelial pericoccygeal canals are characterized by presence of point openings on coccygeal level, fistula's direction is beyond rectum.

Cancer of rectum at the onset of the disease is usually accompanied with no pain. During examination of rectum there is revealed dense formation. Data of punctional biopsia help to prove the diagnosis.

Diseases of sacral bone as tumoral as inflammatory of the basis of osteomyelitis with injury of bone tissue structure are revealed by X-ray examination.

Tactics and choice of treating method

Method of choice for treatment of acute paraproctitis is surgical. But on early stages of pelviorectal paraproctitis with deep infiltration of tissues surrounding rectum, without signs of softening there is indicated conservative treatment (warming compress on area of perineum with 20% spiritus aethylicus, antibiotics of wide spectrum of stion, lumbal novocainum blockade, strict bed regime, exclusion of cellulose from food, usage of cleaning enemas). Surgical treatment means early operation by opening of abscess by semilunar incision with dreanging and liquidation of its inner opening (removal of crypt) through which abscess' cavity is connected with rectum.

Opening ischioanal paraprocitis.

At paraprocitis there may be observed transsphincter and extrasphincter directions of fistulas, at pelviorectal and retrorectal – extrasphincter. Important thing is choice of way of big abscess' opening: through skin or mucosa from rectum. With this aim before opening of abscess by thick needle you should provide puncture of infiltrated area and if exudates is got you should provide the incision. If pus of ischioanal area is spreaded on subcutaneous cellular tissue and there are changes in shape of buttock, fluctuation, question of surgical operation has no doubt. At retrorectal paraprocitis there makes sense to open the abscess from rectal lumen. If in this case there functions inner fistule, it usually brings no troubles for patients (Pic. 4.1.7).

At signs of anaerobic infection they provide wide multiple incisions, necrectomia, wound cavity is washed by solutions of oxidants (permanent washing), you should use antibiotics of wide action spectrum, polyvalent anti-gangrenous serum (250-300,000 units 1 time per 2-3 days), desintoxicative therapy, oxygen barotherapy (10 procedures at pressure 2 atmospheres), introduction of fresh blood, albumine, plasma, hemodes, rheopolyglucinum. At diabetes mellitus they provide insulin therapy and introduction of metrogilum.

After the operation there may appear early complications: bleeding from wound

bottom, especially at anaerobic paraproctitis, and late – insufficiency of distal part of rectum, recidivum of paraproctitis, formation of fistules. If bleeding occurs, they provide tamponade of these areas, and if it does not stop – bleeding places are ligated. At insufficiency of sphincter there should be provided one more operation: renewal of sphincter completeness by Π -like ligations.

RECTAL FISTULAS (CHRONIC PARAPROCTITIS)

Rectal fistulas are tubular purulent canals in cellular tissue surrounding rectum and anus.

Etiology and pathogenesis

Rectal fistulas occur mostly on the basis of acute paraproctitis. Reasons of chronic fistulas are:

- opening of purulent paraproctitis without cutting of crypt;
- shortening of external anal sphincter at which fistula's canal is pressed and

excretion of its content stops;

- decreased resistance to infection and low tissue regeneration;
- epithelization of coccygeal canals.

Classification

I. By etiology and pathogenesis:

1. Innate.
2. Acquired (traumatic, inflammatory, tumoral).

II. By infection character:

1. Vulgaric.
2. Anaerobic.
3. Specific (tuberculous, syphilitic, actinomycotic etc.)

III. By anatomical signs:

1. Depending on connection with intestinal lumen (complete, incomplete, internal, external).
2. By correlation to external sphincter (intrasphincter, extrasphincter, transsphincter).
3. Depending on primary localization of inflammatory process (subcutaneous, submucosal, ischiorectal, pelviorectal).
4. Depending on localization of external and internal fistula's canals (cutaneous, marginal, on crypt level).
5. By fistula's shape (simple – direct, complex – curve and containing cavities).

There define 4 degrees of extrasphincter fistulas:

I degree – scar and inflammatory changes are absent.

II degree – scar process around inner fistula's opening without inflammatory changes in pararectal cellular tissue.

III degree – purulent cavities or infiltrates in pararectal cellular tissue without scars around inner opening.

IV degree – incredible infiltrates or purulent cavities in pararectal cellular tissue and big scar process around inner opening.

Symptoms and clinical course

Self feeling and general status of patient with chronic course of paraproctitis in most cases is satisfying. At long time existing inflammatory focus workability decreases, increased irritability appears, sleep becomes worse. Depending on activity of inflammatory process, character of excretions from fistula changes. After abscess opening pain decreases and may be back when process becomes acute. In most patients with rectal fistulas there are observed signs of proctosigmoiditis and chronic recurrent paraproctitis.

When process becomes acute pain appears and temperature increases. There is formed purulent focus with formation of new fistula's canals.

In most patients fistula situated near anal ring goes inside the sphincter. Fistula situated 4-5 cm from anus and deeper is situated mostly outside the sphincter and may be of IV degree.

Variants of clinical course and complications

Patients with fistulas feel rush and heaviness in areas of rectum and anus. Long existing fistulas are accompanied with scar changes of anal ring (pectenosis) that difficult defecation. After fistula's closing (between acute periods) patients have no troubles and feel healthy. In some patients there stay painful infiltrates where inflammatory process may renew. The most dangerous and rare complication of chronic paraproctitis is malignant transformation of rectal fistulas.

Diagnostic program

1. Anamnesis and physical data.
2. Examination of anal area and anal canal.
3. Finger examination of rectum.
4. Investigation by rectal mirror.
5. Rectoromanoscopy.
6. Bacteriogram of purulent content.
7. General analysis of blood and urine.
8. Biochemical analysis of blood.
9. Sedimental reactions (reaction of Wassermann).
10. Contrast fistulography.
11. Introduction of catheter into fistula's canal.

Differential diagnosis

Chronic paraproctitis are differentiated with suppuration of epithelial paracoccygeal canals, diseases of sacral bone, fissures of rectum and suppurated presacral dermoid cysts.

Suppurated epithelial paracoccygeal canals are primary openings of fistulas in area of intergluteal folds, and fistula's canals are situated behind the dental line and are not connected with rectum.

Diseases of sacral bone on the basis of osteomyelitis are recognized by X-ray method. At this there are revealed disorders of bone structure.

Fissures of rectal mucosa are accompanied with severe pain, bleeding and spasms of sphincter. Presence of wound mostly on posterior commissure proves the diagnosis.

Suppurated presacral dermoid cyst has no connection with rectum. Even if it empties into rectum, fistula's canal is always situated beyond the linea dentata.

Tactics and choice of treating method

At conservative treatment of chronic paraproctitis (fistulas) they use sitting baths and warming compresses with 20% spiritus aethylicus. They also prescribe physiotherapeutic procedures (ultraviolet radiation, local darsonvalization, electrophoresis with 1% solution of potassium iodide, 1% novocainum solution), lavage of fistula with diluted solutions of antiseptics.

Operative treatment is indicated if fistula is present for a long time or closes for some time and then opens again after acute inflammatory period. In patients with intrasphincter fistulas there is used operation by Gabriel. Its basis is that fistula is cut from inner to external opening. Skin that covers the fistula is cut as triangle. Its peak includes internal opening, and basis is situated outside (Pic. 4.1.8).

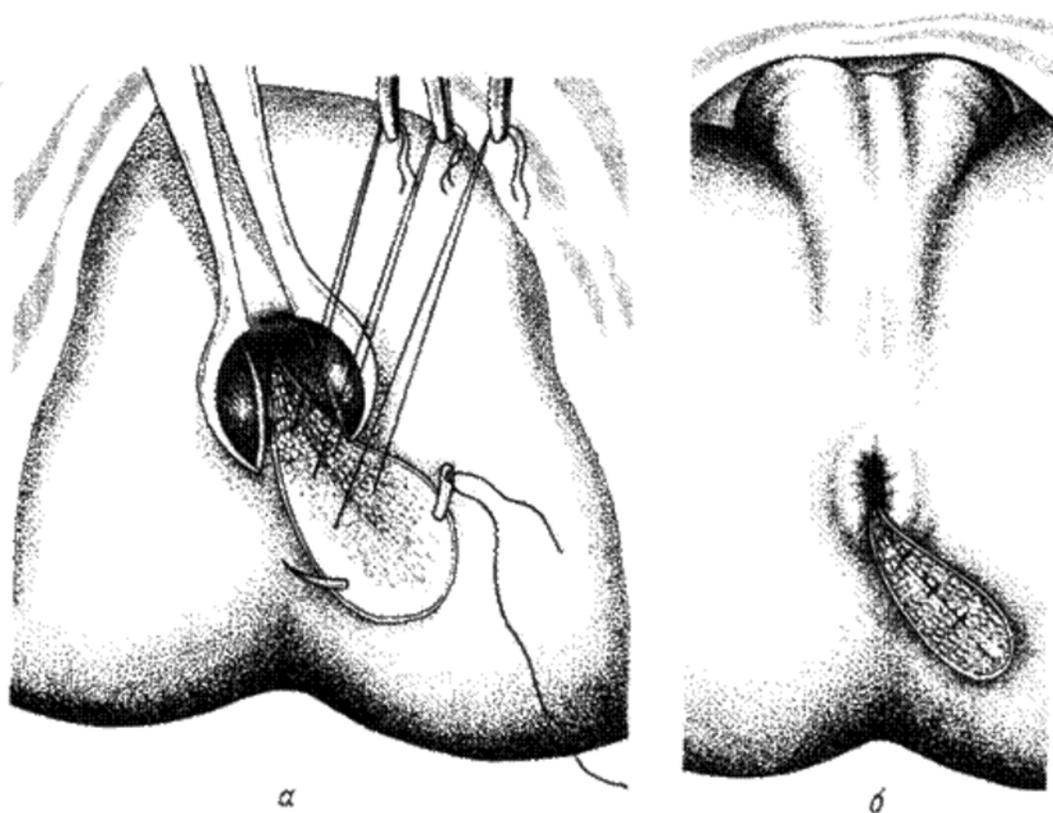

In case of fistula going through inner parts of sphincter (transsphincter fistula) during canal removal there are injured fibers of sphincter. For renewal of cut sphincter there are used node of II-like ligations. At extrasphincter fistulas there are used such operations:

Ryzhykh-I – they remove fistula's canal in perineal wound to rectal wall and cut in basis. Stump of fistula's canal is emptied with Folkmann's spoon, cleaned with iodine solution and ligated with two or three layers of catgut ligations. During this ligated stump of fistula's canal is covered by surrounding tissues. Operation is finished with dosed sphincterotomy of inner fibers. This method is used when inner fistula's opening is localized in posterior crypt.

Ryzhykh-II (second variant) is used when inner fistula's opening is localized in anterior crypt or on lateral wall. Removal of fistula in perineal wound is provided the same as in the first variant. Further, upon the inner fistula's opening there is separated piece of mucosa (width 1-1.5 cm and length to 4 cm). Inner fistula's opening is ligated with node catgut ligations. With this aim threads are knotted after removal of rectal mirror. Then there should be put several ligations between separated and partially cut pieces of mucosa and distal part of the wound. At the end of operation there is provided posterior dosed sphincterotomy.

By Blinnitchev, opening in rectal mucosa is closed by catgut ligations in two stairs. There is separated mucosa upon the ligated opening, it should be fixed including submucosal layer to muscular membrane and ligated by silk ligations to perianal skin. Sometimes mobilized piece is moved downwards. Mobilized mucosal-muscular piece is ligated in such a way that needle should go near the edge of terminal fold to the basis of mobilized piece. After that by separate silk ligations they fix piece's edge to perianal skin.

Ligation method (by Hippocrates). On the wall of anal canal there should be cut inner fistula's opening and perianal skin together with narrow stripe of mucosa. Into this layer there are put ligations No.6 and sphincter fibers are tightened. Thus, thread stretches with 1-1.5 cm width intestinal wall and sphincter fibers. Ligation is tightened again till complete cutting of tissues and sphincter with cellular tissue (Pic. 4.1.9).

At extrasphincter fistulas of I degree there is used operation of Ryzhykh of Blinnitchev, or removal of fistula with ligation of sphincter. At fistulas of II degree fistulas are removed with ligation of sphincter, at III degree – operation of Blinnitchev or ligation method. At fistulas of IV degree there is used ligation method.

EPITHELIAL PARACOCCHIDIOIDAL CANALS

The reasons of origin of paracocchidioidal ducts are: innate defect of development, remain of spinal chord, violation of reduction of coccygeal vertebrae with stretching of tail ligament, theory of moving cells. In the mechanism of occurrence of canal inflammation there play role as trauma as infection penetration. In most cases beginning of inflammatory process in epithelial canals occurs at the same time with period of sexual development (hormonal-endocrine rebuilding of organism).

Classification

There define such stages of course of epithelial paracoccygeal canals (by Yu.V. Dooltsev and L.V. Ryvkin, 1988):

- I. Epithelial paracoccygeal canals without any clinical findings.
- II. Acute inflammation of epithelial paracoccygeal canals:
 - (a) infiltrative stage;
 - (b) abscess formation.
- III. Chronic inflammation of epithelial paracoccygeal canals:
 - (a) infiltrative stage;
 - (b) recurrent abscess;
 - (c) purulent fistula.
- IV. Remission of inflammation of epithelial paracoccygeal canals.

Symptoms and clinical course

Epithelial paracoccygeal canals may have no clinical findings, that's why they are often revealed accidentally during medical examination. In such cases I distal part of intergluteal fold near coccygeal apex upon the edge of anal region there are seen one or several point openings where sometimes hair grows. Diameter of those openings is from 1 to 3 mm, they are situated by middle line one by one. During pressing on the skin upper from epithelial opening you can see excretion of drops of non transparent or purulent fluid. Self feeling and general status of patients are usually not changed. But when there appears also inflammation in coccygeal region there occurs abscess formation. Then patients feel pain, body temperature increases. Investigation of general blood analysis reveals leukocytosis with formula moving to the left, increase of SES.

Variants of clinical course and complications

At non complicated epithelial paracoccygeal canals patients suffer from dull pain, feeling of pressing in coccygeal region, especially during long time walking. Increased sweating in intergluteal region is accompanied with rush, sometimes there appears painful infiltrate that disappears independently.

Acute stage of the disease is characterized by changes of general and local character. Body temperature, as a rule, increases to 39-40 degrees centigrade and is accompanied with chilling. Local symptoms are severe pain in coccygeal region, sometimes with irradiation into rectum. At the same time there appear swelling, infiltration of intergluteal region, skin upon the place of inflammation becomes bluish-violet. Further, abscess is formed. During independent opening of abscess there goes purulent content of dark color with bad smell. Sometimes abscess from coccygeal region spreads to pararectal and even pelviorectal spaces, but as a rule it does not open into rectal lumen.

Diagnostic program

1. Anamnesis and physical data.
2. Examination of coccygeal and anal regions.
3. Finger examination of rectum.
4. Investigation by rectal mirror.
5. Rectoromanoscopy.
6. Bacteriogram of purulent content.
7. General analysis of blood and urine.
8. Biochemical analysis of blood.
9. Sedimental reactions (reaction of Wassermann).
10. Contrast fistulography.
11. X-ray examination of pelvis bones.

Differential diagnosis

Presacral cyst teratoma both with epithelial paracoccygeal canal at the initial stage and period of complications' absence are differentiated easily, because when teratoma is present, finger examination of rectum gives a possibility to reveal tumor-like formation in presacral region. Complication of cyst teratoma with fistulas is differentiated with suppurated paracoccygeal canal with incredible difficulties. Provided contrast fistulography of fistula's canals at cyst teratoma gives a possibility to define its localization in presacral region, and epithelial canal may often be branched and ends blindly in soft tissues behind the coccygeum.

At paraproctitis epithelial opening in intergluteal fold is usually absent, and fistula's

canal in most cases is connected with rectal lumen and is revealed during finger examination or investigation by rectal mirror. At pressing on pararectal region from fistula's canals there appears purulent content. Preliminarily introduced tampon is stained by methylene blue at the moment of its getting into external opening of fistula.

Osteomyelitis of pterygoideal bone and coccygeum is often connected with injury of this region. On observing X-ray grams there is revealed characteristic picture of injured bone (foci of osteoporosis and sequesters). Fistulography helps in proving of diagnosis. Two independent diseases – epithelial paracoccygela canals and osteomyelitis of sacral bone and coccygeum – at the same time may be combined in one patient extremely rarely.

Tactics and choice of treating method

In treatment of epithelial paracoccygela canals surgical method is preferred. Only in stage of infiltrate with the aim of stopping of further inflammation development they provide novocainum blockade (100 ml of 0.25% solution with antibiotics). Every day during 5-6 days there should be applied compresses with Vishnevskiy's ointment, physiotherapeutic methods are used (UHF, diathermia, ultraviolet rays).

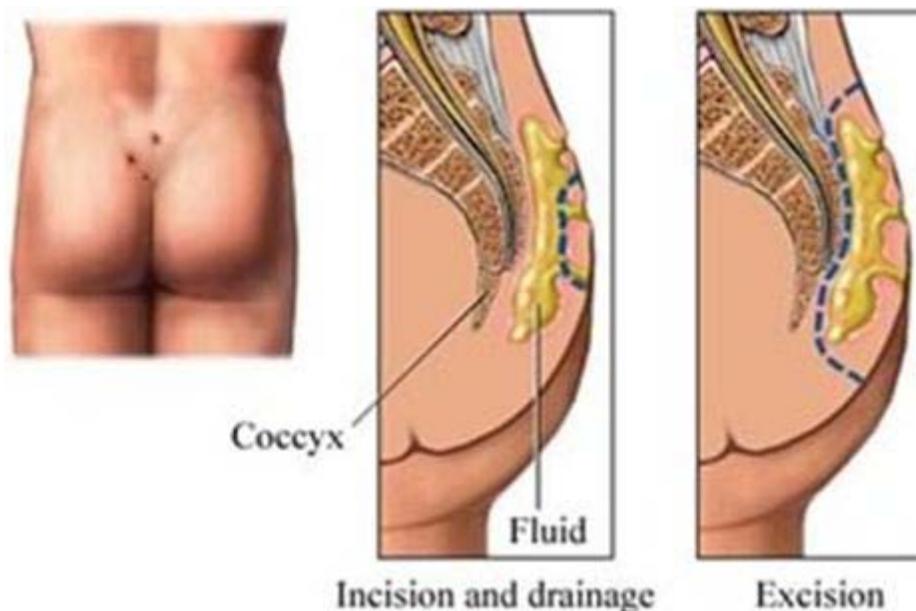

Important meaning in preparation to operation belongs to sanation of purulent fistula's canals. After inoculation of excretion from canals, determination of microflora and sensibility to antibiotics they provide pre operational sanation by some remedies.

In case of abscess formation of paracoccygeal canals abscess is opened in urgent order. During this they use two main positions of patient on operation table: on the abdomen and on the side. When patient lays on back (by Depage) feet end of the table is moved downwards on 45 degrees. Angle corresponds to projection of coxal articulations. Legs are moved to the sides and feet are situated on the support. Such position in most cases is used during operations under local anesthesia. General anaesthesia is used in position on the side. Patient lays on right side with legs bended in coxal articulations. Left leg is situated on the right, during this left thigh is near abdomen. After anesthesia by two semilunar incisions along the middle line surgeon opens the abscess. If it spreads laterally from intergluteal fold it should be opened and removed too. In average 10% of patients where abscess included epithelial canal and got proteolytic action of pus, after not palliative operation of abcess opening there was no recurrent and reconvalescence became. Thus in 90% cases during abscess opening there stay walls of epithelial canal and its branches, there is formed secondary fistula, but after lowering of inflammatory process there is needed one more radical surgical operation. It includes removal of epithelial canal, its branches together with infiltrated surrounding tissues, purulent formations, with this aim they introduce methylene blue preliminary. Further, depending on presence or absence of infiltrate and abscesses, quantity of fistulas, radical operation is finished by one of methods: complete closing of wound, opened wound tamponade, ligation of wound edges to the bottom. When epithelial canals are revealed accidentally or in small symptoms of inflammation, absence of infiltrates, abscesses wound is closed completely including its bottom (Pic. 4.1.10).

In rare cases when after opening and removal of abscesses there stays big wound surface, wound should be treated by opened method. For sanitation of such wounds, except usual remedies, they use laser and ultrasound.

At abscesses and secondary fistulas in most cases there should be provided radical operation: wound edges are to be ligated to its bottom. During removal of lateral fistula's canals because of absence of fossa in this region there are applied rare situational ligations onto wound edges not including the bottom.

In surgical practice in treatment epithelial paracoccygeal canals there should be taken into account anatomical variants of structure of sacral-coccygeal-gluteal region. In most patients there may be high position of buttocks, deep intergluteal fold, acute angle between buttocks and middle line of sacrococcygeal region, close position of primary epithelial opening from anus.

After incision of suppurated paracoccygeal canal before ligation of wound edges to its bottom there appears need to remove subcutaneous cellular tissue through all length from both wound sides. During this narrow skin pieces easily and closely situate during their ligation to wound bottom. The last in this case is healed with narrow scar.

In patients with middle and low localization of buttocks with more dull angle of position, less depth of intergluteal fold, higher position of epithelial paracoccygeal canal after its removal wound edges are ligated to the bottom in such a way that ligation includes skin, cellular skin, bottom and go outside through cellular tissue on the opposite side 1-1.5 cm higher than wound bottom.

POLYPOSIS. DIVERTICULOSIS. UNSPECIFIC ULCEROUS COLITIS. CROHN'S DISEASE.

POLYPOSIS

Polyps are non malignant tumors on legs that grow from mucosa.

Etiology and pathogenesis

Reasons of polyp's appearance are disorders in embryonal development , inflammatory processes of mucosa and also viral infection.

Pathomorphology

Polypus of inflammatory origin differ from adenomatous ones by their incorrect form and size variety. They are soft, filled with blood, often with ulceration and hematomas. Such polypus usually combine with other signs of inflammation in intestine.

Adenomatous polypus are often part of syndromes. Thus, combination with non malignant tumors of bones, skin and soft tissues is characteristic for Gardner's syndrome, combination with focal melanosis of mucosa – for Peitz-Eggers' syndrome, combination with brain tumors – for Turco's syndrome.

Classification

By etiology:

- Innate (hereditary, family)
- Acquired (at inflammatory processes)

Separately they define also children (juvenile, innate and acquired).

By process' spreading:

- Single
- Multiple
- Total (injury of all intestines).

By external appearance and microscopic structure:

- True (glandular, fleesy, from multi layer epithelium)
- False (hypertrophic at ulceric colitis, fibrose).

Symptoms and clinical course

Men get this disease in 2-3 times more than women. Single polypus of colon and rectum have usually latent course and are often revealed accidentally.

Multiple polypus may lead to diarrhea, bleeding, changes in morphological and biochemical blood composition. At this children do not develop properly. At distal localization in some patients polypus prolapse and strangulate in anal ring causing pain. Low situated polypus irritate rectum and cause tenesmas, sometimes they cause prolapse of intestinal wall.

Among disease's symptoms first place belongs to disorders of defecation and blood in feces with further anemia, hypoproteinemia, decrease of workability. Fleesy polypus leads to disorders of water-salt and protein metabolism, because mucus' excretion at defecation may achieve 1.5 liters,

At multiple polyposis they define triad of symptoms:

1. Pigment spots (on the face, lips, mucosal membranes of cheeks, fingers, and other areas of covering epithelium).
2. Polyposis of digestive tract.
3. Hereditary character of disease.

Finger examination of rectum and observation with rectal mirror give a possibility to investigate its lower part. During this procedures you can reveal polypus of different size situated on jucosa of rectum and also polypus prolapsed with invaginate of sygmoid colon.

Irigography reveals single and multiple defects of filling, so called symptom of "shooted aim" that may be seen in different parts of colon. At presence of invaginate as complication of polypus there is charactering defect of filling.

With the help of rectoromanoscope you can examine rectum and sigmoid colon on average height 30 cm, and

fibrocolonoscope is to examine all parts of colon. This investigation method gives a possibility to reveal exact place of polypus' localization, its appearance including leg width, to provide excisional biopsy and also electrocoagulation.

Variants of clinical course and complications

Polypus of small size at the onset have latent course. With their growth during moving of feces may occur disorder of their completeness with further possible complications. More often is bleeding that in most cases occur defecation. Depending on the height of polypus' localization in intestine blood may be dark red to bright red color. Blood loss may be from small, light to severe, with signs of small and incredible anemia.

In most patients polypus have a tendency to malignization. Provided biopsy in pre operation period with morphological investigation reveals malignant transformation of tissues and proves this diagnosis not in all cases. It depends on that in what part polypus becomes malignant. Final diagnosis may be put after the operation during histological investigation of all polypus.

Polypus of big size situated in rectum usually strangulate. During this strangulation takes place on the level of anal ring and is accompanied with severe pain. Not reducible polypus may necrotize.

Polypus are situated in caecum, colon and sigmoid colon. In the most motile areas they may lead to intestinal invagination. In this case there appear spastic pain, blood excretion with feces. During abdominal palpation they reveal painful infiltrate. Invagination may prolapse into rectal lumen.

Diagnostic program

1. Anamnesis and physical data.
2. Finger investigation of rectum.
3. Investigation by rectal mirror.
4. Rectoromanoscopy.
5. Irigography.
6. Fibrocolonoscopy.
7. General analysis of blood and urine.
8. Coagulogram

Polyps. Endoscopic view.

Differential diagnosis

Polypus of colon and rectum should be differentiated with malignant and non epithelial tumors, non specific ulcer colitis and rectal fissures.

Cancer of right part of colon has a course with incredible anemia (toxicoanemic form) due to absorption of tumor's toxic products, their action on hemopoetic organs.

Cancer of left part of colon is usually accompanied with signs of obturative intestinal impassability. Additional examination (finger rectal examination, irigography, endoscopic methods) give a possibility to prove the diagnosis.

At chronic course of non specific ulcer colitis there is injured mucosa of intestine, and little islands of not injured mucosa between multiple big ulcers look like polypus, so called pseudopolyposis. Detailed anamnesis, specialities of clinical

course of the disease, irigography and colonoscopy exclude presence of true polypus.

Not epithelial tumors (leiomyoma, lipoma) are situated under intestinal mucosa and at their small size do not cause any symptoms. With their growth mucosa is injured, there occurs bleeding with its signs. X-ray and endoscopic methods of investigation, and also histological investigation prove the final diagnosis.

Chronic fissure of rectum with not smooth edges and terminal tuberculum often simulates true polypus. Removal of this formation both with fissure and provided histological investigation help in proving of diagnosis.

Tactics and choice of treating method

Conservative method of treatment is rarely used. For this is used solution of green greater celandine for its introduction in enemas (3-4 grams of green mass for 1 kg of patient weight, on the average 50 g for adults). A celandine is ground down on a meat grinder, conduct in hot water in the ratio 1:10. A medical cycle includes 15–30 enemas. Per treatments course is conducted three cycles at intervals in one month. The low located polypuses from a stratified epithelium, pseudopolypuses and malignant polypuses are not treated by celandine.

Because of polypuses of small intestine and rectums are inclined to malignization, the basic method of its treatment is surgical .

Methods of operative treatment at polypus are divided into two groups:

1. Local operations (endoscopic electrocoagulation, polypus's removal). Indication for electrocoagulation is presence of single polypus on narrow leg, rarely – multiple polypus. Depending on the localization polypus on wide leg are removed through rectum or by laparotomy with further colotomy.
2. Radical operations as resection of separate segments of colon, right-side, left-side, subtotal colectomy or colectomy are provided at multiple polypus. [video](#) [video2](#) [video3](#)

EMBRYOLOGY AND ANATOMY

Embryology

The embryonic gastrointestinal tract begins developing during the fourth week of gestation. The primitive gut is derived from the endoderm and divided into three segments: *foregut*, *midgut*, and *hindgut*. Both *midgut* and *hindgut* contribute to the colon, rectum, and anus.

The *midgut* develops into the small intestine, ascending colon, and proximal transverse colon, and receives blood supply from the superior mesenteric artery. During the sixth week of gestation, the midgut herniates out of the abdominal cavity, and then rotates 270 degrees counterclockwise around the superior mesenteric artery to return to its final position inside the abdominal cavity during the tenth week of gestation.

The *hindgut* develops into the distal transverse colon, descending colon, rectum, and proximal anus, all of which receive their blood supply from the inferior mesenteric artery. During the sixth week of gestation, the distal-most end of the hindgut, the *cloaca*, is divided by the urorectal septum into the urogenital sinus and the rectum.

The distal anal canal is derived from ectoderm and receives its blood supply from the internal pudendal artery. The dentate line divides the endodermal hindgut from the ectodermal distal anal canal.

Anatomy

The large intestine extends from the ileocecal valve to the anus. It is divided anatomically and functionally into the *colon*, *rectum*, and *anal canal*. The wall of the colon and rectum comprise five distinct layers: mucosa, submucosa, inner circular muscle, outer longitudinal muscle, and serosa. In the colon, the outer longitudinal muscle is separated into three *teniae coli*, which converge proximally at the appendix and distally at the rectum, where the outer longitudinal muscle layer is circumferential. In the distal rectum, the inner smooth-muscle layer coalesces to form the internal anal sphincter. The intraperitoneal colon and proximal one third of the rectum are covered by serosa; the mid and lower rectum lack serosa.

Colon Landmarks

The colon begins at the junction of the terminal ileum and cecum and extends 3 to 5 feet to the rectum. The rectosigmoid junction is found at approximately the level of the sacral promontory and is arbitrarily described as the point at which the three *teniae coli* coalesce to form the outer longitudinal smooth muscle layer of the rectum. The *cecum* is the widest diameter portion of the colon (normally 7.5 to 8.5 cm) and has the thinnest muscular wall. As a result, the cecum is most vulnerable to perforation and least

vulnerable to obstruction. The ascending colon is usually fixed to the retroperitoneum. The hepatic flexure marks the transition to the transverse colon. The intraperitoneal transverse colon is relatively mobile, but is tethered by the gastrocolic ligament and colonic mesentery. The greater omentum is attached to the anterior/superior edge of the transverse colon. These attachments explain the characteristic triangular appearance of the transverse colon observed during colonoscopy. The splenic flexure marks the transition from the transverse colon to the descending colon. The attachments between the splenic flexure and the spleen (the lienocolic ligament) can be short and dense, making mobilization of this flexure during colectomy challenging. The descending colon is relatively fixed to the retroperitoneum. The sigmoid colon is the narrowest part of the large intestine and is extremely mobile. Although the sigmoid colon is usually located in the left lower quadrant, redundancy and mobility can result in a portion of the sigmoid colon residing in the right lower quadrant. This mobility explains why volvulus is most common in the sigmoid colon and why diseases affecting the sigmoid colon, such as diverticulitis, may occasionally present as right-sided abdominal pain. The narrow caliber of the sigmoid colon makes this segment of the large intestine the most vulnerable to obstruction.

Colon Vascular Supply

The arterial supply to the colon is highly variable (Fig. 28-1). In general, the *superior mesenteric artery* branches into the *ileocolic artery* (absent in up to 20% of people), which supplies blood flow to the terminal ileum and proximal ascending colon, the *right colic artery*, which supplies the ascending colon, and the *middle colic artery*, which supplies the transverse colon. The *inferior mesenteric artery* branches into the *left colic artery*, which supplies the descending colon, several *sigmoidal branches*, which supply the sigmoid colon, and the *superior rectal artery*, which supplies the proximal rectum. The terminal branches of each artery form anastomoses with the terminal branches of the adjacent artery and communicate via the *marginal artery of Drummond*. This arcade is complete in only 15 to 20% of people.

Colon Lymphatic Drainage

The lymphatic drainage of the colon originates in a network of lymphatics in the muscularis mucosa. Lymphatic vessels and lymph nodes follow the regional arteries. Lymph nodes are found on the bowel wall (epicolic), along the inner margin of the bowel adjacent to the arterial arcades (paracolic), around the named mesenteric vessels (intermediate), and at the origin of the superior and inferior mesenteric arteries (main). The *sentinel lymph nodes* are the first one to four lymph nodes to drain a specific segment of the colon, and are thought to be the first site of metastasis in colon cancer. The utility of sentinel lymph node dissection and analysis in colon cancer remains controversial.

Colon Nerve Supply

The colon is innervated by both *sympathetic* (inhibitory) and *parasympathetic* (stimulatory) nerves, which parallel the course of the arteries. Sympathetic nerves arise from T6-T12 and L1-L3. The parasympathetic innervation to the right and transverse colon is from the vagus nerve; the parasympathetic nerves to the left colon arise from sacral nerves S2-S4 to form the *nervi erigentes*.

Anorectal Landmarks

The rectum is approximately 12 to 15 cm in length. Three distinct submucosal folds, the *valves of Houston*, extend into the rectal lumen. Posteriorly, the *preseacral fascia* separates the rectum from the presacral venous plexus and the pelvic nerves. At S4, the *rectosacral fascia (Waldeyer's fascia)* extends forward and downward and attaches to the fascia propria at the anorectal junction. Anteriorly, *Denonvilliers' fascia* separates the rectum from the prostate and seminal vesicles in men and from the vagina in women. The *lateral ligaments* support the lower rectum. The surgical anal canal measures 2 to 4 cm in length and is generally longer in men than in women. It begins at the anorectal junction and terminates at the anal verge. The *dentate* or *pectinate line* marks the transition point between columnar rectal mucosa and squamous anoderm. The 1 to 2 cm of mucosa just proximal to the dentate line shares histologic characteristics of columnar, cuboidal, and squamous epithelium and is referred to as the *anal transition zone*. The dentate line is surrounded by longitudinal mucosal folds, known as the *columns of Morgagni*, into which the anal crypts empty. These crypts are the source of cryptoglandular abscesses

In the distal rectum, the inner smooth muscle is thickened and comprises the *internal anal sphincter* that is surrounded by the *subcutaneous, superficial, and deep external sphincter*. The *deep external anal sphincter* is an extension of the *puborectalis muscle*. The *puborectalis, iliococcygeus, and pubococcygeus muscles* form the *levator ani muscle* of the pelvic floor.

Anorectal Vascular Supply

The *superior rectal artery* arises from the terminal branch of the inferior mesenteric artery and supplies the upper rectum. The *middle rectal artery* arises from the internal iliac; the presence and size of these arteries are highly variable. The *inferior rectal artery* arises from the internal pudendal artery, which is a branch of the internal iliac artery. A rich network of collaterals connects the terminal arterioles of each of these arteries, thus making the rectum relatively resistant to ischemia

The venous drainage of the rectum parallels the arterial supply. The *superior rectal vein* drains into the portal system via the inferior mesenteric vein. The *middle rectal vein* drains into the internal iliac vein. The *inferior rectal vein* drains into the internal pudendal vein, and subsequently into the internal iliac vein. A submucosal plexus deep to the columns of Morgagni forms the *hemorrhoidal plexus* and drains into all three veins.

Anorectal Lymphatic Drainage

Lymphatic drainage of the rectum parallels the vascular supply. Lymphatic channels in the upper and middle rectum drain superiorly into the inferior mesenteric lymph nodes. Lymphatic channels in the lower rectum drain both superiorly into the inferior mesenteric lymph nodes and laterally into the internal iliac lymph nodes. The anal canal has a more complex pattern of lymphatic drainage. Proximal to the dentate line, lymph drains into both the inferior mesenteric lymph nodes and the internal iliac lymph nodes. Distal to the dentate line, lymph primarily drains into the inguinal lymph nodes, but can also drain into the inferior mesenteric lymph nodes and internal iliac lymph nodes.

Anorectal Nerve Supply

Both sympathetic and parasympathetic nerves innervate the anorectum. Sympathetic nerve fibers are derived from L1-L3 and join the preaortic plexus. The preaortic nerve fibers then extend below the aorta to form the *hypogastric plexus*, which subsequently joins the parasympathetic fibers to form the pelvic plexus. Parasympathetic nerve fibers are known as the *nervi erigentes* and originate from S2-S4. These fibers join the sympathetic fibers to form the pelvic plexus. Sympathetic and parasympathetic fibers then supply the anorectum and adjacent urogenital organs.

The internal anal sphincter is innervated by sympathetic and parasympathetic nerve fibers; both types of fibers inhibit sphincter contraction. The external anal sphincter and puborectalis muscles are innervated by the *inferior rectal branch* of the *internal pudendal nerve*. The levator ani receives innervation from both the *internal pudendal nerve* and direct branches of S3 to S5. Sensory innervation to the anal canal is provided by the *inferior rectal branch* of the *pudendal nerve*. While the rectum is relatively insensate, the anal canal below the dentate line is sensate.

Congenital Anomalies

Perturbation of the embryologic development of the midgut and hindgut may result in anatomic abnormalities of the colon, rectum, and anus. Failure of the midgut to rotate and return to the abdominal cavity during the tenth week of gestation results in varying degrees of intestinal malrotation and colonic nonfixation. Failure of canalization of the primitive gut can result in colonic duplication. Incomplete descent of the urogenital septum may result in imperforate anus and associated fistulas to the genitourinary tract. Many infants with congenital anomalies of the hindgut have associated abnormalities in the genitourinary tract.

Normal Physiology

Fluid and Electrolyte Exchanges

Water, Sodium, Potassium, Chloride, Bicarbonate, and Ammonia

The colon is a major site for water absorption and electrolyte exchange. Approximately 90% of the water contained in ileal fluid is absorbed in the colon (1000 to 2000 mL/d), and up to 5000 mL of fluid can be absorbed daily. Sodium is absorbed actively via a Na-K ATPase. The colon can absorb up to 400 mEq of sodium per day. Water accompanies the transported sodium and is absorbed passively along an osmotic gradient. Potassium is actively secreted into the colonic lumen and absorbed by passive diffusion. Chloride is absorbed actively via a chloride-bicarbonate exchange.

Bacterial degradation of protein and urea produces ammonia. Ammonia is subsequently absorbed and transported to the liver. Absorption of ammonia depends in part upon intraluminal pH. A decrease in colonic bacteria (e.g., broad spectrum antibiotic usage) and/or a decrease in intraluminal pH (e.g., lactulose administration) will decrease ammonia absorption.

Short-Chain Fatty Acids

Short-chain fatty acids (acetate, butyrate, and propionate) are produced by bacterial fermentation of dietary carbohydrates. Short-chain fatty acids are an important source of energy for the colonic mucosa, and metabolism by colonocytes provides energy for processes such as active transport of sodium. Lack of a dietary source for production of short-chain fatty acids, or diversion of the fecal stream by an ileostomy or colostomy, may result in mucosal atrophy and "diversion colitis."

Colonic Microflora and Intestinal Gas

Approximately 30% of fecal dry weight is composed of bacteria (10^{11} to 10^{12} bacteria/g of feces). Anaerobes are the predominant

class of microorganism, and *Bacteroides* species are the most common (10^{11} to 10^{12} organisms/mL). *Escherichia coli* are the most numerous aerobes (10^8 to 10^{10} organisms/mL). Endogenous microflora are crucial for the breakdown of carbohydrates and proteins in the colon and participate in the metabolism of bilirubin, bile acids, estrogen, and cholesterol. Colonic bacteria also are necessary for production of vitamin K. Endogenous bacteria also are thought to suppress the emergence of pathogenic microorganisms, such as *Clostridium difficile*. However, the high bacterial load of the large intestine may contribute to sepsis in critically ill patients and may contribute to intra-abdominal sepsis, abscess, and wound infection following colectomy.

Intestinal gas arises from swallowed air, diffusion from the blood, and intraluminal production. Nitrogen, oxygen, carbon dioxide, hydrogen, and methane are the major components of intestinal gas. Nitrogen and oxygen are largely derived from swallowed air. Carbon dioxide is produced by the reaction of bicarbonate and hydrogen ions, and by the digestion of triglycerides to fatty acids. Hydrogen and methane are produced by colonic bacteria. The production of methane is highly variable. The gastrointestinal tract usually contains between 100 and 200 mL of gas and 400 to 1200 mL per day are released as flatus, depending upon the type of food ingested.

Motility, Defecation, and Continence

Motility

Unlike the small intestine, the large intestine does not demonstrate cyclic motor activity characteristic of the migratory motor complex. Instead, the colon displays intermittent contractions of either low or high amplitude. Low-amplitude, short-duration contractions occur in bursts and appear to move the colonic contents both antegrade and retrograde. It is thought that these bursts of motor activity delay colonic transit and thus increase the time available for absorption of water and exchange of electrolytes. High-amplitude contractions occur in a more coordinated fashion and create "mass movements." Bursts of "rectal motor complexes" also have been described. In general, cholinergic activation increases colonic motility.

Defecation

Defecation is a complex, coordinated mechanism involving colonic mass movement, increased intra-abdominal and rectal pressure, and relaxation of the pelvic floor. Distention of the rectum causes a reflex relaxation of the internal anal sphincter (the rectoanal inhibitory reflex) that allows the contents to make contact with the anal canal. This "sampling reflex" allows the sensory epithelium to distinguish solid stool from liquid stool and gas. If defecation does not occur, the rectum relaxes and the urge to defecate passes (the *accommodation response*). Defecation proceeds by coordination of increasing intra-abdominal pressure via the Valsalva maneuver, increased rectal contraction, relaxation of the puborectalis muscle, and opening of the anal canal.

Continence

The maintenance of fecal continence is at least as complex as the mechanism of defecation. Continence requires adequate rectal wall compliance to accommodate the fecal bolus, appropriate neurogenic control of the pelvic floor and sphincter mechanism, and functional internal and external sphincter muscles. At rest, the puborectalis muscle creates a "sling" around the distal rectum, forming a relatively acute angle that distributes intraabdominal forces onto the pelvic floor. With defecation, this angle straightens, allowing downward force to be applied along the axis of the rectum and anal canal. The internal and external sphincters are tonically active at rest. The internal sphincter is responsible for most of the resting, involuntary sphincter tone (resting pressure). The external sphincter is responsible for most of the voluntary sphincter tone (squeeze pressure). Branches of the pudendal nerve innervate both the internal and external sphincter. Finally, the hemorrhoidal cushions may contribute to continence by mechanically blocking the anal canal. Thus, impaired continence may result from poor rectal compliance, injury to the internal and/or external sphincter or puborectalis, or nerve damage or neuropathy.

Clinical Evaluation

Clinical Assessment

A complete history and physical examination is the starting point for evaluating any patient with suspected disease of the colon and rectum. Special attention should be paid to the patient's past medical and surgical history to detect underlying conditions that might contribute to a gastrointestinal problem. If patients have had prior intestinal surgery, it is essential that one understand the resultant gastrointestinal anatomy. In addition, family history of colorectal disease, especially inflammatory bowel disease, polyps, and colorectal cancer, is crucial. Medication use must be detailed as many drugs cause gastrointestinal symptoms. Before recommending operative intervention, the adequacy of medical treatment must be ascertained. In addition to examining the abdomen, visual inspection of the anus and perineum and careful digital rectal exam are essential.

Endoscopy

Anoscopy

The anoscope is a useful instrument for examination of the anal canal. Anoscopes are made in a variety of sizes and measure approximately 8 cm in length. A larger anoscope provides better exposure for anal procedures such as rubber band ligation or sclerotherapy of hemorrhoids. The anoscope, with obturator in place, should be adequately lubricated and gently inserted into the anal canal. The obturator is withdrawn, inspection of the visualized anal canal is done, and the anoscope should then be withdrawn. It is rotated 90 degrees and reinserted to allow visualization of all four quadrants of the canal. If the patient complains of severe perianal pain and cannot tolerate a digital rectal examination, anoscopy should not be attempted without anesthesia.

Proctoscopy

The rigid proctoscope is useful for examination of the rectum and distal sigmoid colon and is occasionally used therapeutically. The standard proctoscope is 25 cm in length and available in various diameters. Most often, a 15- or 19-mm diameter proctoscope is used for diagnostic examinations. The large (25-mm diameter) proctoscope is useful for procedures such as polypectomy, electrocoagulation, or detorsion of a sigmoid volvulus. A smaller "pediatric" proctoscope (11-mm diameter) is better tolerated by patients with anal stricture. Suction is necessary for an adequate proctoscopic examination.

Flexible Sigmoidoscopy and Colonoscopy

Video or fiberoptic flexible sigmoidoscopy and colonoscopy provide excellent visualization of the colon and rectum. Sigmoidoscopes measure 60 cm in length. Full depth of insertion may allow visualization as high as the splenic flexure, although the mobility and redundancy of the sigmoid colon often limit the extent of the examination. Partial preparation with enemas is usually adequate for sigmoidoscopy and most patients can tolerate this procedure without sedation. Colonoscopes measure 100 to 160 cm in length and are capable of examining the entire colon and terminal ileum. A complete oral bowel preparation is usually necessary for colonoscopy and the duration and discomfort of the procedure usually require conscious sedation. Both sigmoidoscopy and colonoscopy can be used diagnostically and therapeutically. Electrocautery should generally not be used in the absence of a complete bowel preparation because of the risk of explosion of intestinal methane or hydrogen gases. Diagnostic colonoscopes possess a single channel through which instruments such as snares, biopsy forceps, or electrocautery can be passed; this channel also provides suction and irrigation capability. Therapeutic colonoscopes possess two channels to allow simultaneous suction/irrigation and the use of snares, biopsy forceps, or electrocautery.

Imaging

Plain X-Rays and Contrast Studies

Despite advanced radiologic techniques, plain x-rays and contrast studies continue to play an important role in the evaluation of patients with suspected colon and rectal diseases. Plain x-rays of the abdomen (supine, upright, and diaphragmatic views) are useful for detecting free intra-abdominal air, bowel gas patterns suggestive of small or large bowel obstruction, and volvulus. Contrast studies are useful for evaluating obstructive symptoms, delineating fistulous tracts, and diagnosing small perforations or anastomotic leaks. While Gastrografin cannot provide the mucosal detail provided by barium, this water-soluble contrast agent is recommended if perforation or leak is suspected. Double-contrast barium enema has been reported to be 70 to 90% sensitive for the detection of mass lesions greater than 1 cm in diameter. 1 Detection of small lesions can be extremely difficult, especially in a patient with extensive diverticulosis. For this reason, a colonoscopy is preferred for evaluating nonobstructing mass lesions in the colon. Double-contrast barium enema has been used as a back-up examination if colonoscopy is incomplete.

Computed Tomography

Computed tomography (CT) is commonly employed in the evaluation of patients with abdominal complaints. Its utility is primarily in the detection of extraluminal disease, such as intra-abdominal abscesses and pericolic inflammation, and in staging colorectal carcinoma, because of its sensitivity in detection of hepatic metastases. 2 Extravasation of oral or rectal contrast may also confirm the diagnosis of perforation or anastomotic leak. Nonspecific findings such as bowel wall thickening or mesenteric stranding may suggest inflammatory bowel disease, enteritis/colitis, or ischemia. A standard CT scan is relatively insensitive for the detection of intraluminal lesions.

Virtual Colonoscopy

Virtual colonoscopy is a new radiologic technique that is designed to overcome some of the limitations of traditional CT scanning. This technology uses helical CT and three-dimensional reconstruction to detect intraluminal colonic lesions. Oral bowel preparation, oral and rectal contrast, and colon insufflation are used to maximize sensitivity. Early evaluation of virtual colonoscopy suggests that accuracy may approach that of colonoscopy for detection of lesions 1 cm in diameter or greater.

Magnetic Resonance Imaging

The main use of magnetic resonance imaging (MRI) in colorectal disorders is in evaluation of pelvic lesions. MRI is more sensitive than CT for detecting bony involvement or pelvic sidewall extension of rectal tumors. MRI also can be helpful in the detection and delineation of complex fistulas in ano. The use of an endorectal coil may increase sensitivity.

Positron Emission Tomography

Positron emission tomography (PET) is used for imaging tissues with high levels of anaerobic glycolysis, such as malignant tumors. ¹⁸F-fluorodeoxyglucose (FDG) is injected as a tracer; metabolism of this molecule then results in positron emission. PET has been used as an adjunct to CT in the staging of colorectal cancer and may prove useful in discriminating recurrent cancer from fibrosis. At present, the efficacy and utility of PET in the detection of recurrent and/or metastatic colorectal cancer remains unproven.

Angiography

Angiography is occasionally used for the detection of bleeding within the colon or small bowel. To visualize hemorrhage angiographically, bleeding must be relatively brisk (approximately 0.5 to 1.0 mL per minute). If extravasation of contrast is identified, infusion of vasopressin or angiographic embolization can be therapeutic.

Endorectal and Endoanal Ultrasound

Endorectal ultrasound is primarily used to evaluate the depth of invasion of neoplastic lesions in the rectum. The normal rectal wall appears as a five-layer structure (Fig. 28-6). Ultrasound can reliably differentiate most benign polyps from invasive tumors based upon the integrity of the submucosal layer. Ultrasound can also differentiate superficial T1-T2 from deeper T3-T4 tumors. Overall, the accuracy of ultrasound in detecting depth of mural invasion ranges between 81 and 94%.³ This modality also can detect enlarged perirectal lymph nodes, which may suggest nodal metastases; accuracy of detection of pathologically positive lymph nodes is 58 to 83%. Ultrasound may also prove useful for early detection of local recurrence after surgery.

Endoanal ultrasound is used to evaluate the layers of the anal canal. Internal anal sphincter, external anal sphincter, and puborectalis muscle can be differentiated. Endoanal ultrasound is particularly useful for detecting sphincter defects and for outlining complex anal fistulas.

Physiologic and Pelvic Floor Investigations

Anorectal physiologic testing uses a variety of techniques to investigate the function of the pelvic floor. These techniques are useful in the evaluation of patients with incontinence, constipation, rectal prolapse, obstructed defecation, and other disorders of the pelvic floor.

Manometry

Anorectal manometry is performed by placing a pressure-sensitive catheter in the lower rectum. The catheter is then withdrawn through the anal canal and pressures recorded. A balloon attached to the tip of the catheter also can be used to test anorectal sensation. The *resting pressure* in the anal canal reflects the function of the internal anal sphincter (normal: 40 to 80 mm Hg), while the *squeeze pressure*, defined as the maximum voluntary contraction pressure minus the resting pressure, reflects function of the external anal sphincter (normal: 40 to 80 mm Hg above resting pressure). The *high-pressure zone* estimates the length of the anal canal (normal: 2.0 to 4.0 cm). The *rectoanal inhibitory reflex* can be detected by inflating a balloon in the distal rectum; absence of this reflex is characteristic of Hirschsprung's disease.

Neurophysiology

Neurophysiologic testing assesses function of the pudendal nerves and recruitment of puborectalis muscle fibers. Pudendal nerve terminal motor latency measures the speed of transmission of a nerve impulse through the distal pudendal nerve fibers (normal: 1.8 to 2.2 msec); prolonged latency suggests the presence of neuropathy. EMG recruitment assesses the contraction and relaxation of the puborectalis muscle during attempted defecation. Normally, recruitment increases when a patient is instructed to "squeeze," and decreases when a patient is instructed to "push." Inappropriate recruitment is an indication of paradoxical contraction (nonrelaxation of the puborectalis). Needle EMG has been used to map both the pudendal nerves and the anatomy of the internal and external sphincters. However, this examination is painful and poorly tolerated by most patients. Needle EMG has largely been replaced by pudendal nerve motor-latency testing to assess pudendal nerve function and endoanal ultrasound to map the sphincters.

Rectal Evacuation Studies

Rectal evacuation studies include the balloon expulsion test and video defecography. Balloon expulsion assesses a patient's ability to expel an intrarectal balloon. Video defecography provides a more detailed assessment of defecation. In this test, barium paste is placed in the rectum and defecation is then recorded fluoroscopically. Defecography is used to differentiate nonrelaxation of the puborectalis, obstructed defecation, increased perineal descent, rectal prolapse and intussusception, rectocele, and enterocele. The addition of vaginal contrast and intraperitoneal contrast is useful in delineating complex disorders of the pelvic floor.

Laboratory Studies

Fecal Occult Blood Testing

Fecal occult blood testing (FOBT) is used as a screening test for colonic neoplasms in asymptomatic, average-risk individuals. The efficacy of this test is based upon serial testing because the majority of colorectal malignancies will bleed intermittently. FOBT has been a nonspecific test for peroxidase contained in hemoglobin; consequently, occult bleeding from any gastrointestinal source will produce a positive result. Similarly, many foods (red meat, some fruits and vegetables, and vitamin C) will produce a false-positive result. Patients were counseled to eat a restricted diet for 2 to 3 days prior to the test. Increased specificity is now possible by using immunochemical FOBT. These tests rely on monoclonal or polyclonal antibodies to react with the intact globin portion of human hemoglobin. Because globin does not survive in the upper gastrointestinal tract, the immunochemical tests are more specific for identifying occult bleeding from the colon or rectum. Dietary restrictions are not necessary. Any positive FOBT mandates further investigation, usually by colonoscopy.

Stool Studies

Stool studies are often helpful in evaluating the etiology of diarrhea. Wet-mount examination reveals the presence of fecal leukocytes, which may suggest colonic inflammation or the presence of an invasive organism such as invasive *E. coli* or *Shigella*. Stool cultures can detect pathogenic bacteria, ova, and parasites. *C. difficile* colitis is diagnosed by detecting bacterial toxin in the stool. 4 Steatorrhea may be diagnosed by adding Sudan red stain to a stool sample.

Serum Tests

Specific laboratory tests that should be performed will be dictated by the clinical scenario. Preoperative studies generally include a complete blood count and electrolyte panel. The addition of coagulation studies, liver function tests, and blood typing/cross-matching depends upon the patient's medical condition and the proposed surgical procedure.

Tumor Markers

Carcinoembryonic antigen (CEA) may be elevated in 60 to 90% of patients with colorectal cancer. Despite this, CEA is not an effective screening tool for this malignancy. Many practitioners follow serial CEA levels after curative-intent surgery in order to detect early recurrence of colorectal cancer. However, this tumor marker is nonspecific, and no survival benefit has yet been proven. Other biochemical markers (ornithine decarboxylase, urokinase) have been proposed, but none has yet proven sensitive or specific for detection, staging, or predicting prognosis of colorectal carcinoma. 5

Genetic Testing

Although familial colorectal cancer syndromes, such as familial adenomatous polyposis (FAP) and hereditary nonpolyposis colon cancer (HNPCC) are rare, information about the specific genetic abnormalities underlying these disorders has led to significant interest in the role of genetic testing for colorectal cancer. 6 Tests for mutations in the adenomatous polyposis coli (APC) gene responsible for FAP, and in mismatch repair genes responsible for HNPCC, are commercially available and extremely accurate in families with known mutations. Although many of these mutations are also present in sporadic colorectal cancer, the accuracy of genetic testing in average-risk individuals is considerably lower and these tests are not recommended for screening. Because of the potential psychosocial implications of genetic testing, it is strongly recommended that professional genetic counselors be involved in the care of any patient considering these tests.

Evaluation of Common Symptoms

Pain

Abdominal Pain

Abdominal pain is a nonspecific symptom with a myriad of causes. Abdominal pain related to the colon and rectum can result from obstruction (either inflammatory or neoplastic), inflammation, perforation, or ischemia. Plain x-rays and judicious use of contrast studies and/or a CT scan can often confirm the diagnosis. Gentle retrograde contrast studies (barium or Gastrografin enema) may be useful in delineating the degree of colonic obstruction. Sigmoidoscopy and/or colonoscopy performed by an experienced

endoscopist can assist in the diagnosis of ischemic colitis, infectious colitis, and inflammatory bowel disease. However, if perforation is suspected, colonoscopy and/or sigmoidoscopy are generally contraindicated. Evaluation and treatment of abdominal pain from a colorectal source should follow the usual surgical principles of a thorough history and physical examination, appropriate diagnostic tests, resuscitation, and appropriately timed surgical intervention.

Pelvic Pain

Pelvic pain can originate from the distal colon and rectum or from adjacent urogenital structures. Tenesmus may result from proctitis or from a rectal or retrorectal mass. Cyclical pain associated with menses, especially when accompanied by rectal bleeding, suggests a diagnosis of endometriosis. Pelvic inflammatory disease also can produce significant abdominal and pelvic pain. The extension of a peridiverticular abscess or periappendiceal abscess into the pelvis may also cause pain. CT scan and/or MRI may be useful in differentiating these diseases. Proctoscopy (if tolerated) also can be helpful. Occasionally, laparoscopy will yield a diagnosis.

Anorectal Pain

Anorectal pain is most often secondary to an anal fissure or perirectal abscess and/or fistula. Physical examination can usually differentiate these conditions. Other, less common causes of anorectal pain include anal canal neoplasms, perianal skin infection, and dermatologic conditions. Proctalgia fugax results from levator spasm and may present without any other anorectal findings. Physical exam is critical in evaluating patients with anorectal pain. If a patient is too tender to examine in the office, an examination under anesthesia is necessary. MRI may be helpful in select cases where the etiology of pain is elusive.

Lower Gastrointestinal Bleeding

The first goal in evaluating and treating a patient with gastrointestinal hemorrhage is adequate resuscitation. The principles of ensuring a patent airway, supporting ventilation, and optimizing hemodynamic parameters apply and coagulopathy and/or thrombocytopenia should be corrected. The second goal is to identify the source of hemorrhage. Because the most common source of gastrointestinal hemorrhage is esophageal, gastric, or duodenal, nasogastric aspiration should always be performed; return of bile suggests that the source of bleeding is distal to the ligament of Treitz. If aspiration reveals blood or nonbile secretions, or if symptoms suggest an upper intestinal source, esophagogastroduodenoscopy is performed. Anoscopy and/or limited proctoscopy can identify hemorrhoidal bleeding. A technetium-99 (^{99m}Tc)-tagged red blood cell (RBC) scan is extremely sensitive and is able to detect as little as 0.1 mL/h of bleeding; however, localization is imprecise. If the ^{99m}Tc -tagged RBC scan is positive, angiography can then be employed to localize bleeding. Infusion of vasopressin or angioembolization may be therapeutic. Alternatively, a catheter can be left in the bleeding vessel to allow localization at the time of laparotomy. If the patient is hemodynamically stable, a rapid bowel preparation (over 4 to 6 hours) can be performed to allow colonoscopy. Colonoscopy may identify the cause of the bleeding, and cautery or injection of epinephrine into the bleeding site may be used to control hemorrhage. Colectomy may be required if bleeding persists despite these interventions. Intraoperative colonoscopy and/or enteroscopy may assist in localizing bleeding. If colectomy is required, a segmental resection is preferred if the bleeding source can be localized. "Blind" subtotal colectomy may very rarely be required in a patient who is hemodynamically unstable with ongoing colonic hemorrhage of an unknown source. In this setting, it is crucial to irrigate the rectum and examine the mucosa by proctoscopy to ensure that the source of bleeding is not distal to the resection margin.

Occult blood loss from the gastrointestinal tract may manifest as iron-deficiency anemia or may be detected with fecal occult blood testing. Because colon neoplasms bleed intermittently and rarely present with rapid hemorrhage, the presence of occult fecal blood should always prompt a colonoscopy. Unexplained iron-deficiency anemia is also an indication for colonoscopy.

Hematochezia is commonly caused by hemorrhoids or fissure. Sharp, knife-like pain and bright-red rectal bleeding with bowel movements suggest the diagnosis of fissure. Painless, bright-red rectal bleeding with bowel movements is often secondary to a friable internal hemorrhoid that is easily detected by anoscopy. In the absence of a painful, obvious fissure, any patient with rectal bleeding should undergo a careful digital rectal examination, anoscopy, and proctosigmoidoscopy. Failure to diagnose a source in the distal anorectum should prompt colonoscopy.

Constipation and Obstructed Defecation

Constipation is an extremely common complaint, affecting more than 4 million people in the United States. Despite the prevalence of this problem, there is lack of agreement about an appropriate definition of constipation. Patients may describe infrequent bowel movements, hard stools, or excessive straining. A careful history of these symptoms often clarifies the nature of the problem.

Constipation has a myriad of causes. Underlying metabolic, pharmacologic, endocrine, psychologic, and neurologic causes often contribute to the problem. A stricture or mass lesion should be excluded by colonoscopy or barium enema. After these causes have

been excluded, evaluation focuses upon differentiating *slow-transit constipation* from *outlet obstruction*. Transit studies, in which radiopaque markers are swallowed and then followed radiographically, are useful for diagnosing slow-transit constipation. Anorectal manometry and electromyography can detect nonrelaxation of the puborectalis, which contributes to outlet obstruction. The absence of an anorectal inhibitory reflex suggests Hirschsprung's disease and may prompt a rectal mucosal biopsy. Defecography can identify rectal prolapse, intussusception, rectocele, or enterocele.

Medical management is the mainstay of therapy for constipation and includes fiber, increased fluid intake, and laxatives. Outlet obstruction from nonrelaxation of the puborectalis often responds to biofeedback. 7 Surgery to correct rectocele and rectal prolapse has a variable effect on symptoms of constipation, but can be successful in selected patients. Subtotal colectomy is considered only for patients with severe slow-transit constipation (colonic inertia) refractory to maximal medical interventions. While this operation almost always increases bowel movement frequency, complaints of diarrhea, incontinence, and abdominal pain are not infrequent, and patients should be carefully selected. 8

Diarrhea and Irritable Bowel Syndrome

Diarrhea is also a common complaint and is usually a self-limited symptom of infectious gastroenteritis. If diarrhea is chronic or is accompanied by bleeding or abdominal pain, further investigation is warranted. Bloody diarrhea and pain are characteristic of colitis; etiology can be an infection (invasive *E. coli*, *Shigella*, *Salmonella*, *Campylobacter*, *Entamoeba histolytica*, or *C. difficile*), inflammatory bowel disease (ulcerative colitis or Crohn's colitis), or ischemia. Stool wet-mount and culture can often diagnose infection. Sigmoidoscopy or colonoscopy can be helpful in diagnosing inflammatory bowel disease or ischemia. However, if the patient has abdominal tenderness, particularly with peritoneal signs, or any other evidence of perforation, endoscopy is contraindicated.

Chronic diarrhea may present a more difficult diagnostic dilemma. Chronic ulcerative colitis, Crohn's colitis, infection, malabsorption, and short gut syndrome can cause chronic diarrhea. Rarely, carcinoid syndrome and islet cell tumors (vasoactive intestinal peptide-secreting tumor [VIPoma], somatostatinoma, gastrinoma) present with this symptom. Large villous lesions may cause secretory diarrhea. Collagenous colitis can cause diarrhea without any obvious mucosal abnormality. Along with stool cultures, tests for malabsorption, and metabolic investigations, colonoscopy can be invaluable in differentiating these causes. Biopsies should be taken even if the colonic mucosa appears grossly normal.

Irritable bowel syndrome is a particularly troubling constellation of symptoms consisting of crampy abdominal pain, bloating, constipation, and urgent diarrhea. Work-up reveals no underlying anatomic or physiologic abnormality. Once other disorders have been excluded, dietary restrictions and avoidance of caffeine, alcohol, and tobacco may help to alleviate symptoms. Antispasmodics and bulking agents may be helpful.

Incontinence

The incidence of fecal incontinence has been estimated to occur in 10 to 13 individuals per 1000 people older than age 65 years. Incontinence ranges in severity from occasional leakage of gas and liquid stool to daily loss of solid stool. The underlying cause of incontinence is often multifactorial and diarrhea is often contributory. In general, causes of incontinence can be classified as *neurogenic* or *anatomic*. Neurogenic causes include diseases of the central nervous system and spinal cord along with pudendal nerve injury. Anatomic causes include congenital abnormalities, procidentia, overflow incontinence secondary to impaction or neoplasm, and trauma. The most common traumatic cause of incontinence is injury to the anal sphincter during vaginal delivery. Other causes include anorectal surgery, impalement, and pelvic fracture.

After a thorough medical evaluation to detect underlying conditions that might contribute to incontinence, evaluation focuses on assessment of the anal sphincter and pudendal nerves. Pudendal nerve terminal motor latency testing may detect neuropathy. Anal manometry can detect low resting and squeeze pressures. Defecography can detect rectal prolapse. Endoanal ultrasound is invaluable in diagnosing sphincter defects.

DIVERTICULAR DISEASE OF THE COLON

Diverticula are saclike protrusions of the colonic wall, varying in size from a few millimeters to several centimeters. True diverticula contain all layers of the colon wall and are believed to be congenital. They are very uncommon in the colon. False or *pseudodiverticula* represent herniations of the mucosa and submucosa through the circular muscle of the bowel wall. Unless otherwise stated in the text, the term *diverticula* refers to the predominant lesion, namely, colonic pseudodiverticula. The term *diverticulosis* simply indicates the presence of multiple diverticula of the colon.

PREVALENCE, PATHOGENESIS, AND PATHOLOGIC ANATOMY

The prevalence of diverticular disease in the general population ranges between 35% and 50%, as estimated by several large autopsy and radiographic series.¹³ Prevalence directly correlates with age, estimated to be less than 5% at age 40, increasing to 30% by age 60, and as high as 65% by age 85.²⁵ Males and females appear to be affected equally. Geographically, diverticular disease is much more common in the United States and Western Europe than in other less industrialized regions such as Africa, South America, and Asia. Although diet is thought by many to contribute significantly to the development of diverticular disease, the complete etiology is likely to involve other, as yet unrecognized, factors. For example, diverticular disease in Asian populations is localized predominantly to the right colon, in distinct contrast to the left-sided predilection observed in Western civilizations. Such variations in the anatomic distribution of diverticula among civilizations might suggest that factors other than diet alone exert a substantial influence on the character of this disease worldwide.

Mechanical Factors. Clinical studies within the past 30 years have implicated low fiber diets as a prominent etiologic factor in the development of diverticular disease.^{24, 25} Diets lacking vegetable fiber are presumed to predispose to the development of diverticula by altering colonic motility. Colonic motility is a complex process serving to transport feces distally while also permitting storage, thereby facilitating fluid and electrolyte absorption. Colonic motility is modulated by myogenic, hormonal, and neural influences. There is evidence that patients with diverticular disease manifest exaggerated contractile responses to feeding and hormonal stimuli. Resting pressures are usually normal, however. These abnormal muscular contractions are believed to cause colonic smooth muscle hypertrophy, a characteristic of diverticular disease.

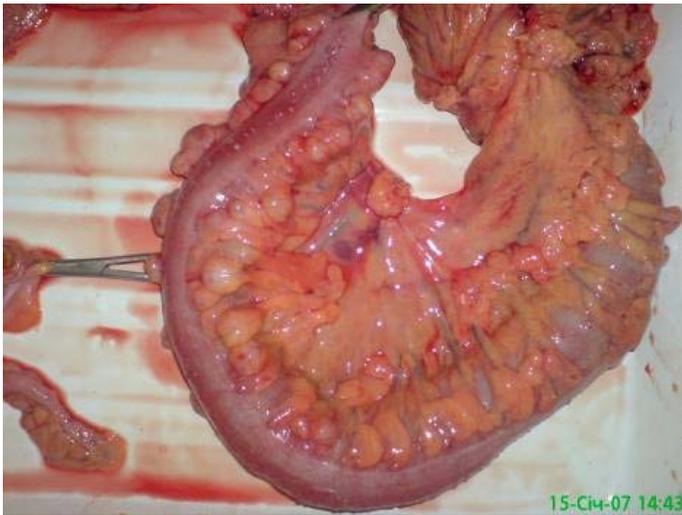

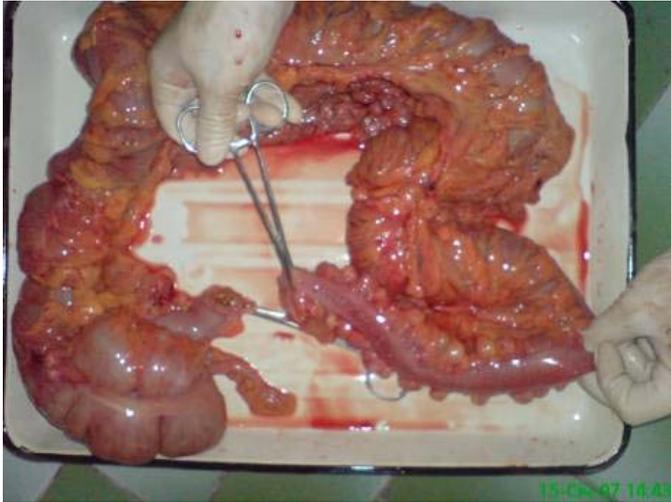

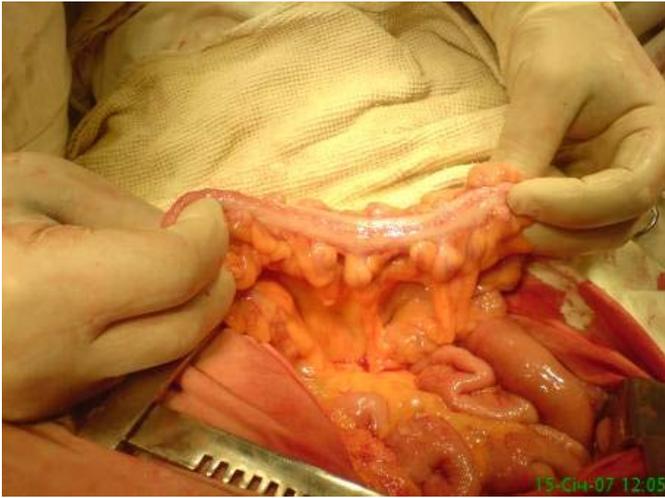

The possible role of dietary fiber in the development of diverticula is best explained by effects on colonic diameter and stool consistency. It has been postulated that colonic segments with bulky fecal contents and large luminal diameters are less likely to exhibit exaggerated segmentation. Low-fiber diets are associated with a narrowed colon filled with small, hardened feces; segmentation is enhanced, and high luminal pressures tend to develop. Although this concept has been widely disseminated, definitive evidence for a causal relationship between low dietary fiber and the development of diverticular disease does not exist.^{31, 39} Nonetheless, high-residue diets are in widespread use in the management of diverticular disease. Whether such therapy has a significant influence on the natural history of diverticular disease is unclear.

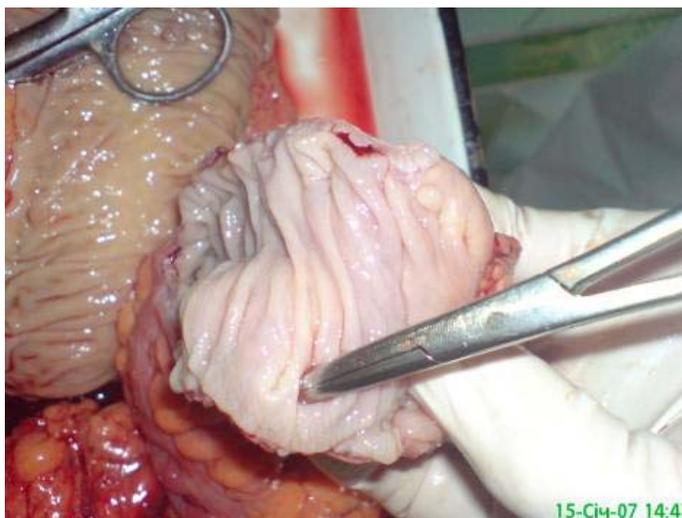

Anatomic Features. Diverticula tend to develop at specific points in the circumference of the colon. This localization is determined, in part, by the anatomic relationship between the colonic musculature and its nutrient blood supply. Diverticula form at so-called weak points where the nutrient blood vessels (*vasa recta*) penetrate the circular muscle layer en route to the mucosa. These *perforating* vessels tend to penetrate the colonic wall along the mesenteric border of the two antimesenteric taeniae. The gaps in the circular muscle layer where the *vasa recta* penetrate constitute points of potential weakness through which the mucosa and submucosa can herniate, forming diverticula. Diverticula, therefore, are usually located between the single mesenteric taenia and either of the two antimesenteric taeniae. Less commonly, diverticula form in the area between the antimesenteric taeniae. Although also consisting of mucosal herniation through the muscular layers of the colonic wall, these diverticula tend to be less prominent. In many instances the mucosal herniation does not quite extend to the serosa, causing these to be referred to as intramural diverticula.

The distribution of diverticula throughout the colon also tends to follow a pattern, but with considerable individual variation. The overwhelming majority of diverticula occur in the descending and sigmoid colon. It is estimated that 90% to 95% of patients with diverticulosis will have involvement of the sigmoid colon. Approximately 65% of patients will have disease limited to the sigmoid colon alone. Conversely, only a small number of patients (2% to 10%) will have disease confined to the right colon. Solitary diverticula occur most commonly in the cecum.

NATURAL HISTORY

After the first episode of diverticulitis, approximately one third of patients will sustain a second attack, usually within 3 to 5 years. Another 30% to 40% will suffer from intermittent symptoms of discomfort and crampy abdominal pain, without requiring hospitalization. The remainder can be expected to remain symptom free. The prognosis is worse after a second attack, with only 10% of patients remaining symptom free. The morbidity and the mortality from recurrent attacks are also higher than that associated with an initial episode. Complications such as abscess formation or fistulization develop in approximately 20% of patients after a single attack of diverticulitis, while the complication rate approaches 60% in patients who have had previous episodes.

Because diverticulosis is an acquired disease, the incidence of which clearly increases with age, it would seem logical that the number and size of diverticula would also increase with time. However, only 30% of patients demonstrate radiologic evidence of progression of their disease, either in the form of an increased number of diverticula or involvement of other segments of the colon. Progression of disease after resection of involved colon is also unusual, occurring in less than 10% to 15% of patients. [video](#) [video2](#) [video3](#) [video4](#)

CROHN'S DISEASE

Crohn's disease is a chronic, nonspecific inflammatory disease of the gastrointestinal tract of unknown etiology. It involves mainly the ileum and large intestine, most often producing symptoms of obstruction or localized perforation with fistula. Both medical and surgical treatments are palliative. Nonetheless, operative excision provides effective symptomatic relief and produces reasonable long-term benefit.

Epidemiology

Crohn's disease is a chronic, idiopathic inflammatory disease with a propensity to affect the distal ileum, although any part of the alimentary tract can be involved. Recent estimates of the incidence of Crohn's disease in the United States have ranged from 3.6 to 8.8 per 100,000. ³⁴ A dramatic increase in incidence in the United States was observed to occur from the mid-1950s through the early 1970s. Incidence rates have been stable since the 1980s. Substantial regional variations in incidence have been observed, with the highest incidences reported to exist in northern latitudes. The incidence of Crohn's disease varies among ethnic groups within the same geographic region. For example, members of the East European Ashkenazi Jewish population are at two- to fourfold higher risk of developing Crohn's disease than are members of other populations living in the same location.

Most studies suggest that Crohn's disease is slightly more prevalent in females than in males. The median age at which patients are diagnosed with Crohn's disease is approximately 30 years; however, age of diagnosis can range from early childhood through the entire life span.

Both genetic and environmental factors appear to influence the risk for developing Crohn's disease. The relative risk among first-degree relatives of patients with Crohn's disease is 14 to 15 times higher than that of the general population. Approximately 1 of 5 patients with Crohn's disease will report having at least one affected relative. The concordance rate among monozygotic twins is as high as 67%; however, Crohn's disease is not associated with simple mendelian inheritance patterns. Although there is a tendency within families for either ulcerative colitis or Crohn's disease to be present exclusively, mixed kindreds also occur, suggesting the presence of some shared genetic traits as a basis for both diseases.

Higher socioeconomic status is associated with an increased risk of Crohn's disease. Most studies have found breastfeeding to be protective against the development of Crohn's disease. Crohn's disease is more prevalent among smokers. Furthermore, smoking is associated with the increased risk for both the need for surgery and the risk of relapse after surgery for Crohn's disease.

Crohn's disease is characterized by sustained inflammation. Whether this inflammation represents an appropriate response to a yet unrecognized pathogen or an inappropriate response to a normally innocuous stimulus is unknown. Various

hypotheses on the roles of environmental and genetic factors in the pathogenesis of Crohn's disease have been proposed.

Many infectious agents have been suggested to be the causative organism of Crohn's disease. Candidate organisms have included Chlamydia, *Listeria monocytogenes*, *Pseudomonas* species, reovirus, *Mycobacterium paratuberculosis*, and many others. There is no conclusive evidence that any of these organisms is the causative agent.

Studies using animal models suggest that in a genetically susceptible host, nonpathogenic, commensal enteric flora are sufficient to induce a chronic inflammatory response resembling that associated with Crohn's disease. In these models, the sustained intestinal inflammation is the result of either abnormal epithelial barrier function or immune dysregulation. Poor barrier function is hypothesized to permit inappropriate exposure of lamina propria lymphocytes to antigenic stimuli derived from the intestinal lumen. In addition, a variety of defects in immune regulatory mechanisms, e.g., overresponsiveness of mucosal T cells to enteric flora-derived antigens, can lead to defective immune tolerance and sustained inflammation.

Specific genetic defects associated with Crohn's disease in human patients are beginning to be defined. For example, the presence of a locus on chromosome 16 (the so-called IBD1 locus) has been linked to Crohn's disease. The IBD1 locus has been identified as the NOD2 gene. 35,36 Persons with allelic variants on both chromosomes have a 40-fold relative risk of Crohn's disease when compared to those without variant NOD2 genes. The relevance of this gene to the pathogenesis of Crohn's disease is biologically plausible, because the protein product of the NOD2 gene mediates the innate immune response to microbial pathogens.

Although the pathologic hallmark of Crohn's disease is focal, transmural inflammation of the intestine, a spectrum of pathologic lesions can be present. The earliest lesion characteristic of Crohn's disease is the aphthous ulcer. These superficial ulcers are up to 3 mm in diameter and are surrounded by a halo of erythema. In the small intestine, aphthous ulcers typically arise over lymphoid aggregates. Granulomas are highly characteristic of Crohn's disease and are reported to be present in up to 70% of intestinal specimens obtained during surgical resection. These granulomas are noncaseating and can be found in both areas of active disease and apparently normal intestine, in any layer of the bowel wall, and in mesenteric lymph nodes.

As disease progresses, aphthae coalesce into larger, stellate-shaped ulcers. Linear or serpiginous ulcers may form when multiple ulcers fuse in a direction parallel to the longitudinal axis of the intestine. With transverse coalescence of ulcers, a cobblestone appearance of the mucosa may arise.

With advanced disease, inflammation can be transmural. Serosal involvement results in adhesion of the inflamed bowel to other loops of bowel or other adjacent organs. Transmural inflammation also can result in fibrosis, with stricture formation, intra-abdominal abscesses, fistulas, and, rarely, free perforation. Inflammation in Crohn's disease can affect discontinuous portions of intestine: so-called "skip lesions" that are separated by intervening normal-appearing intestine.

A feature of Crohn's disease that is grossly evident and helpful in identifying affected segments of intestine during surgery is the presence of fat wrapping (Fig. 27-17). This finding is virtually pathognomonic of Crohn's disease. It is the encroachment of mesenteric fat onto the serosal surface of the bowel. The presence of fat wrapping correlates well with the presence of underlying acute and chronic inflammation.

ETIOLOGY

No specific etiology of the disease has been identified. There are two main schools of investigation: the microbiologic and the immunologic. Microbiologists have long sought a specific micro-organism that might be the cause of the disease; however, none has yet been identified. Recent reports of the isolation of *Mycobacterium paratuberculosis* from segments of bowel affected with Crohn's disease excited interest, but this organism as a specific etiology for the disease has yet to be proved. Also, no virus has been identified as an etiologic agent.

An immunologic origin of the disease has also been sought. No doubt an immunologic response to the condition does exist. Some have postulated that a childhood sensitization to milk impairs mucosal integrity and allows bacteria or bacteriologic products to enter the body. A cellular and humoral immune response to these products then ensues. The ileocolic epithelium, in particular, may be the target of a necrotizing immune response, with ensuing ulceration, tissue destruction, and the clinical appearance of the disease. Although an immunologic response certainly plays a role in the pathogenesis of the condition, its role as an etiologic agent is still unclear.

Other data suggest that environmental factors have an etiologic role in the disease. The disease is more common among persons living in temperate climates than among those living in tropical climates. Smoking may exert a stimulating effect on the disease; many patients with Crohn's disease are heavy smokers. Spouses of persons with Crohn's disease have a higher incidence of the disease than persons in the general population. Although these data suggest that environmental factors have a role, no specific environmental factor has been identified.

SYMPTOMS

The most common symptoms of Crohn's disease are those from the intestinal lesions, with abdominal pain, especially of a cramping nature, topping the list. Diarrhea is frequent. The stools may contain blood, although they often do not. Patients experience abdominal distention or flatulence and sometimes nausea and vomiting. Eating becomes difficult, because it induces symptoms. Patients therefore decrease their food intake and lose weight. Should fistulas develop, the pain and discharge of intestinal content at the site of the fistulas to the skin or in the perianal area produce localized symptoms in these areas. Systemic responses include fever and malaise; localized pain and discomfort are related to the sites of extraintestinal involvement in the skin, eyes, and joints.

The course of the disease is one of exacerbations and remissions, but as the lesions mature and complications develop, the symptoms continue unabated and the disease becomes relentlessly progressive. About 70% of patients eventually come to operation, in spite of spontaneous remissions and medical or dietary therapy.

DIAGNOSIS

Diagnosis is based on the history, physical findings, and appropriate laboratory tests. The physical findings include the palpation of the thickened bowel wall or adjacent inflammatory response or abscesses in the abdomen. Hyperactive bowel tones are heard using auscultation, and peristaltic rushes in the small intestine may even be seen through a thin abdominal wall. Abdominal distention occurs. Fistulas are apparent, and probes and catheters can be passed through the cutaneous openings and into the lumen of the bowel through the tracts. On inspection, the perianal skin appears bluish, and perianal fissures, abscesses, and fistulas can be identified.

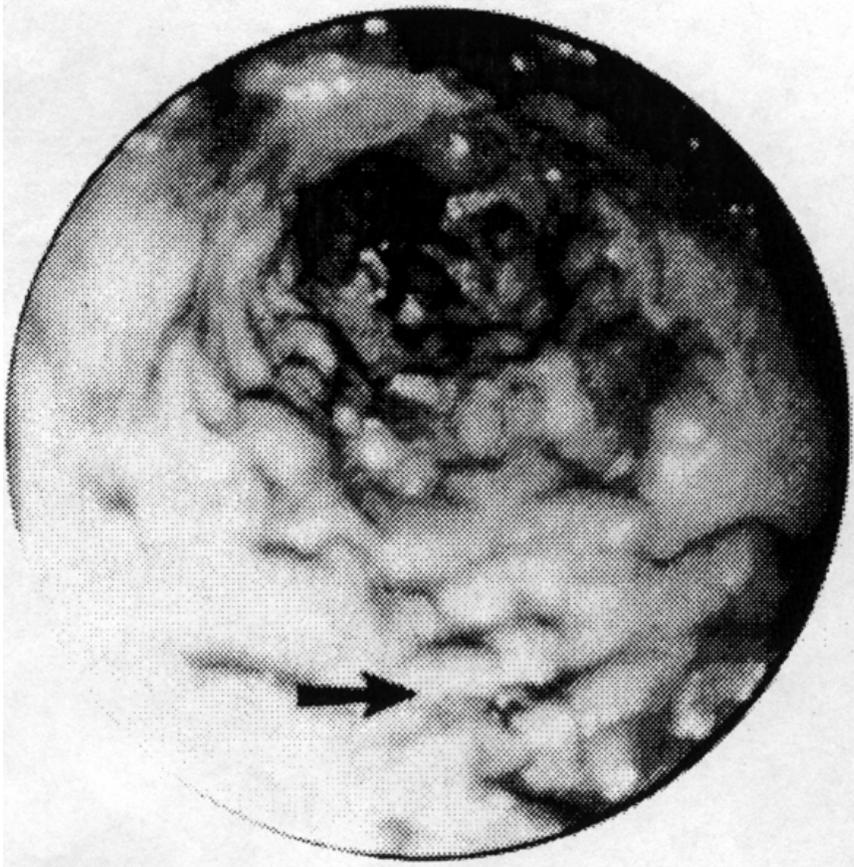

Proctoscopy often reveals the characteristic rectal aphthous ulcer with surrounding normal-appearing mucosa. With progressive and extensive involvement, the ulcerations involve more and more of the lumen of the bowel, with diminishing isolated segments of normal mucosa remaining. Anoscopy can show perianal abscesses, perianal fistulas, and even rectovaginal fistulas. Colonoscopy delineates the extent of the lesions in the large intestine. Sometimes the colonoscope can be passed through the colon and into the ileum to identify the ileal lesions of the disease. The hallmarks of Crohn's disease are the discontinuous and asymmetrical nature of the endoscopic findings. Biopsies taken during endoscopy show chronic inflammation and sometimes granulomas.

Roentgenographic examination of the gastrointestinal tract using BaSO₄. Proximal dilatation of the bowel accompanies obstructing lesions. Long lengths of narrowed terminal ileum may reduce the caliber of the lumen to the size of a string. Areas of dilatation may alternate with areas of constriction. The cobblestone appearance of the mucosa may be apparent, as may the rake ulcers. Fissures, fistulas, and perienteric abscesses may be found. Computed axial tomography may help delineate thickened bowel, perienteric abscesses, and perforations. In toxic megacolon, the transverse colon is greatly dilated and the bowel wall is thickened. A mass accompanying a narrowed or ulcerated area suggests cancer. Free air in the abdomen is present with free perforation.

The differential diagnosis includes both specific and nonspecific causes of intestinal inflammation. Specific microbiologic diseases that may be confused with Crohn's disease include bacterial inflammations such as those caused by salmonella and shigella, typhoid fever, intestinal tuberculosis, and protozoan infections such as amebiasis. Appropriate cultures and biopsies reveal the causative organisms in these conditions and rule them out. In regard to nonspecific intestinal inflammation, chronic ulcerative colitis can usually be differentiated from Crohn's disease. Although ulcerative colitis involves the mucosa of the large intestine, it does not extend deep into the wall of the bowel, as does Crohn's disease. Ulcerative colitis nearly always involves the rectum most severely, with lessening inflammation from the rectum to the ileocolic area. In contrast, Crohn's disease may be worse on the right side of the colon than on the left side, sometimes sparing the rectum. Ulcerative colitis also shows continuous involvement from rectum to proximal segments, whereas Crohn's disease shows segmental lesions. Although nonspecific, so-called backwash ileitis may be present in ulcerative colitis, ileal and small intestinal involvement suggests Crohn's disease. Bleeding is a more common symptom in ulcerative colitis and is less common in Crohn's disease. Perianal involvement and rectovaginal fistulas are unusual in ulcerative colitis but are more common in Crohn's disease. In most instances, the two diseases can be clearly separated, but a subgroup of 5% to 10% of all patients with chronic nonspecific inflammatory bowel disease cannot be clearly classified as having ulcerative colitis or Crohn's disease. These patients are usually given a diagnosis of "indeterminate" colitis. The true diagnosis often becomes apparent as the patients are followed through the years.

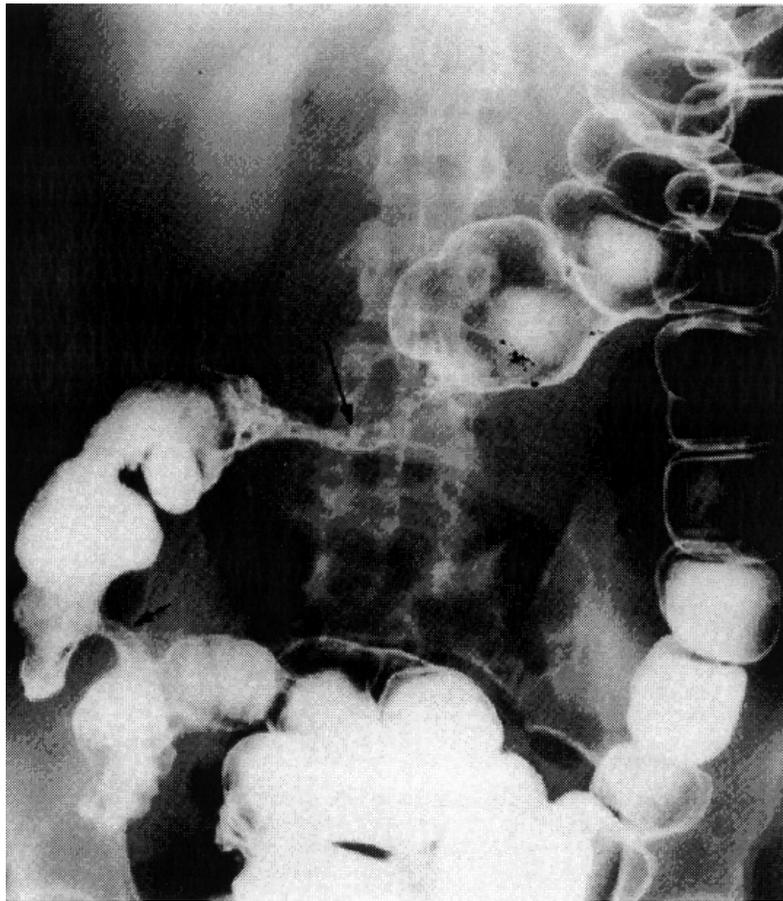

Endoscopic view

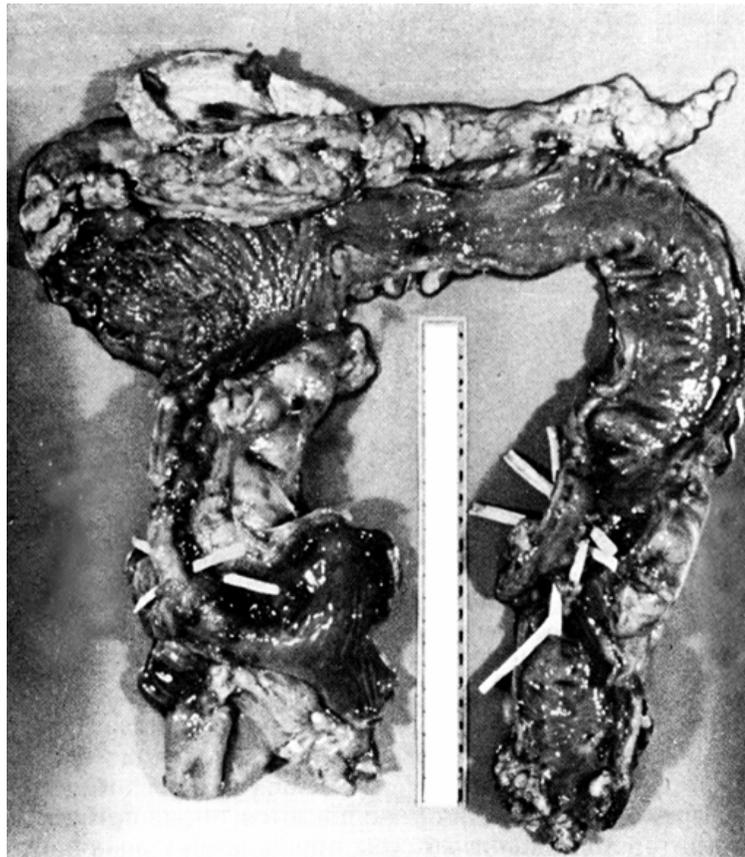

Crohn's disease, symptom of "roadway". Endoscopy examination

Crohn's disease. Hyperemia and deep cracks of mucus membrane of colon, ulcers, symptom of "roadway"

Stricture ascending part of the colon. Crohn's disease. Irrigogram.

Crohn's disease. Multiple fistulas.

Acute distal ileitis may be a manifestation of early Crohn's disease, but it also may be unrelated, such as when it is caused by a bacteriologic agent such as *Campylobacter* or *Yersinia*. Patients usually present in a manner similar to patients with acute appendicitis. They have a sudden onset of right lower quadrant pain, nausea, vomiting, and fever, with tenderness over the area of involvement. The diagnosis is made at operation by identifying an acutely inflamed segment of terminal ileum. No biopsy or resection should be done. The condition almost always subsides spontaneously, and the segment should not be excised. If the cecum is not involved, the appendix should be removed to prevent subsequent bouts of right lower quadrant inflammation from being confused with appendicitis.

THERAPY

Medical and Dietary Therapy

Medical therapy consists of sulfasalazine, 5-aminosalicylic acid, corticosteroids, antibiotics such as metronidazole and ampicillin, and immunosuppressive agents such as azathioprine and cyclosporine. Because no specific etiology has been identified for Crohn's disease, the treatments are also nonspecific. They suppress inflammation and improve symptoms but are not curative.

Manipulations of the diet ordinarily have little effect on the progress of Crohn's disease. However, complete abstinence of oral intake with total parenteral nutrition may lead to temporary remission of symptoms in some patients with Crohn's disease. Sometimes enteroenteric or enterocutaneous fistulas close. Few long-term benefits of total parenteral nutrition have been achieved, however. When oral intake is resumed, the patients usually have recurring difficulty, and the symptoms of the disease return.

Pharmacologic agents used to treat Crohn's disease include antibiotics, aminosalicylates, corticosteroids, and immunomodulators. Antibiotics have an adjunctive role in the treatment of infectious complications associated with Crohn's disease. They are also used to treat patients with perianal disease, enterocutaneous fistulas, and active colonic disease.

Most studies have shown sulfasalazine, the parent compound of all aminosalicylates used to treat Crohn's disease, to be superior to placebo in inducing disease remission. Its efficacy in the maintenance of remission is less clear. Aminosalicylates are associated with minimal toxicity and are available in a variety of formulations that allow for their delivery to specific regions of the alimentary tract.

Orally administered glucocorticoids are used to treat patients with mildly to moderately severe disease that does not respond to aminosalicylates. Patients with severe active disease usually require intravenous administration of glucocorticoids. Although glucocorticoids are effective in inducing remission, they are ineffective in preventing relapse and their adverse side-effect profile makes long-term use hazardous. Therefore, they should be tapered once remission is achieved. Some patients are unable to undergo glucocorticoid tapering without suffering recurrence of symptoms. Such patients are said to have glucocorticoid dependence and are candidates for therapy with glucocorticoid-sparing immune modulators.

The thiopurine antimetabolites azathioprine and 6-mercaptopurine have demonstrated efficacy in inducing remission, in maintaining remission, and in allowing for glucocorticoid tapering in glucocorticoid-dependent patients. There is also some evidence that they decrease the risk of relapse after intestinal resection for Crohn's disease. These agents are relatively safe, but can induce bone marrow suppression and promote infectious complications. For patients who do not respond to the thiopurines, methotrexate is an alternative. There is little role for cyclosporine in Crohn's disease; its efficacy/toxicity profile in this disease is poor.

Infliximab is a chimeric monoclonal anti-tumor-necrosis-factor antibody that has efficacy in inducing remission and in promoting closure of enterocutaneous fistulas. 37 Infliximab is generally well tolerated but should not be used in patients with ongoing septic processes, such as undrained intra-abdominal abscesses.

Surgical Therapy

Indications for Operation. Patients with Crohn's disease are usually operated on because an intestinal complication of Crohn's disease mandates the operation. All in all, about 70% of patients with Crohn's disease will come to operation. The most common complications leading to operation are recurrent intestinal obstruction, intestinal perforation with fistula formation and abscess, or a gastrointestinal bleeding.² Obstruction is usually partial and is seldom complete. With nasogastric suction and intravenous nutrition, the distended bowel usually decompresses, and bowel movements resume. Failure to achieve complete resolution or recurrence of obstructive symptoms with the resumption of oral feedings usually leads to operation. Perforation with fistula formation and resultant abdominal mass usually causes continuing pain, fever, malaise, and weight loss until operation can be accomplished. Perianal complications, such as abscess and fistula, commonly lead to operation. Bleeding, a less frequent cause of operation, is usually not massive, but it may be persistent and contribute to chronic anemia until the offending lesion or lesions can be resected. Patients with small intestinal Crohn's disease usually require operation for obstruction or perforation, whereas those with large intestinal Crohn's are usually operated on for chronic debility and failure to respond to medical therapy.

Severe systemic symptoms, intractable medical therapy, and weight loss, especially with growth failure in children, can also lead to operation. Prepubertal and early pubertal patients experiencing growth failure from Crohn's can be expected to sustain *catch-up* and accelerated growth after resection.¹⁶ Toxic megacolon and cancer of the small or large intestine are less common intestinal complications requiring operation. Extraintestinal complications in and of themselves seldom require intestinal operation, but they often contribute to the decision to operate. Most of the extraintestinal complications, with the exception of ankylosing spondylitis and the hepatic complications, subside with the excision of intestine grossly involved with Crohn's disease.

Preoperative Preparation. The nutritional status of the patient is optimized before operation. This sometimes, but not often, requires parenteral caloric supplementation. Anemia is treated by blood transfusion. For patients currently on or recently receiving corticoid therapy, additional steroids— usually 100 mg. of hydrocortisone intravenously every 8 hours—are given to ensure an adequate supply during the operative stress. The bowels are cleansed with laxatives and enemas the day prior to operation. Alternatively, 4 liters of an electrolyte solution (GoLYTELY) can be given by mouth the night before operation.³⁶ Diet is restricted to clear liquids the day before operation.

The growth of enteric bacteria in patients having the laxative-enema preparation is suppressed by giving oral neomycin 0.5 gm. every 4 hours, and tetracycline, erythromycin, or metronidazole 250 mg. every 4 hours, for 18 hours prior to operation. When the GoLYTELY preparation is used, 2 gm. neomycin and 2 gm. metronidazole are given by mouth 12 hours and 8 hours before operation. With both preparations, cefazolin 0.5 gm. is given intravenously just prior to operation and is continued every 8 hours for two more doses.

General Principles of Operation. Because Crohn's disease involves nearly the entire gastrointestinal tract in most patients, total excision of the disease is not possible. Thus, surgical treatment is directed at the most severe areas of involvement, including those that account for the complications of obstruction, bleeding, or perforation.

The two main operative approaches are to excise the lesions or to bypass them. Currently, most surgeons advise excision rather than bypass. Bypass allows the diseased intestine to remain in place, where it can cause continuing symptoms, require treatment, and perhaps even develop malignancy. The risk of cancer in bypassed small and large intestine with Crohn's disease is greater than the risk in healthy bowel. Excision is done with 3-cm. "disease-free" margins on both sides of the area of involvement. The disease-free margins are established by gross inspection. Most surgeons do not use microscopic confirmation of healthy borders. Although the authors have found that when borders are free of microscopic involvement there are fewer recurrences over the long term than when the border is involved,³⁷ others have not found a higher recurrence rate when histologic findings of

Crohn's are present in the margins. Certainly, demanding microscopic borders that are free of disease may lead to excessively large resections and result in the short bowel syndrome. Patients with this syndrome do not have enough intestine remaining to digest and absorb their food properly.

After resection and anastomosis of the index segment (or segments) of intestine that has led to the operation, fistulas from the index segment to adjacent organs, such as the stomach, colon, duodenum, bladder, or vagina, can usually be closed by suture of the entrance of the fistula into the adjacent segment. Resection of the adjacent segment is seldom required, unless it is primarily involved with gross Crohn's disease.

UNSPECIFIC ULCEROUS COLITIS

Ulcerative colitis, a diffuse inflammatory disease of the mucosal lining of the colon and rectum, is characterized by bloody diarrhea that exacerbates and abates without apparent cause. It is difficult to realize that a disease so devastating remains without an identified etiology or specific medical therapy. Total removal of the affected organs—the colon and rectum—provides a complete cure, but at a sacrifice, since patients so treated must learn to live with an external abdominal stoma (an ileostomy) for the remainder of their lives. Since the disease has its peak onset in early and middle adulthood, this represents a long time span for most patients. Fortunately, new surgical alternatives have eliminated the need for a permanent ileostomy without sacrificing definitive treatment of the disease.

ETIOLOGY

The etiology of ulcerative colitis remains unknown despite intensive work by many investigators. The examination of bacterial and viral agents continues to be an area of great activity. Whether the infectious agents are more likely to be triggers of disease or perpetuators of disease is of great controversy. To be a trigger, an infectious agent would have to act by initiation or reactivation. Agents could initiate an autoimmune response by altering antigens, affecting molecular immunity, or increasing immune responsiveness. The microbial agent might also trigger the pathologic response by increasing mucosal permeability or stimulating epithelial injury or localized ischemia. The microbial agent could reactivate the inflammatory process directly, by secondary infection, or by the release of toxins. Evidence for microbial agents as triggers in inflammatory bowel disease is only indirect.

Psychologic factors have long been thought to have a critical role in exacerbations of the disease. It is now clear that patients with ulcerative colitis have no unusual predisposing factors when compared with matched controls. Moreover, colectomy is usually followed by a marked improvement in pre-existing morbid psychologic states such as depression or social estrangement. Psychosomatic factors most likely only facilitate the colonic mucosal reaction to another as yet unidentified causative agent.

Another area of great interest has been that of cytokines and immunoregulatory molecules involved in the control of the immune response.⁶¹ The production of interferon during inflammation could have a significant role in the differentiation of mature memory and effector cells within the intestine. Specific activities of interleukins that are potentially relevant to inflammatory bowel disease have been identified. Most important of these may be interleukin-1 (IL-1), which activates T and B lymphocytes as well as macrophages and neutrophils. IL-1 stimulates production of eicosanoids, cytokines, growth factors, and destructive enzymes; increases adhesion of neutrophils and monocytes to endothelial cells; induces acute-phase response as well as fever, anorexia, and sleep; and stimulates collagen production and thus fibrosis. IL-1 has been shown to be elevated in ulcerative colitis as well as in experimental models of colitis. The increase in IL-1 levels seems to correlate with severity of disease. Alterations in IL-2, IL-6, IL-8, and interferon-gamma have been identified in tissues from patients with ulcerative colitis. The production of interferon during inflammation could play a significant role in the differentiation of mature memory and effector cells within the intestine. Tumor necrosis factor may also be particularly important in the activation of mesenchymal cells but has not been fully evaluated in ulcerative colitis. Thus, it appears that cytokines are integrally involved in the pathogenesis of inflammatory bowel disease with both immunoregulatory and proinflammatory properties.

PATHOLOGY

Ulcerative colitis is, for the most part, a disease confined to the mucosal and submucosal layers of the colonic wall, progressing from mucosal edema and lipemia to vascular congestion, superficial ulcers, increased cellular infiltration of the lamina propria, and cyst abscesses beginning in the rectum and advancing proximally to involve the entire colon. In 10% of patients, the terminal ileum may show mild inflammation and dilation, a process that has been called *backwash ileitis*. On gross inspection, the colonic mucosa demonstrates healed granular superficial ulcers superimposed on a friable and thickened mucosa with increased vascularity. Patients may also demonstrate superficial fissures and small and regular pseudopolyps. This is in contradistinction to the transmural inflammatory changes found in Crohn's disease of the colon, in which all layers may

be involved in a granulomatous inflammatory process. The pathologic changes observed in ulcerative colitis, however, are nonspecific and can be seen in shigellosis, amebiasis, and gonorrheal colitis.

CLINICAL MANIFESTATIONS

The initial presentation of ulcerative colitis can take many forms. Bloody diarrhea is the most common early symptom. Occasionally, extraintestinal manifestations, including arthritis, iritis, hepatic dysfunction, and skin lesions, may be paramount. The disease presents as a chronic, relatively low-grade illness in most patients. In a small number of patients (15%), it has an acute and catastrophic fulminating course. Such patients present with frequent bloody bowel movements (up to 30 per day), high fever, and abdominal pain. The disease therefore has a wide spectrum of clinical manifestations, ranging from a mild diarrheal illness to an overwhelming life-threatening event of short duration that demands immediate medical attention.

Onset of the disease occurs in patients less than 15 years of age in approximately 15% of cases, and presentation in patients over 40 years of age is not uncommon. The incidence of ulcerative colitis is 3.5 to 6.5 per 100,000 population, and the prevalence is 60 per 100,000. A slight female predominance has been reported.

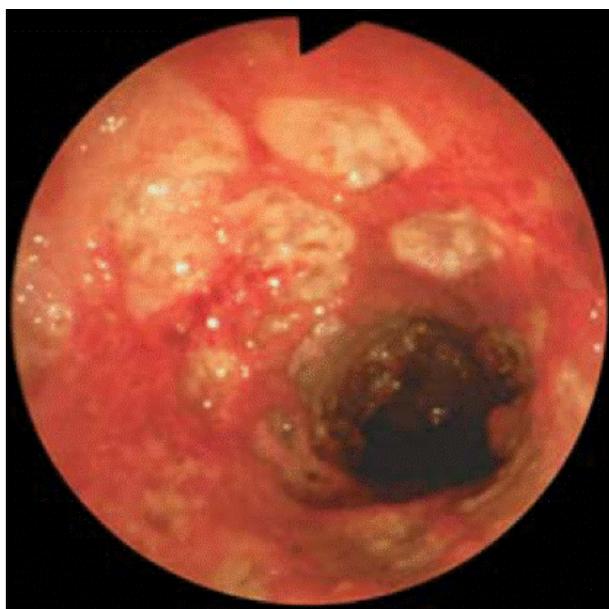

Physical findings are directly related to the duration and presentation of the disease. Weight loss and pallor are usually present. In the active phase, the abdomen, in the region of the colon, is usually tender to palpation. There may be signs of an acute abdomen accompanied by fever and decreased bowel sounds. This is especially true during acute attacks or in the fulminating form of the disease. Abdominal distention is unusual, except in patients who have toxic megacolon, in which case the patient is usually febrile and has signs of an acute abdomen. The perianal area may be excoriated from the numerous wipings associated with bowel movements. There may be evidence of perianal inflammation in the form of a fissure, abscess, or fistula in ano, although the last is more common in Crohn's disease. Rectal examination is almost always painful and, in the presence of perianal inflammation, should be done with gentle care. Examination of the integument, tongue, joints, and eyes is important, since the presence of disease in these areas suggests ulcerative colitis as a likely cause of the diarrheal illness.

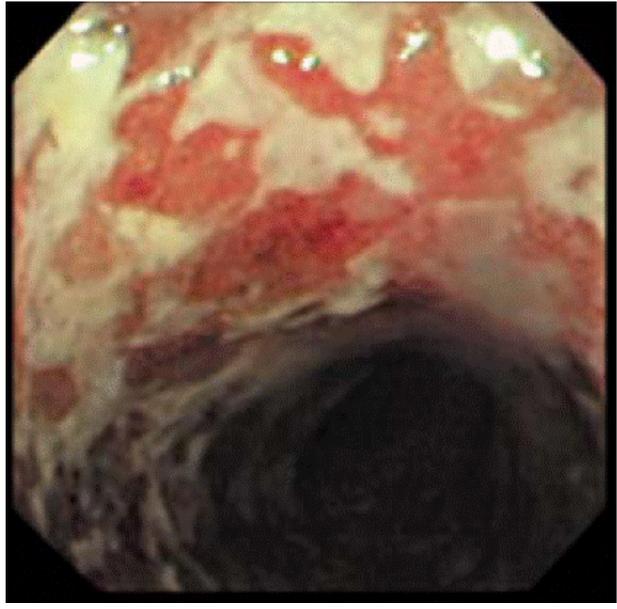

The contracted appearance of this colon, as viewed by barium roentgenogram, is typical of advanced ulcerative colitis in its chronic phase.

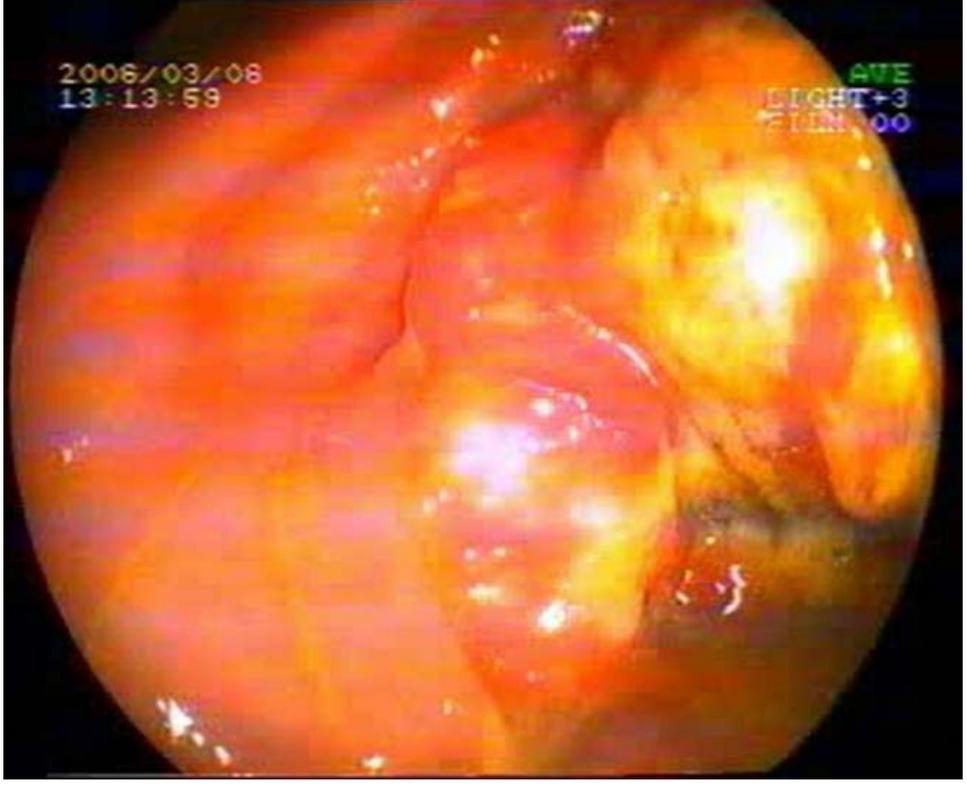

Proctosigmoidoscopy is a helpful and specific diagnostic aid, since ulcerative colitis involves the distal colon and rectum in 90% to 95% of cases. In fact, the mucosa of both the rectum and the sigmoid colon is usually erythematous and granular and bleeds easily when touched by the endoscope or rubbed with a cotton swab. Normal colonic vascular markings may be absent, or the mucosa may be hyperemic; in the disease-bearing mucosa, superficial (less than 2 mm.) mucosal alterations are seen. The intercolonic haustra are thick and blunted. Cobblestoning and deep linear ulceration, which are common endoscopic findings in Crohn's disease, are unusual in ulcerative colitis. In advanced disease, ulcers may be present, surrounded by hyperplastic areas of granulation tissue and edematous mucosa, which may assume a polypoid appearance (pseudopolyps). Mucosal bridging is also commonly found. In chronic advanced disease, the lumen of the rectosigmoid may be remarkably contracted. The use of flexible sigmoidoscopy has improved diagnostic accuracy and patient acceptance. Colonoscopic examination is of value in determining the extent and activity of the disease. Unless a distinct granuloma is identified, endoscopic biopsies are of little value in differentiating ulcerative colitis from Crohn's colitis.

Although recent studies suggest that previous reports may have overestimated the risk of cancer in the adult population with ulcerative colitis, patients with this disease still appear to be confronted with at least a 10% to 20% likelihood of developing carcinoma within 20 years of the diagnosis of ulcerative colitis. Adenocarcinoma in association with ulcerative colitis is multicentric in 15% of patients. In addition, the cancers tend to be flatter and perhaps more infiltrating. These tumors are more evenly distributed throughout the colon, with approximately 50% being found proximal to the splenic flexure. Carcinoma in association with ulcerative colitis is more difficult to diagnose by history and physical examination, stool guaiac testing, and radiographic studies. The likelihood of carcinoma in patients with ulcerative colitis appears to relate to both the extent of colonic involvement and the duration of disease. Although it is generally accepted that patients with extensive total ulcerative colitis are at increased risk of developing carcinoma, the question of what constitutes extensive colitis is still not fully resolved. In addition, the assessment is variable if judged radiographically or colonoscopically. The evidence that patients with left-sided ulcerative colitis, by any criteria, are at increased risk when compared with the general population—which carries a 4% to 6% likelihood of developing colorectal carcinoma, with three fourths of these cancers occurring on the left side—is far from overwhelming. The likelihood of cancer may be related to duration of activity and age of onset, although this has not been clearly established. Although it was held for some time that the carcinoma associated with ulcerative colitis was more aggressive than that in the general population, recent studies have demonstrated that the natural evolution of the cancer is likely the same in both groups.

Unspecific ulcerative colitis

Unspecific ulcerative colitis. Malignization

Unspecific ulcerative colitis. Pseuopoliposis

Rectal biopsies have also been advocated to assess the presence or absence of dysplasia. Morson and Pang⁷¹ advocate a surveillance program of rectal biopsy to assess the point at which a patient becomes at high risk for colonic cancer. When dysplasia of the rectal mucosa is identified, colectomy has been advocated. Other investigators in this field have found the test less useful, with false-negative results of 20% to 40% and false-positive results of 30% to 40%.⁹⁰ Colonoscopy may improve the accuracy of surveillance; however, random biopsies have a very low yield because of the immense sampling problem. Between 20 and 25 equally spaced biopsies are required on a 10-cm. length of colon to reasonably detect a patch of dysplasia 2 cm. in diameter. Moreover, the endoscopic appearances of both dysplasia and carcinoma in ulcerative colitis remain nearly undocumented. The biopsy of target lesions, that is, any lesion that cannot be reasonably accepted as part of the chronic disease state, is recommended. In addition, the end-point of surveillance remains controversial. Many gastroenterologists recommend colectomy only in the presence of high-grade dysplasia, a dysplasia-associated mass lesion, or a frank carcinoma. Unfortunately, the presence of dysplasia, whether low-grade or high-grade, can give rise directly to an invasive carcinoma, and all large centers have had patients under surveillance who developed and died of colorectal carcinoma. Some evidence suggests that even low-grade dysplasia unassociated with severe inflammation, if it is unequivocal, should prompt colectomy. To date, no prospective study has clearly demonstrated that surveillance lowers the mortality from colorectal cancer in association with ulcerative colitis, although a large review from St. Marks suggested an overall 5-year survival of 87% in those patients who underwent surveillance and 55% in those who did not.

A plain abdominal film may reveal a variant of the disease called *toxic megacolon*, in which there may be free air within the peritoneal cavity from perforation of the colon. A more common sign is a remarkable dilation of the transverse colon.

Barium enema examination, usually with air contrast, can be performed safely in most patients and is extremely helpful in identifying the extent and severity of the disease. Barium roentgenographic signs include loss of haustral markings and irregularities of the colon wall, which represent small ulcerations. These are well demonstrated in picture, which contrasts the appearance of the left side of the splenic flexure and that of the right. As the disease progresses, pseudopolyps become a prominent roentgenographic sign. In advanced disease, the colon assumes the appearance of a rigid contracted tube. The

barium roentgenogram, although useful, should be avoided in the presence of toxic megacolon, since it may exacerbate the colitis. When diarrhea is not present, a liquid diet for 3 days prior to examination is recommended. Barium roentgenogram should be omitted when the clinical signs of toxic megacolon are present. Upper gastrointestinal contrast studies are also indicated in most patients to exclude Crohn's disease.

The aforementioned clinical manifestations and simple diagnostic tests usually help identify the presence of ulcerative colitis. It is necessary, however, to obtain stool smears and cultures to exclude colitis due to viruses, *Chlamydia*, bacterial pathogens, and parasites. Particularly important and difficult to exclude are pseudomembranous colitis, the proctocolitis seen increasingly in homosexual males, and traveler's diarrhea. Cello and Meyer¹² provided a useful schema for distinguishing ulcerative colitis from granulomatous colitis. Note, however, the low frequency of discriminating clinical characteristics, except for associated small bowel disease or skip areas within the colon, when the etiology is Crohn's disease.

The strong association of cancer of the colon with ulcerative colitis bears further emphasis.¹¹⁵ For example, 40% of patients with total colonic involvement may die of cancer if they survive their disease and the colon is left in place.⁶² Three percent of children with ulcerative colitis have cancer of the colon at 10 years; 20% develop cancer during each ensuing decade.²⁰ With the availability of far more acceptable surgical alternatives to proctocolectomy and ileostomy, it is hoped that patients will obtain definitive treatment for the disease well before they enter the phase of accelerating cancer risk. These data support close medical management for such patients and surgical intervention, on this basis alone, when chronicity is well established.

The extracolonic manifestations of ulcerative colitis can be categorized as the colitis group, the pathophysiologic group, and the miscellaneous group of disorders. The colitis group of extracolonic manifestations generally parallels the activity of the underlying bowel disease, being present and most active when the colitis is active and usually subsiding when the colitis goes into remission induced by medical therapy, by surgical intervention, or spontaneously. It appears most likely that these extracolonic disorders represent antigen-antibody immune complex disorders. Ocular manifestations are common in ulcerative colitis and include conjunctivitis, iritis, and choroiditis. These are closely related to disease activity and respond to steroid therapy. More severe and rare eye diseases, including ulcerative panophthalmitis, are more difficult to treat, even with high-dose steroid suppression. Articular disorders, including peripheral joint disease, arthralgias, swelling, pain, and redness with migratory involvement, usually parallel the intensity of the colitis and respond to medical or surgical treatment. The joints of the lower extremities are most frequently involved. Fortunately, permanent deformity of these joints is very uncommon. A certain percentage of patients go on to develop clear evidence of rheumatoid arthritis even after colectomy. Ankylosing spondylitis and sacroiliitis, in contrast, can cause permanent fixation of the spine and need to be treated aggressively. Bone involvement specific to the axial skeleton is less closely related to the severity of the inflammatory state of the colon and, in fact, may precede frank evidence of ulcerative colitis. Patients with ulcerative colitis frequently experience dermatologic disorders, including erythema nodosum and pyoderma gangrenosum. Although these difficult problems resolve after colectomy in most patients, in others, they may precede the colonic disease or may not become manifest until after proctocolectomy has been performed.

Pathophysiologic disorders are more often seen in Crohn's disease than in ulcerative colitis, since in ulcerative colitis, the normal physiology of the terminal ileum is not disturbed. Liver disease is common in patients with both ulcerative colitis and Crohn's disease. Nonspecific inflammation and fatty metamorphosis manifested by mild increases in the serum transaminase values are common in ulcerative colitis. Pruritus and elevation of the alkaline phosphatase are commonly associated with the pericholangitis that occasionally accompanies ulcerative colitis. The most dreaded complication, sclerosing cholangitis, presents with pruritus, alkaline phosphatase elevation, right upper quadrant pain and tenderness, and jaundice. The diagnosis is most often made by endoscopic retrograde cholangiopancreatography or transhepatic cholangiography. It has been estimated that 50% of patients who present with sclerosing cholangitis already have or will develop frank ulcerative colitis. Controversy surrounds the treatment of this disorder. Whereas some patients respond to colectomy, many others show progression of their disease even after colon resection. Surgical drainage, internal stent placement, antibiotics, and ultimately liver transplantation have all been reported to be of value in the treatment of symptomatic sclerosing cholangitis. Cholangiocarcinomas have also been reported in patients with ulcerative colitis, usually after many years of sclerosing cholangitis.

MEDICAL MANAGEMENT

The outcome of an acute episode of ulcerative colitis relates to the severity of the disease as manifested by systemic symptoms. Duration of the disease and extent of involvement of the colon do not appear to be determinants of survival if ulcerative proctitis is excluded from consideration. Those who present with advanced signs of acute illness require hospitalization and supportive, as well as specific, therapy for associated metabolic and hematologic derangements. Because of the massive fluid and electrolyte loss per rectum, such patients often present with metabolic acidosis, contracted extracellular volume, and prerenal azotemia. The serum potassium level is usually low because of excessive loss in stool and urine. Intravenous administration of balanced salt solutions in amounts sufficient to replace these losses is an initial step in management. Patients with long-standing disease may have lost considerable protein and probably are in a depleted nutritional

state. The precise role of specialized nutritional support in ulcerative colitis and, in particular, of total parenteral nutrition is unclear. Despite early enthusiasm, total parenteral nutrition does not appear to have a specialized therapeutic role in this disease. Total parenteral nutrition improves the overall nutritional state of patients with ulcerative colitis and may reverse growth retardation in children, but it certainly does not replace conventional medical treatment or prevent or delay colectomy. In fact, in patients with severe acute colitis, it may be impossible to attain a positive nitrogen balance while the colon is still in place.

Corticosteroids and immunosuppressive agents have both been demonstrated to be effective in the management of ulcerative colitis. Both agents, however, are capable of producing significant side effects. In general, corticosteroids have been more readily accepted by the medical community as therapeutic agents and remain the mainstay of therapy in acute attacks. Between 40 and 60 mg. of prednisone in a single daily dose is effective in inducing remission.¹¹⁰ Rectal steroids have been shown to be effective in left colon disease or proctitis and may have therapeutic efficacy in universal colitis as well, perhaps because approximately 30% of the steroid given rectally is absorbed into the systemic circulation. In an attempt to avoid systemic effects of steroid enemas, tixocortol pivalate was synthesized by adding a thiol ester group at position 21 on the hydrocortisone molecule. In trials, this agent has been useful for treating patients with left-sided colitis and has resulted in a reduction in systemic steroid side effects. The controversy over intravenous steroids versus intravenous adrenocorticotropic hormone (ACTH) has now been resolved by a randomized trial that revealed a similar response to equipotent doses of either hormone.⁴⁹ A recent study suggests that ACTH may be more effective in patients not previously treated with corticosteroids, whereas corticosteroids appear to be preferable for patients already receiving steroid therapy.⁶⁸ A steroid-induced remission is not more likely to exacerbate than a spontaneous remission, and an ACTH-induced remission is not more likely to exacerbate than a corticosteroid-induced remission. The usual recommended doses are 300 mg. of hydrocortisone or 40 units of ACTH per day. Occasionally, massive doses of steroids (over 1 gm. per day) are required. The usual response is rapid, and acute signs of inflammation subside within a few days. The optimal duration of intravenous steroid therapy is 5 to 7 days, although this may be extended in patients supported nutritionally with total parenteral nutrition. Proctoscopic examination is useful in following response to therapy. There is still controversy as to whether maintenance steroid thereby reduces recurrence of the disease. Although maintenance steroids may be useful in controlling symptoms of patients with continuing activity, maintenance therapy with low-dose corticosteroids for patients with inactive disease has not been demonstrated to prevent relapse.⁵⁹ Patients must be monitored carefully for the long-term adverse sequelae of corticosteroid use, including hypertension, hyperglycemia, cataracts, osteoporosis, and osteomalacia.

Sulfasalazine has enjoyed widespread use in the chronic phases of ulcerative colitis. Its mode of action is unknown. Sulfasalazine may exert this prophylactic effect by inhibiting mucosal prostaglandin synthesis,⁴⁹ although not all studies have supported this mechanism.⁸¹ Whatever the mechanism of action, sulfasalazine appears to be associated with fewer exacerbations as assessed by controlled randomized trials.^{21, 108} The drug appears to be of lesser value in severe ulcerative colitis. Sulfasalazine is metabolized by bacteria to 5-aminosalicylic acid (5-ASA) and sulfapyridine. Dose-related side effects of sulfasalazine include nausea, vomiting, headache, and abdominal discomfort. Reversible hypospermia and infertility are observed in males. Hypersensitivity effects include fever, skin rash, agranulocytosis, and hemolytic anemia. Studies have indicated that the sulfapyridine produced by bacterial degradation of sulfasalazine is responsible for the majority of the side effects, whereas the 5-ASA component appears to be the effective moiety of the drug. Five-aminosalicylic acid is now available in this country for clinical use. In all studies to date, these compounds have been shown to be as efficacious as sulfasalazine in treating acute ulcerative colitis as well as in preventing relapse.

A third approach has been the use of immunosuppressive agents. Rosenberg and colleagues⁸⁸ concluded, based on a well-controlled study, that azathioprine allows reduction of the use of steroids in chronic cases but does not, in itself, control exacerbation of the disease. In a more recent controlled trial, however, Kirk and Lennard-Jones⁵⁴ demonstrated that clinical improvement may occur in about 25% of patients treated with a dose of azathioprine at 2 to 2.5 mg. per kg. Uncontrolled trials have demonstrated a favorable response to 6-mercaptopurine (6-MP) in 64% to 70% of patients with refractory ulcerative colitis.⁸¹ Because these drugs do not produce a clinical response for several months, they have no role in the treatment of acute flares of ulcerative colitis. Cyclosporine (CS), which has a more rapid onset of action, has been advocated for the treatment of severe, refractory acute ulcerative colitis. Both uncontrolled trials and one controlled study suggest that high-dose CS is efficacious for severe ulcerative colitis. There is, however, significant theoretical risk of irreversible CS-associated nephropathy following treatment with high-dose CS. Severe infectious complications may also occur.⁹² A trial of 6-MP or CS may be warranted when steroids and sulfasalazine have failed, when the disease is confined to the left side of the colon or rectum, when the patient is compliant, and when there is no absolute indication for immediate surgical therapy.⁸⁰ However, before prescribing these immunosuppressive agents, one must be fully familiar with the dosing, monitoring, toxicity, and possible induction of lymphoma or other malignancies associated with these drugs.

Although widely prescribed for both ulcerative colitis and Crohn's disease, metronidazole and other antibiotics have no proven value in the treatment of inflammatory bowel disease.

The major therapeutic problem between acute episodes is control of diarrhea and maintenance of nutrition. Diet therapy is

no longer recommended, and patients are encouraged to eat a substantial diet of their choice. Milk products are to be avoided only if they cause problems such as increasing diarrhea or cramps (as they may in about half of patients with ulcerative colitis). The reason for this is not clear but relates to something specific in cow's milk rather than to the lactase deficiency that exists in many patients with ulcerative colitis. Opiates such as codeine or paregoric should be avoided. Nocturnal diarrhea can be controlled by anticholinergics or diphenoxylate with atropine. The synthetic peripheral-acting opioid loperamide may be more effective than diphenoxylate in this situation and avoids the atropine side effect associated with this drug.⁷⁴ Stool bulk formers, such as psyllium, are also helpful. Finally, the importance of rest and peace of mind cannot be overemphasized. Patients are advised to remain at rest during episodes of exacerbation.

INDICATIONS FOR SURGICAL TREATMENT

Since total removal of the colon and rectum (proctocolectomy) cures ulcerative colitis, one might reasonably ask why all patients with established chronicity are not so treated. The incidence of surgical intervention appears to be related to the availability of skilled and knowledgeable gastrointestinal surgeons and enlightened physicians. For example, the clinic at Leeds offers surgical care to approximately half of its patient population,³⁸ whereas in another center the reported operative rate is below 10%.³⁵ There are several well-identified complications that require urgent operation for survival.³⁶ These include massive, unrelenting hemorrhage; toxic megacolon with impending or frank perforation; fulminating acute ulcerative colitis that is unresponsive to steroid therapy; obstruction from stricture; and suspicion or demonstration of colonic cancer. Surgical therapy is also recommended in children who fail to mature at an acceptable rate. The largest number of colectomies for ulcerative colitis are performed for less dramatic indications, as the disease enters an intractable chronic phase and becomes both a physical and a social burden to the patient.

Acute perforation occurs infrequently, with the incidence directly related to both the severity of the initial episode and the extent of the disease in the bowel. Although the overall incidence of perforation during a first attack is less than 4%, if it is severe, the incidence rises to 9.7%. If the total colon is involved, the perforation rate is 14.6%, and if the attack is both severe and involves the total colon, it increases to 19.2%.³⁷

Obstruction caused by benign stricture formation occurs in 11% of patients, 34% of these occurring in the rectum.¹⁹ They usually follow submucosal fibrosis and occasionally mucosal hyperplasia. Although they do not usually cause acute obstruction, the lesions must be differentiated from carcinoma by biopsy or excision, and particular attention should be given to excluding Crohn's disease. Strictures caused by carcinoma are less common than those caused by benign disease and are more prone to perforate.

Massive hemorrhage secondary to ulcerative colitis is rare, occurring in less than 1% of patients.³⁷ Prompt surgical intervention is indicated after hemodynamic stabilization. More than 50% of patients with acute colonic bleeding have toxic megacolon, so one should be suspicious of the coexistence of the two complications. Uncontrollable hemorrhage from the entire colorectal mucosa may be the one clear indication for emergency proctocolectomy. If possible, the rectum should be spared for later mucosal proctectomy with ileoanal anastomosis.

Acute toxic megacolon can occur in both ulcerative colitis and Crohn's disease. Its incidence is between 6% and 13% in patients with ulcerative colitis.³⁰ Patients usually present clinically with the onset of abdominal pain and severe diarrhea (greater than 10 stools per day), followed by abdominal distention and generalized tenderness. Once megacolon and toxicity develop, fever, leukocytosis, tachycardia, pallor, lethargy, and shock ensue. It is important to note that any of these manifestations can be masked by chronic steroid use and the generally poor nutritional condition of the patient. An abdominal radiograph usually shows dilation of the transverse and occasionally the sigmoid colon that is greater than 5 cm. and averages 9.2 cm. Thickening and nodularity of the bowel wall due to mucosal inflammation are also noted. Caprilli and colleagues¹⁰ reported abnormal gaseous distention of the small bowel in association with toxic megacolon; thus, this finding may be a useful predictor of its development in patients with severe colitis.

The morbidity and mortality for acute toxic megacolon remain high. Soyer and Aldrete¹⁰³ reported a series of 12 patients in which the incidence of postoperative sepsis was 50%, wound infection 58%, abscess of fistula 33%, and delayed wound healing 25%. Postoperative mortality ranges from 11% to 16%; for the subset of patients with perforation, mortality is 27% to 44%.^{42, 47} These data support the use of combined aggressive medical and surgical treatment of this disease.

Initial treatment for toxic megacolon includes intravenous fluid and electrolyte resuscitation, nasogastric suction, broad-spectrum antibiotics to include anaerobic and aerobic gram-negative coverage, and total parenteral nutrition to improve nutritional status. Proctoscopy may be helpful in determining the etiology of the attack, as may culture of the stool. Although the efficacy of steroids is still in question,⁶⁷ most patients presenting with toxic megacolon are already on steroid therapy and thus need stress doses of corticosteroids to prevent adrenal crisis. Most clinicians think that steroids help reduce the inflammation and may *cool down* an acute toxic episode in up to 50% of patients, although long-term remissions are not achieved.⁴⁰ Moreover, the short-term use of corticosteroids does not appear to increase surgical morbidity. Long-term use of larger doses, however, does increase the incidence of wound and septic complications. The authors agree with Fazio³⁰ that,

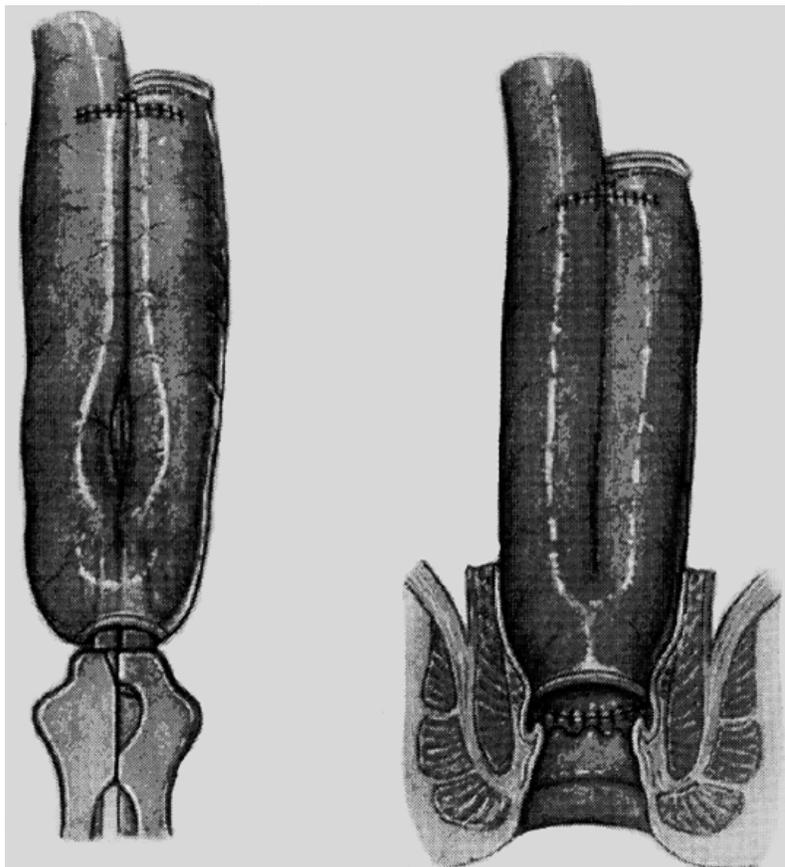

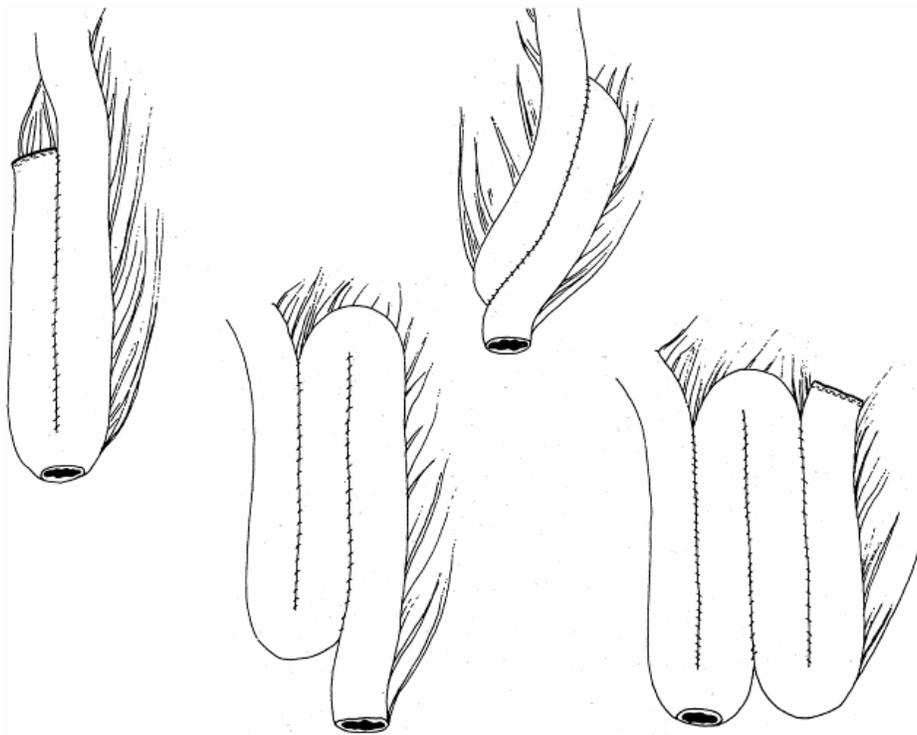

provided the patient is stable, initial medical trial is warranted in order to make the operation elective rather than urgent. If no clear response is obtained within 24 to 48 hours, surgical therapy is warranted. Larger doses of steroids after initial medical failure probably will not benefit the patient and, as noted, may be deleterious. During medical therapy, serial blood counts, serum electrolyte levels, and abdominal roentgenograms should be closely monitored.

In the presence of acute toxic megacolon caused by ulcerative colitis, surgical therapy can be associated with a high operative morbidity and mortality. Block and colleagues⁶ noted an overall mortality following emergency operation of 8.7%; 6.1% after total abdominal colectomy, and 14.7% after proctocolectomy. This suggests that more conservative surgical intervention is appropriate in the acute setting. Also, with the recent popularity of anal sphincter-sparing procedures, when operating for acute ulcerative colitis, one should weigh the possibility of subsequent surgical correction for continence. Specifically, leaving the rectum intact allows its use for subsequent surgical mucosal proctectomy and ileoanal anastomosis. When urgent colectomy is required, total abdominal colectomy, Brooke ileostomy, and Hartmann's pouch are appropriate.³⁹ 97 Although ileostomy alone for acute complications has been abandoned, it has been used in the recent past with good success by Turnbull and co-workers,¹¹¹ in combination with skin-level transverse and sigmoid colostomies, for toxic megacolon. This is a relatively simple procedure that spares such desperately ill patients a major operative intervention until their acute illness has subsided. Because the procedure involves only decompression of the colon and does not remove the acutely inflamed tissue, most surgeons prefer colon resection.

SURGICAL MANAGEMENT

Total proctocolectomy with permanent Brooke ileostomy offers definitive treatment for ulcerative colitis by eliminating diseased mucosa and the risk of malignant transformation. Nevertheless, it remains controversial and is poorly accepted by patients and their physicians. Patients with a permanent ileostomy are incontinent of gas and stool and must wear a collecting bag day and night. As many as 40% to 50% of patients with Brooke ileostomies have appliance-related problems, and the psychologic and social implications, particularly for young patients, are tremendous.⁷⁸ 89 Therefore, the search has continued for adequate alternatives to proctocolectomy and ileostomy.

Until recently, single-stage total proctocolectomy was the procedure of choice when complications of the disease were treated electively. This procedure is performed through a midline incision. The rectum is excised from the abdomen after mobilization and circumferential incision from the perineum. When cancer is not suspected, excision is performed rapidly, with division of the mesentery close to the bowel wall. This principle is especially important in the pelvic colon and rectum, where injury to the sacral parasympathetic nerves may lead to bladder and sexual dysfunction. Endorectal mucosal resection, as described later, appears to offer the best way to avoid such serious complications.³⁴ After standard proctocolectomy, management of the perineal wound is a problem, since chronic infection and poor healing may cause a lingering sinus tract between the buttocks. The authors' preference is to apply active closed drainage to this area for 3 to 5 days following operation. Gauze packing of the perineum should be reserved for pelvic hemorrhage that cannot otherwise be controlled. Perineal wound problems may be reduced by performing an intersphincteric proctectomy, which entails dissecting between the internal and external anal sphincter when removing the rectum, thus preserving the levator ani and external anal sphincter muscles. These muscles can then be included in the closure of the perineum. Using this technique, complete healing of the perineum approaches 95% at 6 months.

The most important modification of the operation was the creation of an ileal pouch or reservoir proximal to the ileoanal anastomosis.

The most frequent late complication in patients undergoing ileoanal anastomosis is ileal pouch dysfunction or pouchitis, which has been reported to occur in 10% to 50% of patients undergoing this procedure for ulcerative colitis. Pouchitis is an incompletely defined and poorly understood clinical syndrome consisting of increased stool frequency, watery stools, cramping, urgency, nocturnal leakage of stool, arthralgias, malaise, and fever. The syndrome is similar to that found in patients with Kock continent

ileostomy pouches. The etiology of this condition is unknown; speculations have included early Crohn's disease, bacterial overgrowth or bacterial dysbiosis, either primary or secondary malabsorption, stasis, ischemia, and nutritional or immune deficiencies.

Mortality for elective surgical therapy is in the range of 0% to 2%; for emergency operation, it is about 4% to 5%; and for toxic megacolon, it rises to 17%.⁵ These are remarkable statistics when one considers the debilitating nature of the disease and the fact that many patients have had long-term steroid therapy. The major complication in all reported series is sepsis, either in the wound or in the intra-abdominal cavity. There is little evidence that the development of more potent and specific antibiotics has significantly reduced the incidence of this complication; attention to the details of operative management continues to be the best way to ensure a smooth postoperative course. The most common late complication of resectional therapy with ileostomy or ileoanal anastomosis is intestinal obstruction, which occurs in about 10% of patients. Other bothersome but nonlethal complications following proctocolectomy include delay in perineal closure (25%), sexual dysfunction (5% to 10%), and renal stones (10%). Ileostomy dysfunction as a consequence of stenosis has been reduced to 2% by the Brooke-Turnbull ileostomy. Additional uncommon complications include prolapse, herniation, and ulceration of the stoma, which is usually a sign of the development of Crohn's disease within the ileal stoma. Whether the outcome following surgical therapy for Crohn's disease of the colon is as favorable as for ulcerative colitis continues to be a source of controversy.

The formation of social groups (ileostomy clubs) has provided an important mechanism for the education of patients by those who have already mastered the technique of ileostomy management. Some hospitals have enterostomal therapists. These professionals are highly skilled in dealing with the physical and emotional problems of stomal management. In institutions that perform a large number of ileal pouch operations, specialized patient-oriented support groups are essential.

OBTURATIVE ICTERUS

A obturative icterus is the type of icterus the reason of which is violation of patency of bilious ways as a result of their obstruction from within or external compression, or cicatrix narrowing.

Obstructive jaundice, also called post-hepatic jaundice, is caused by an interruption to the drainage of bile in the biliary system. The most common causes are gallstones in the common bile duct, and pancreatic cancer in the head of the pancreas. Also, a group of parasites known as "liver flukes" can live in the common bile duct, causing obstructive jaundice. Other causes include strictures of the common bile duct, biliary atresia, cholangiocarcinoma, pancreatitis and pancreatic pseudocysts. A rare cause of obstructive jaundice is Mirizzi's syndrome.

In complete obstruction of the bile duct, no urobilinogen is found in the urine, since bilirubin has no access to the intestine and it is in the intestine that bilirubin gets converted to urobilinogen to be later released into the general circulation. In this case,

presence of bilirubin (conjugated) in the urine without urine-urobilinogen suggests obstructive jaundice, either intra-hepatic or post-hepatic.

The presence of pale stools and dark urine suggests an obstructive or post-hepatic cause as normal feces get their color from bile pigments. However, although pale stools and dark urine are a feature of biliary obstruction, they can occur in many intra-hepatic illnesses and are therefore not a reliable clinical feature to distinguish obstruction from hepatic causes of jaundice.

Patients also can present with elevated serum cholesterol, and often complain of severe itching or "pruritus" because of the deposition of bile salts.

No single test can differentiate between various classifications of jaundice. A combination of liver function tests is essential to arrive at a diagnosis.

Etiology and pathogenesis

Obstruction of external bilious ducts can arise for many reasons: as a result of inflammatory processes of surrounding organs (pancreas, paracholedochus lymphatic knots), damage of walls of ducts during operations. However, in most cases it is a gallstone disease, choledocholithiasis and related to them scar changes of large papilla of duodenum. The second place among the reasons of obturation icterus is taken by tumours of which the cancer of head of pancreas and large papilla of duodenum is most widespread.

Disregarding the fact that each of the adopted diseases has special clinical passing, obturation of bilious ducts causes the changes which have general character. At complete blockade of external bilious ducts and growth of pressure higher than 300 mm of waters. an item or 2,94 kPa (after a norm — not higher 150 mm or 1,47 kPa) in them, excretions of bile in bilious capillaries are halted. It is conditioned by the fact that the secretory mechanism of hepatic cells (hepatocyte) can not overcome such resistance. Thus bile through the blasted particles and lymphatic and vein vessels of liver gets into blood, causing the syndrome of mechanical icterus.

Classification

(by O.O. Shalimov, 1993)

Obturation icteruses are divided into:

I. According to the level of barrier:

- 1) obstruction of distal parts of general bilious duct;
- 2) obstruction of supraduodenal part of general bilious duct;
- 3) obstruction of initial part of general hepatic duct and fork of hepatic ducts.

II. According to the etiologic factor:

1) conditioned by obturation by bilious concrement, strange bodies, grume of blood during hemobilia, parasite, iatrogenic influence during operation;

2) obstruction at the diseases of wall of bilious ways — innate anomalies (hypoplasia, cysts and atresia), inflammatory diseases (obstructing papillitis and cholangitis), scar strictures (posttraumatic and inflammatory), bilious ways tumours of high quality;

3) obstruction caused by the out-of-ducts diseases, that pull them in the process (tubular stenosis of general bilious duct of pancreatic genesis, ulcerous disease of duodenum, paracholedocheal lymphadenitis, peritoneal commissures).

Except that, *according to the duration the disease is distinguished:*

- 1) acute obturative icterus, that to 10 days last;
- 2) protracted, that proceeds from 10 to 30 days;
- 3) chronic, that more than a month lasts.

Symptoms and clinical passing

The clinical picture of obturative icterus is founded, first of all, on the symptoms caused by violation of outflow of bile.

A *pain syndrome* is a characteristic accompaniment of gallstone disease and choledocholithiasis, that run with the attacks of hepatic colic. However, pain syndrome at these pathologies can often be not acutely expressed or quite absent. Pain is often observed at stricture of bilious ducts, but it is not quite typical of patients with the cancer of bile ducts.

An *icterus* is an important sign of obstruction of bilious ways, speed of origin and intensity of which depend on whether well-kept or broken passage of bile in intestine is. For choledocholithiasis with “valve” character of concretions transitional passing of icterus is inherent, and for cancer it is more proof and progressive.

The itch of body is a frequent accompaniment of icterus, that arises up as a result of action of bilious acids. It is thus needed to remember, that under the conditions of damage by tumour the itch which proceeds for a long time appears at first, only later there appears icterus. During examination the yellowness of sclera, mucus shells and skin are observed. At the same time patients specify urines and discolorations of excrement darkening (“argil”). The increase of temperature of body testifies the development of cholangitis, metastasis of tumors in liver is rarer.

In emaciated patients in right hypochondrium it is sometimes possible to see formation, that moves during breathing, probably it is a gall-bladder. If it is elastic, unpainful and it is accompanied by icterus (*the Courvoisier's symptom*), a patient then suffers from cancer of head of pancreas or distal parts of general bilious ducts.

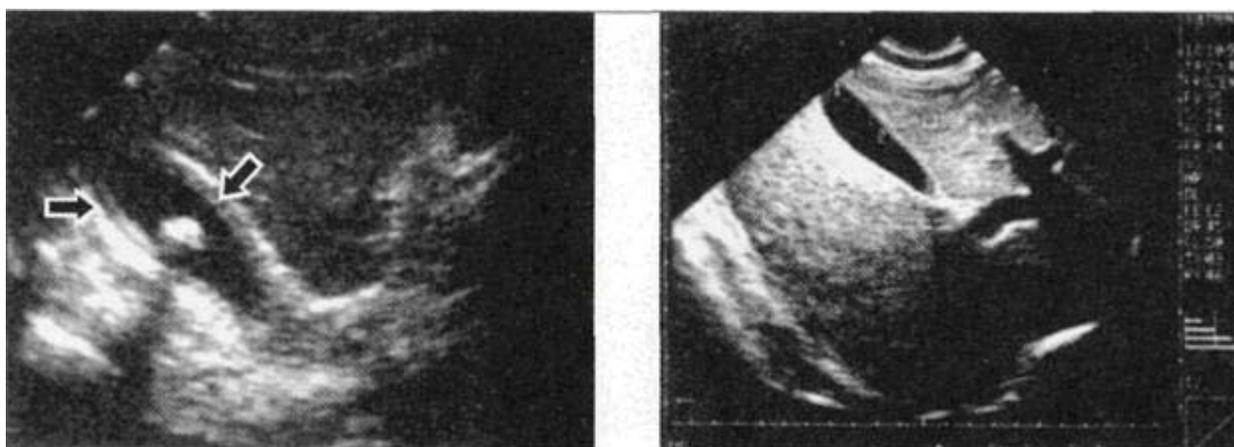

However, it is necessary to warn, that determination of character of icterus only on the basis of clinical signs to a great extent carries only conditional character. It must be connected to the fact that at parenchymatous hepatitis expressed cholestasis often is observed, and at obturation icterus damage of hepatic cells is characteristic. Therefore for establishment of diagnosis of obturative icterus, except for clinical information, special methods of examination are necessary.

Laboratory information. For obturative icterus a cholestatic syndrome with high bilirubinemia mainly due to direct fraction of bilirubin and bilirubinuria is characteristic,

by absence of urobilin in urine and stercobilin in excrement, by high activity of alkaline phosphatase at the insignificantly promoted transaminase activity and negative thymol test.

At growth of hyperbilirubinemia this intercommunication changes in the side of increase of direct bilirubin. In general analysis of blood unsteady changes are which depend on the degree of intoxication or occult bleeding (in cancer patients).

Sonography examination allows to define the sizes of liver, gall-bladder, state of internal and external hepatic ducts, presence and degree of expansion or narrowing, presence or absence of concrement and new formation in hepatic parenchyma.

Sonography examination

Duodenography in the conditions of artificial low blood pressure apply for the exposure of pathology of organs of pancreatoduodenal area.

Retrograde cholangiopancreatography enables to examine stomach, duodenum by endoscope, to conduct biopsy, to extract bile and pancreatic juice for examination, to get the roentgenologic image of ducts: external and internal hepatic ducts and duct of pancreas, and in a number of cases at presence of concrement to conduct endoscopic papillotomy and extraction of them through papillotomic access.

Retrograde cholangiopancreatography

Percutaneous transhepatic cholangioduodenography is used for the exposure of pathology of bilious ways. It to certain extent allows to expose both character and localization of obturation in the area of hepatoduodenal area.

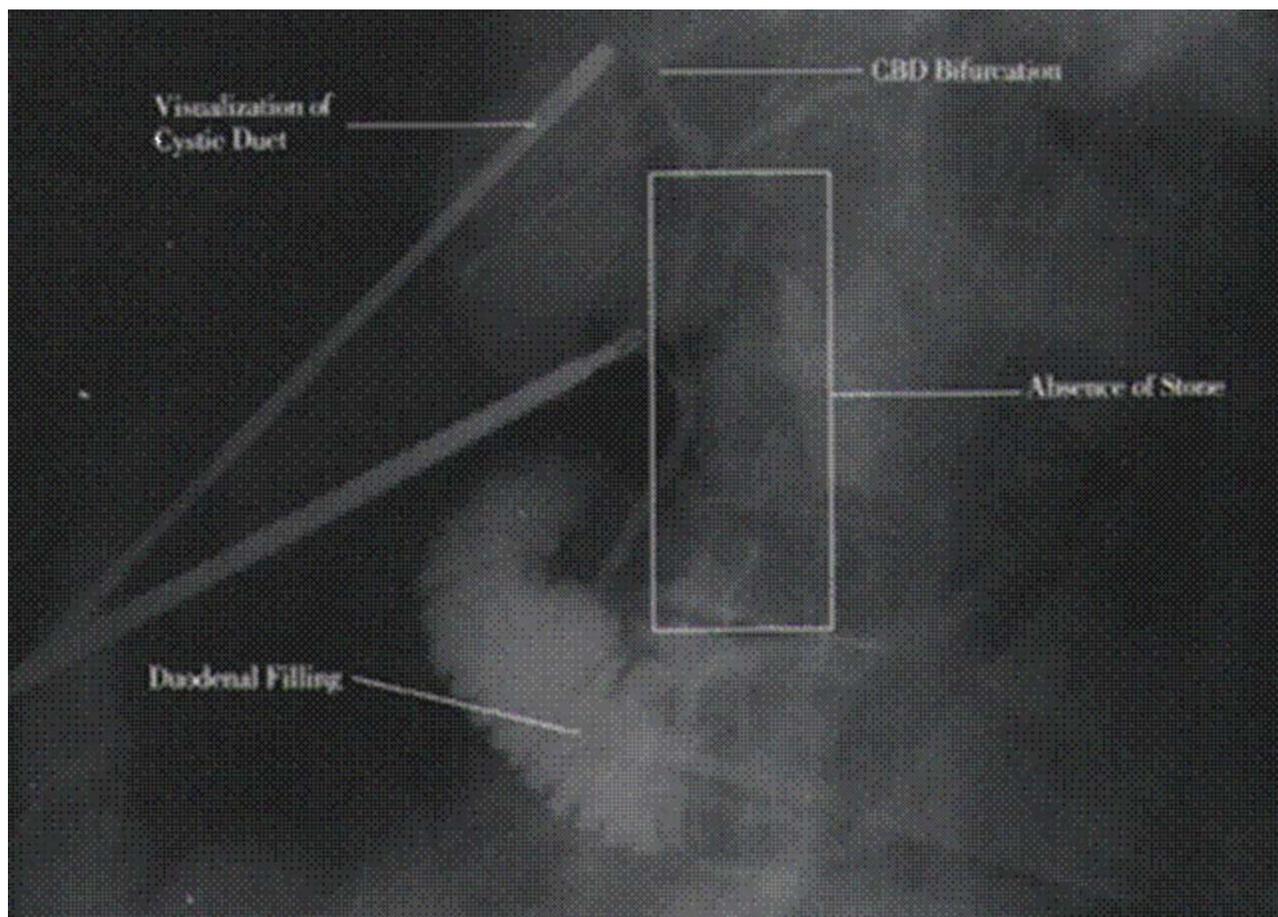

Laparoscopy is a diagnostic remedy that enables to define the sizes of liver, its colouring, character of surface, presence of metastases, size and degree of tension of gall-bladder. Under the control laparoscope it is possible to execute puncture of gall-bladder and conduct cholecystocholangiography and cholecystostomy.

The scanning of liver creates terms in which it is possible to expose the primary and metastatic tumours of liver or other pathology of organ.

Intraoperative cholangiography

Intraoperative cholangiography is contrasting of bilious ducts by introduction iodine preparations (bilignost, cardiost, verigraphine in the concentration 30–33 %) in them through stump of cystic duct of soluble. Cholangiography enables to define the width of ducts, presence or absence of concrement in them, and also cone-shaped narrowing of terminal part of choledochus characteristic of stenosis.

Cholangiomanometry

Cholangiomanometry is a method, that allows to expose the degree of bilious hypertension in ducts by the water manometer of the Valdmann device. Normal pressure is within the limits of 80–120 mm of waters. item (0,78–1,17 kPa), and the higher testifies to bilious hypertension.

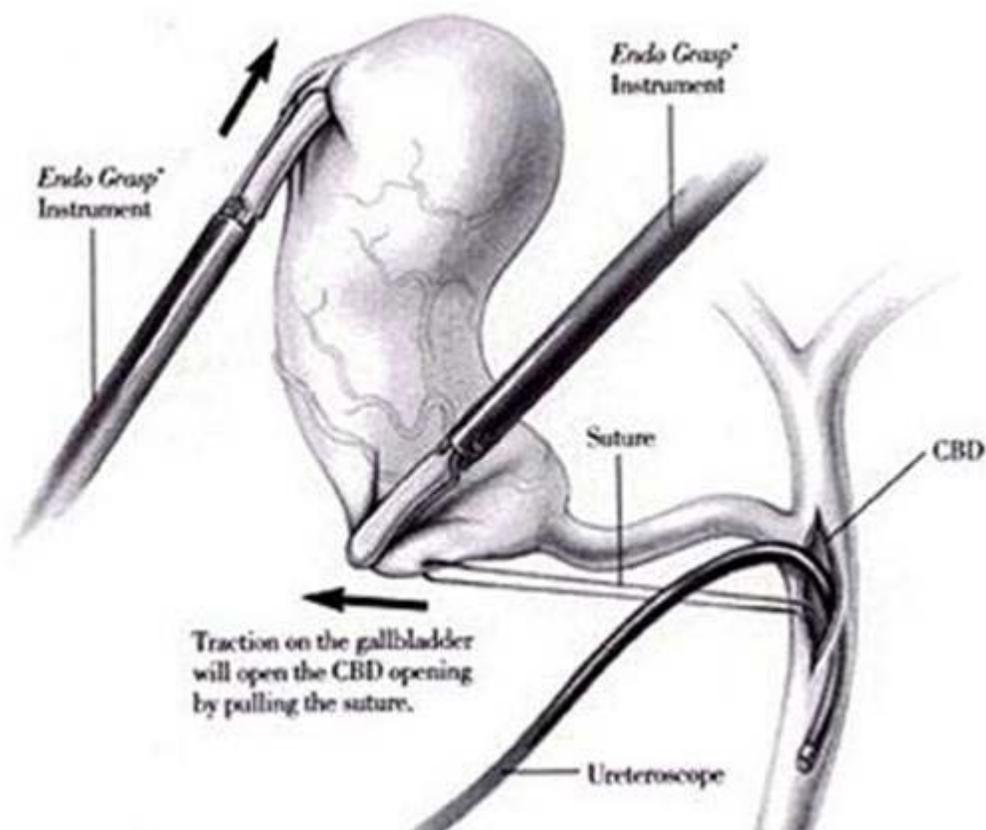

Debitomanometry

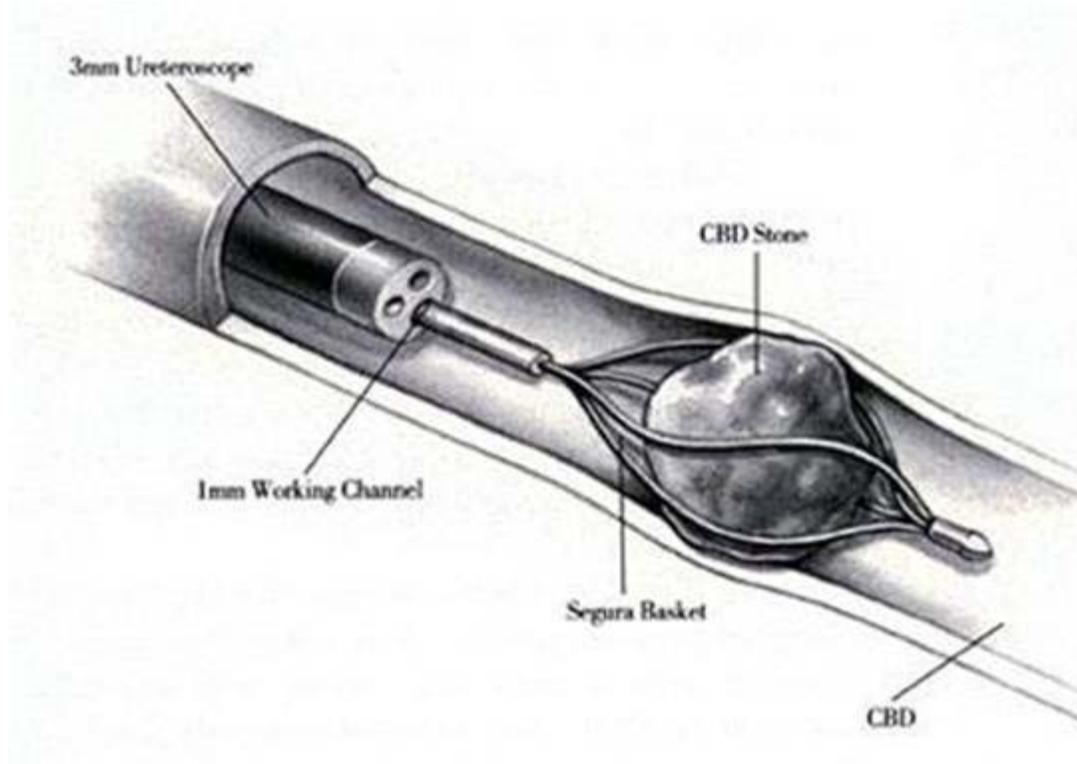

Debitomanometry is a method of determination of amount of liquid at perfusion through the Vater's papilla under permanent pressure for time unit (1 min). In patients with normal passing of bilious ducts the size to the debit of liquid at pressure 150 mmwater.col. (1,47 kPa) makes from 5 to 8 ml/min. In similar terms, at their obturation,

this debit diminishes, and at insufficiency of sphincteric device — is increased. However, much cholangio- and debitomanometry at operations in patients with acute cholecystitis are applied rarely. These methods of examination are used for chronic cholecystitis mainly.

Choledochoscopy

Choledochoscopy is a method of endoscopy examination of bilious ducts by choledochoscope during choledochostomy.

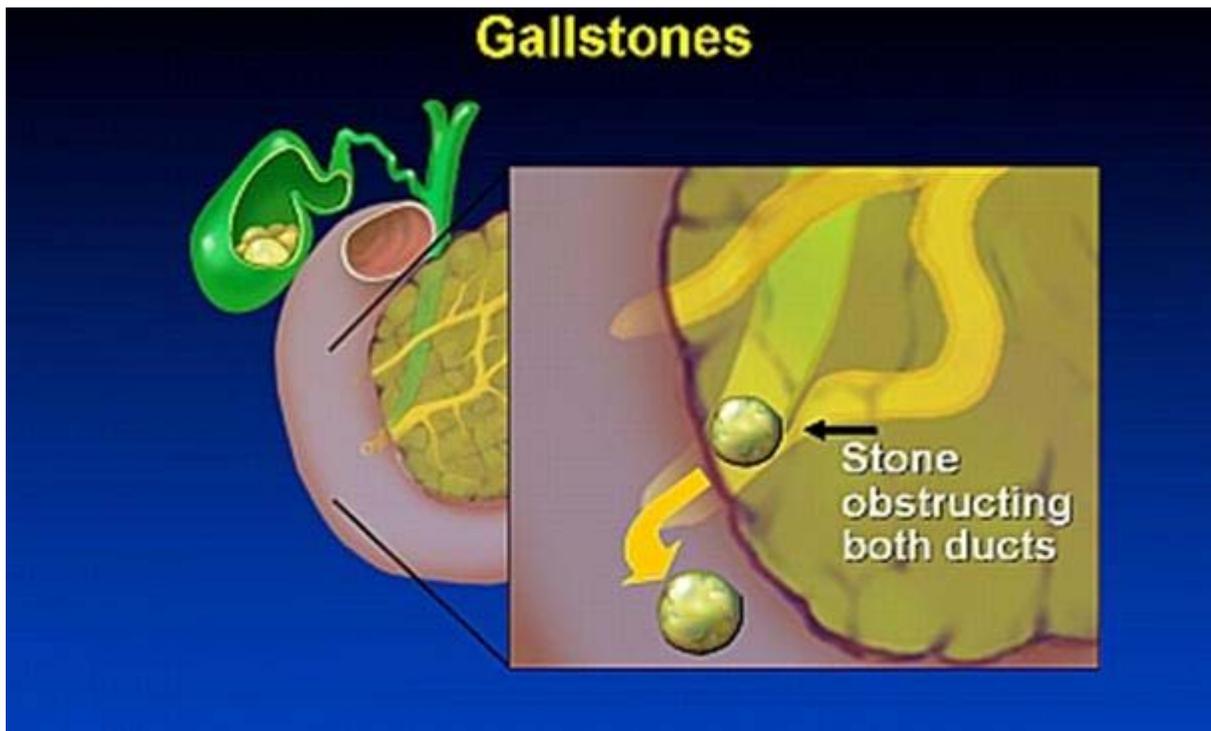

The Choledochoscopy. Retrieving the CBD Stones

Variants of clinical passing and complications

Clinical passing of icterus almost always depends on the reasons of obturation of bilious duct. In patients with tumours an icterus gradually makes progress and results in complete and permanent obturation, together with that, at presence of concrement in bilious ducts intensity of icterus can vary. Its temporal, transitional character takes place at choledocholithiasis, acute cholecystitis or pancreatitis.

On this background in the case of joining of infection cholangitis, abscess formation in liver and sepsis quickly develops. In other case there can be the bleeding (more frequent gastroduodenal) or hepatic-kidney insufficiency.

In some patients internal bilious fistula, which clinically is proof cholangitis, appears as a result of inflammatory and necrosis processes. On the sciagram survey of organs of abdominal cavity in such cases it is possible to see air in the hepatic ducts, the so called “aerocholia”.

Diagnosis program

1. Anamnesis and physical methods of examination.
2. General analysis of blood and urine.
3. Analysis of urine on diastasis.
4. Biochemical blood test (bilirubin, urea, albumin-globulin coefficient, blood on an australian antigen, amylase, alanine aminotransferase, asparaginase, alkaline phosphatase).
5. Coagulogram.
6. Sonography.

7. Endoscopy.
8. Retrograde cholangiopancreatography.
9. Laparoscopy with biopsy.
10. Percutaneous transhepatic cholangioduodenography.
11. Computer tomography.

CLASSIFYING THE BILIARY STONE PATIENT

Asymptomatic Cholelithiasis	Incidental Finding on Sonogram
Acute Cholecystitis	Cholelithiasis on Sonogram, clinical Cholecystitis diagnosis or Positive Pipida Scan
Symptomatic Cholelithiasis	Positive Sonogram, normal Liver Function Tests
Cholelithiasis with Suspected Choledocholithiasis	Abnormal Liver Function Tests (Serum Transaminases elevation or Bilirubin >3.0, gallstone pancreatitis)
Cholelithiasis with Choledocholithiasis	CBD Stone on Sonogram, MR Cholangiography or Jaundice
Cholelithiasis with Resolving Gallstone Pancreatitis	Pancreatitis on Sonogram, CT or MER Cholangiography or clinically, Documented High Serum Amylase and Lipase - WITH - Decreasing Serum Pancreatic Enzymes after initial attack

IDENTIFYING PATIENTS WITH CHOLEDOCHOLITHIASIS

MANAGEMENT PROTOCOLS FOR UNCOMPLICATED BILIARY STONE DISEASES	PROPOSED MANAGEMENT
Asymptomatic Cholelithiasis	No Surgical Intervention
Asymptomatic Cholelithiasis in Diabetic Patients	No Surgical Intervention
Symptomatic Cholelithiasis or Acute Cholecystitis	LapChole
Symptomatic Cholelithiasis with Suspected Choledocholithiasis	LapChole with Insertion of Cystic Duct Cannula with Cholangiography, if Choledocholithiasis, postop ERCP
Symptomatic Cholelithiasis with Choledocholithiasis	LapChole with Insertion of Cystic Duct Cannula with Cholangiography, if Choledocholithiasis, postop ERCP
Cholelithiasis with Resolving Pancreatitis	LapChole with Insertion of Cystic Duct Cannula with Cholangiography, if Choledocholithiasis, postop ERCP
Cholelithiasis with Unresolved Pancreatitis	After acute phase subsides, MRI Cholangiography or ERC, if Choledocholithiasis ERCP followed by LapChole

Asymptomatic Gallbladder Polyps	No Surgical Intervention
Symptomatic Gallbladder Polyps	LapChole
Severe, Gangrenous Cholecystitis with Subhepatic Phlegmon	LapChole, if not safely feasible, Anterior-subtotal LapChole
Post Cholecystectomy (Lap or open) Suspected Choledocholithiasis	MR Cholangiogram or ERC
Post Cholecystectomy (Lap or open) Choledocholithiasis	ERCP, if failure Laparoscopic Common Bile Duct Exploration.

Differential diagnostics

The main task of differential diagnostics of icterus is a determination of surgical or unsurgical nature. In fact the decision of this question enables to take the amount of doubtful diagnostic laparotomy to the minimum.

Taking it into account, it is always needed to remember, that among the diseases which can show up as icterus, viral hepatitis take a considerable place, mostly its cholestatic form, new formation of hepatopancreatoduodenal area and gallstone disease.

Viral hepatitis is one of many clinical forms of viral infection the characteristic feature of which is proof and protracted cholestasis. The disease carries the protracted character. For the pre-icteric period of hepatitis the inherent clinical triad is the itch of skin, fever, arthralgia. Approximately in half of patients it is possible to palpate a spleen

and moderately increased liver. Laboratory the increase of activity of alanine aminotransferase and aspartate aminotransferase and positive thymol test are determined. Also the reaction on bilious pigments, bilious acids and urobilin in urine is positive.

Difficult from the point of view of verification of diagnosis it is needed to count combination of such diseases, as viral hepatitis in patients with cholelithiasis or obturation by tumour in patients who suffer from alcoholism.

Taking into account information of previous methods, only successive application of sonography, endoscopic retrograde pancreatocholangiography or percutaneous transhepatic cholangioduodenography and laparoscopy, allows maximally exactly to set diagnosis. Thus on the first stage it is needed to use the non-invasive methods of diagnostics (sonography), on the second useful are invasive methods of the direct contrasting of bilious ways (retrograde endoscopic cholangiopancreatography, percutaneous transhepatic cholangiopancreatography) which in the case of necessity can transform from diagnostic into medical (endoscopic papillosphincterotomy at stenotic papillitis and choledocholithiasis, dilatation and endoprosthesis replacement of bilious ways at cicatrix stricture and tumours of bilious ducts).

Table of diagnostic tests

Function test	Pre-hepatic Jaundice	Hepatic Jaundice	Post-hepatic Jaundice
Total bilirubin	Normal / Increased	Increased	
Conjugated bilirubin	Normal	Increased	Increased
Unconjugated bilirubin	Normal / Increased	Increased	Normal
Urobilinogen	Normal / Increased	Increased	Decreased / Negative

Urine Color	Normal	Dark (urobilinogen + conjugated bilirubin)	Dark (conjugated bilirubin)
Stool Color	Normal	Normal/Pale	Pale
Alkaline phosphatase levels	Normal	Increased	
Alanine transferase and Aspartate transferase levels		Increased	
Conjugated Bilirubin in Urine	Not Present	Present	
Splenomegaly	Present	Present	Absent

Tactics and choice of treatment method

Final diagnosis, that maximally represents the character of obturative icterus and volume of the most operative treatment, as a rule, is set only during the intraoperative revision. At determination of medical tactics and choice of method of surgical treatment of such icterus it is needed also to objectively estimate weight of general condition of patients. For this purpose it is necessary to take into account the character of icterus, stage of hepatic insufficiency keeping in mind the duration and intensity of cholestasis, presence and character of cholangitis, weight and expression of accompanying pathology, eyelids of patients.

Medical measures in preoperative period must be directed on correction of violations of homeostasis, hemocoagulation (aminocapronic acid, vicasol, 10 % solution of chlorous calcium, one-group fresh-frozen plasma, inhibitor of protease), improvement

of microcirculation in liver (10 % solution of glucose with insulin, reopolyhucine, hepatoprotectors), deoxidation organism (neohemodes, enterosorbent), biliary decompression (percutaneous transhepatic cholangiopancreatocholangiostomy or cholecystostomy), antibacterial therapy at the phenomena of cholangitis taking into account the character of sown microflora and its sensitiveness to the antibiotics and vitamins.

In case of the gallstone disease complicated by choledocholithiasis and mechanical icterus, the volume of surgical interference must include: cholecystectomy, choledocholithotomy and external or internal draining of general bilious duct. At presence of the special apparatus in case of choledocholithiasis complicated by mechanical icterus, two-stage tactics of treatment is the method of choice — endoscopic papillosphincterotomy with subsequent extraction of concrement and their lithotripsy on the first stage and cholecystectomy — on the second. Endoscopic papillosphincterotomy is the method of choice at treatment of remaining (after cholecystectomy) choledocholithiasis.

For declining patients with heavy accompanying pathology combination of extracorporal shock-wave lithotripsy with endoscopic sanitation of hepaticocholedochus is an effective method. For some of them at the high risk of operative treatment and small concrement of general bilious duct (by the diameter of to 10 mm) endoscopic papillotomy can be effective.

At malignant new formations of bile-excreting ways with a obturative icterus, depending on distribution of tumour process, radical or palliative operative treatment are executed.

For patients with the tumours of head of pancreas, large papilla of duodenum and terminal part of choledochus, that is exposed to radical operation, a pancreatoduodenal resection is performed, thus in the case of high icterus on the first stage of treatment bilious decompression of the hepatobiliary system is performed (percutaneous hepaticocholangiostomy, forming of biliary-enteric anastomosis). A pancreatoduodenal resection is executed on the second stage, in 30–35 days after imposition of bile-excreting anastomosis and liquidation of icterus.

Palliative bile-excreting operations at the neglected tumours are mainly directed on liquidation of obstruction of bilious ducts. In such patients, as a rule, roundabout biliary-enteric anastomosis is imposed: cholecystoentero- or hepaticojejunostomy. If through technical difficulties and bad general condition of patients it is impossible to execute this, external draining of bilious ways is applied.

[video](#)

LAPAROSCOPIC MANAGEMENT OF BILIARY STONE DISEASE

The management of biliary stones diseases has dramatically changed with the advent of the Laparoscopic Cholecystectomy. It has now become a true outpatient laparoscopic procedure with negligible morbidity.

In the past few years, our surgical team has designed and revised numerous management protocols for various clinical settings effectively achieving impressive improvements in our surgical performance for the treatment of biliary stone diseases. This chapter will describe these management protocols and our latest technical updates.

The original Laparoscopic Cholecystectomy technique has undergone a vast maturation process over the past decade. Various technical steps has been modified and adapted to improve surgical performance and clinical outcome. As a result, nowadays, most surgeons in the Western World can safely perform a Laparoscopic Cholecystectomy with a minimal conversion rate.

ROUTINE INTRA-OPERATIVE CHOLANGIOGRAPHY

Routine operative cholangiography is recommended by most laparoscopic authors in the United States. However, recent reports demonstrate it does not significantly decrease the rate of common bile duct injury in cases where the anatomy is well-identified. Our recommendation is that routine intraoperative cholangiography should be performed by inexperienced laparoscopic surgeons and in cases where the

anatomy is not well-defined.

IDENTIFYING PATIENTS WITH CHOLEDOCHOLITHIASIS

In order to achieve the level of Maximum Surgical Performance with this procedure, patients at high risk of presenting with Common Bile Duct Stones need to be identified pre-operatively. The simplest methods to initially identify these patients are:

- 1) History and Physical Examination,
- 2) Liver Function Studies,
- 3) Sonographic Findings.

Patients with a recent history of gallstone pancreatitis, jaundice, or presenting with such symptoms are at a high risk of having common bile duct pathology; the same is valid for patients with altered liver function studies. The most accurate studies are the Serum Transaminases (SGOT, SGPT). Elevations of these enzymes over 20% of their normal values are significant. But patients with severe, acute cholecystitis can occasionally generate such elevations. Also, extreme elevations of these two enzymes could represent hepatocytes necrosis as seen in hepatitis. The bilirubin level may also be elevated in certain patients with acute cholecystitis, but elevations above 2.5 or 3.0 mg/dl could identify a patient with choledocholithiasis. Finally, we find the enzymes LDH and GGTP to have no real specific value in this clinical setting.

It is interesting that in spite of our intensive efforts to identify Common Bile Duct pathology preoperatively, missed Common Bile Duct Stones are found in 1.92% of all patients. Of these patients 76% will require additional surgical intervention (ERCP).

ROUTINE INTRA-OPERATIVE CHOLANGIOGRAPHY

This technology is being used with increasing frequency in our surgical service to

identify patients with choledocholithiasis. A GE Magnetic Resonance machine was used for all studies. To date the specificity and accuracy of these studies in our services is 98.2% for common bile duct stones over 1 mm in size.

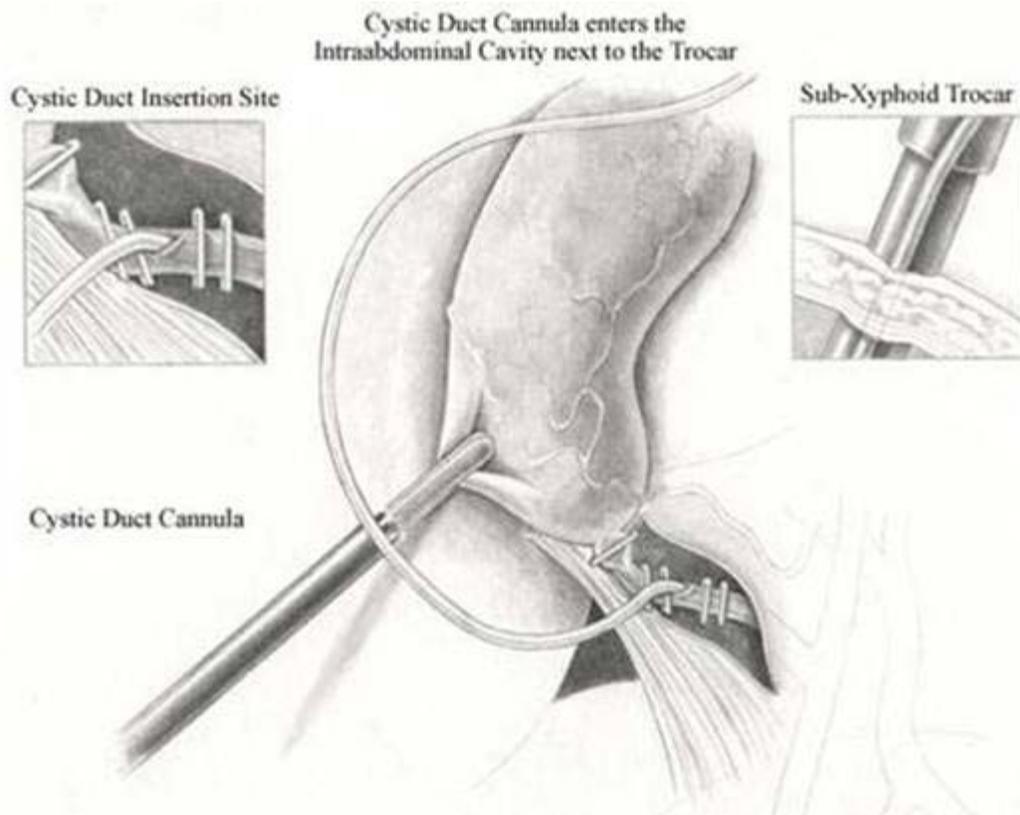

ROUTINE INTRA-OPERATIVE CHOLANGIO-SONOGRAPHY

Intra-operative cholangio-sonography is being used in many medical centers to rule out common bile duct stone. Although this modality was used on numerous occasions, we found it too time consuming to be used on a routine basis.

Methods of external draining

External draining of bilious ducts can be executed by such methods:

- 1) by Pickovskyy – polyethylene catheter which is entered through stump of cystic duct;
- 2) by Kehr — by T-shaped latex drainage;
- 3) by Vyshnevsky — drainage to the gate of liver;
- 4) by Holsted.

Indication to external draining: 1) after diagnostic choledochostomy; 2) after choledocholytotomy; 3) at accompanying cholangitis, pancreatitis.

For internal draining of bilious ducts are applied by transduodenal sphincteroplasty or choledochoduodenostomy. At acute cholecystitis these operations are executed under absolute indications. Such is the structure and tired out concrement of large duodenal papilla, multiple choledocholithiasis, presence of putty in ducts or their expansion.

The best method of renewal of normal outflow of bile at stenosis and jammed concrement of large duodenal papilla is considered its transduodenal dissection. This method of internal draining allows to liquidate the reason of impassability of ducts and store the physiology passage of bile in intestine.

At forming choledochoduodenoanastomosis most distribution acquired methods by Jurash, Flerken, Finsterer and Kirschner's methods. The principle difference of them consists in correlations of direction of cut of choledochus and duodenum (longitudinal, slanting, transversal). The width of anastomosis must be not less than 2,5–3 cm. It is thus

needed to remember, that imposition of choledochoduodenoanastomosis in the conditions of presence of inflammatory process in abdominal cavity always needs to be connected with external draining of choledochus by Pikovskyy (double draining).

Portal hypertension syndrome

Portal hypertension refers to abnormally high pressure in the hepatic portal vein. It is defined as a portal pressure of 12 mm Hg or more (compared with the normal 5-10 mm Hg).

See related articles dealing with ascites, cirrhosis, hepatic encephalopathy, hepatorenal syndrome, liver failure and oesophageal varices, listed below under 'Complications'.

Etiology

Causes can be divided into: prehepatic, hepatic and posthepatic. Cirrhosis is a common cause.

Causes of portal hypertension

Prehepatic - blockage of the portal vein before the liver

Congenital atresia or stenosis.

Portal-vein thrombosis (idiopathic, umbilical and portal sepsis, malignancy, hypercoagulable states, pancreatitis).

Splenic vein thrombosis.

Extrinsic compression, eg tumours.

Hepatic

Cirrhosis.

Chronic hepatitis.

Schistosomiasis.

Myeloproliferative diseases.

Idiopathic portal hypertension.

Granulomata, eg sarcoid.

Nodular (nodular regenerative hyperplasia, partial nodular transformation).

Toxins (arsenic, vinyl chloride).

Fibropolycystic disease (including congenital hepatic fibrosis).

Posthepatic - blockage of hepatic veins or venules

Budd-Chiari syndrome (hepatic vein obstruction).

Constrictive pericarditis.

Right heart failure.

Veno-occlusive disease of the smaller hepatic veins/venules (due to ingestion of pyrrolizidine alkaloids; antileukaemic drugs, radiation).

Sclerosing hyaline necrosis.

Other causes

Increased hepatic blood flow:

Increased splenic blood flow, eg massive splenomegaly.

Hepatoportal arteriovenous fistula.

Idiopathic (a diagnosis of exclusion).

Left-sided (sinistral) portal hypertension

Rare. It is confined to the left side of the portal system.

It may present as bleeding from gastric varices.

Usually it is due to pathology involving the splenic vein or the pancreas.

Pathophysiology

Portal hypertension develops due to:

Increased vascular resistance in the portal venous system - from various mechanical causes (above), and also as an active process in which liver damage activates stellate cells and myofibroblasts, contributing to the abnormal blood flow patterns.

Increased blood flow in the portal veins - from splanchnic arteriolar vasodilatation, caused by an excessive release of endogenous vasodilators.

The raised portal pressure opens up venous collaterals, connecting the portal and systemic venous systems. These occur in various sites:

Gastro-oesophageal junction - producing varices which are superficial and easily bleed.

Anterior abdominal wall:

Via the umbilical vein - visible as caput medusae radiating from the umbilicus.

May also occur where adhesions exist between abdominal viscera and the parietal peritoneum, or at sites of stomas or previous surgery.

Anorectal junction - rarely cause bleeding.

Veins from retroperitoneal viscera - communicate with systemic veins on the posterior abdominal wall.

Other patterns of blood flow:

If individual tributaries of the portal vein are thrombosed, this causes local venous hypertension. With splenic vein block, oesophageal and gastric varices may result.

In Budd-Chiari syndrome (hepatic vein occlusion), collaterals open up within the liver; blood tends to be diverted through the caudate lobe whose short hepatic veins drain directly into the inferior vena cava.

Portosystemic venous anastomoses can cause encephalopathy, possibly due to

various 'toxins' bypassing the liver's 'detoxification' process.

Circulatory disturbances:

Portal hypertension and cirrhosis produce a hyperdynamic circulation, with splanchnic vasodilatation, increased cardiac output, arterial hypotension, and hypervolaemia.

There is salt and water retention, ascites and hyponatraemia.

Presentation

History

For causes of liver disease:

History of jaundice.

Alcohol consumption.

Blood transfusion, especially abroad; lifestyles that predispose to hepatitis B or hepatitis C.

Family history, eg Wilson's disease or hereditary haemochromatosis.

For complications of portal hypertension:

Haematemesis or melaena - suggest bleeding varices.

Lethargy, irritability and changes in sleep pattern - suggest encephalopathy.

Increased abdominal girth, weight gain - suggest ascites.

Abdominal pain and fever - suggest spontaneous bacterial peritonitis.

Examination

Signs of portal hypertension:

Dilated veins in the anterior abdominal wall and caput medusae (tortuous collaterals around the umbilicus). A venous hum, loudest during inspiration, is sometimes heard over large upper abdominal collaterals.

Splenomegaly.

Ascites.

Signs of liver disease:

Jaundice, spider naevi, palmar erythema.

Confusion, liver flap and fetor hepaticus are signs of encephalopathy.

Signs of hyperdynamic circulation: bounding pulse, low blood pressure, warm peripheries.

Enlarged or small liver.

Gynaecomastia and testicular atrophy.

Investigations

Blood tests:

LFTs, U&Es, glucose, FBC, clotting screen.

Investigations for liver disease if the cause not known, e.g ferritin (for haemochromatosis), hepatitis serology, autoantibodies, alpha-1-antitrypsin (for alpha-1-antitrypsin deficiency), ceruloplasmin (for Wilson's disease).

Scans:

Abdominal ultrasound - for liver and spleen size, ascites, portal blood flow and thrombosis of the portal or splenic veins.

Doppler ultrasound - can show direction of flow in blood vessels.

CT scan, especially spiral CT, may show portal vasculature - can be useful if ultrasound was inconclusive.

MRI scan - gives similar information to CT.

Elasticity measurement (FibroScan®) - a new technique based on the velocity of an elastic wave via an intercostally placed transmitter. Results correlate with liver stiffness and so with fibrosis.

Endoscopy - for oesophageal varices - essential for those with suspected portal hypertension. Varices indicate portal hypertension, but their absence does not exclude it.

Portal hypertension measurement:

Portal pressure is indirectly measured in clinical practice by the hepatic venous pressure gradient (HVPG).

Normal HVPG values are <5 mm Hg. HVPG >10 mm Hg predicts the development of oesophageal varices.

However, HVPG is moderately invasive and its clinical role is uncertain.

Liver biopsy - if indicated, may help diagnose the underlying cause.

Vascular imaging:

The site of the portal venous block can be demonstrated by examining the venous phase of a coeliac or superior mesenteric arteriogram, by splenic portography following injection of dye into the splenic pulp, or by retrograde portography via a hepatic vein.

Hepatic venography is helpful when hepatic vein block or idiopathic portal hypertension is suspected.

Management

The portal hypertension itself is difficult to treat effectively, except by:

Treating the underlying cause, where possible.

Liver transplantation, if indicated and feasible.

Portal venous pressure can be reduced by:

Betablockers \pm nitrates.

Shunt procedures - create an anastomosis between the portal and hepatic veins (below).

Complications

Complications of portal hypertension \pm cirrhosis are:

Bleeding from oesophageal or gastric varices - the most common complication of portal hypertension.

Ascites and its complications:

Spontaneous bacterial peritonitis.

Hepatorenal syndrome (a complication of cirrhosis with ascites).

Hepatic hydrothorax.

Pulmonary complications:

Portopulmonary hypertension (pulmonary arterial hypertension complicating portal hypertension in patients with liver disease).

Hepatopulmonary syndrome (a triad of hepatic dysfunction, hypoxemia and extreme vasodilation in the form of intrapulmonary vascular dilations).

Liver failure.

Hepatic encephalopathy.

Cirrhotic cardiomyopathy.

For specific management, see separate articles Ascites, Cirrhosis, Hepatic Encephalopathy, Hepatorenal Syndrome, Liver Failure and Oesophageal Varices.

The following gives an overview of treatments used on the portal vascular system:

Drug treatments

Betablockers:

Nonselective betablockers reduce portal pressure in many patients.

They reduce rates of bleeding and rebleeding in patients with oesophageal varices.

They may also protect against spontaneous bacterial peritonitis (perhaps through increasing intestinal transit).

Carvedilol (a nonselective betablocker with anti-alpha1-adrenergic effects) showed promising results in a recent study, and may have a role in preventing variceal bleeds.

Nitrates:

Added to betablocker therapy, they contribute to reducing portal pressure and

may reduce rates of variceal rebleeding.

Vasoactive drugs:

Terlipressin and octreotide are used to assist the control of acute variceal bleeding.

Endoscopic procedures

Endoscopy - to detect and monitor oesophageal varices.

Endoscopic vein ligation - to prevent bleeding of oesophageal varices.

For gastric varices with acute bleeding, endoscopic variceal obturation with tissue adhesives (eg cyanoacrylate) is effective - but there are recognised complications (mucosal ulceration and thromboembolism).

Transjugular intrahepatic portosystemic shunt (TIPS)

This is a radiological procedure, connecting the portal and hepatic veins using a stent. The purpose of a TIPS is to decompress the portal venous system, to prevent rebleeding from varices or to reduce the formation of ascites.

However, there are potential complications - hepatic encephalopathy and deteriorating liver function. The stent may stenose; it requires follow-up and may require repeat procedures. There are various contra-indications, detailed in recent guidelines.

TIPS is an established treatment option for:

Ascites - for patients requiring repeated and frequent paracentesis.

Oesophageal variceal bleeding refractory to medical treatment (acute bleeding or secondary prevention).

Bleeding from non-oesophageal varices, eg gastric varices.

TIPS may also have a role in treating:

Hepatorenal syndrome.

Hepatic hydrothorax.

Hepatopulmonary syndrome.

Budd-Chiari syndrome.

Surgical procedures

Surgical portosystemic shunts:

These require major surgery and an experienced surgeon. They are less likely to stenose than TIPS and can be used where TIPS is not feasible.

Shunts may be total, partial or selective.

Devascularisation procedures:

Include gastro-oesophageal devascularisation, splenectomy and oesophageal transection.

Generally used where other therapies are unsuitable.

Management of rectal varices

These are common in patients with portal hypertension but don't usually bleed. They are located at the anorectal junction.

If they bleed, suggested treatment is similar to that used for upper gastrointestinal varices - using drugs to reduce portal pressure, endoscopic banding and TIPS if bleeding persists.

Prognosis

This depends on the prognosis of the underlying disease, and on the outcome of any complications such as variceal bleeding.

Other scoring systems have been developed, including:

Model for End Stage Liver Disease (MELD).

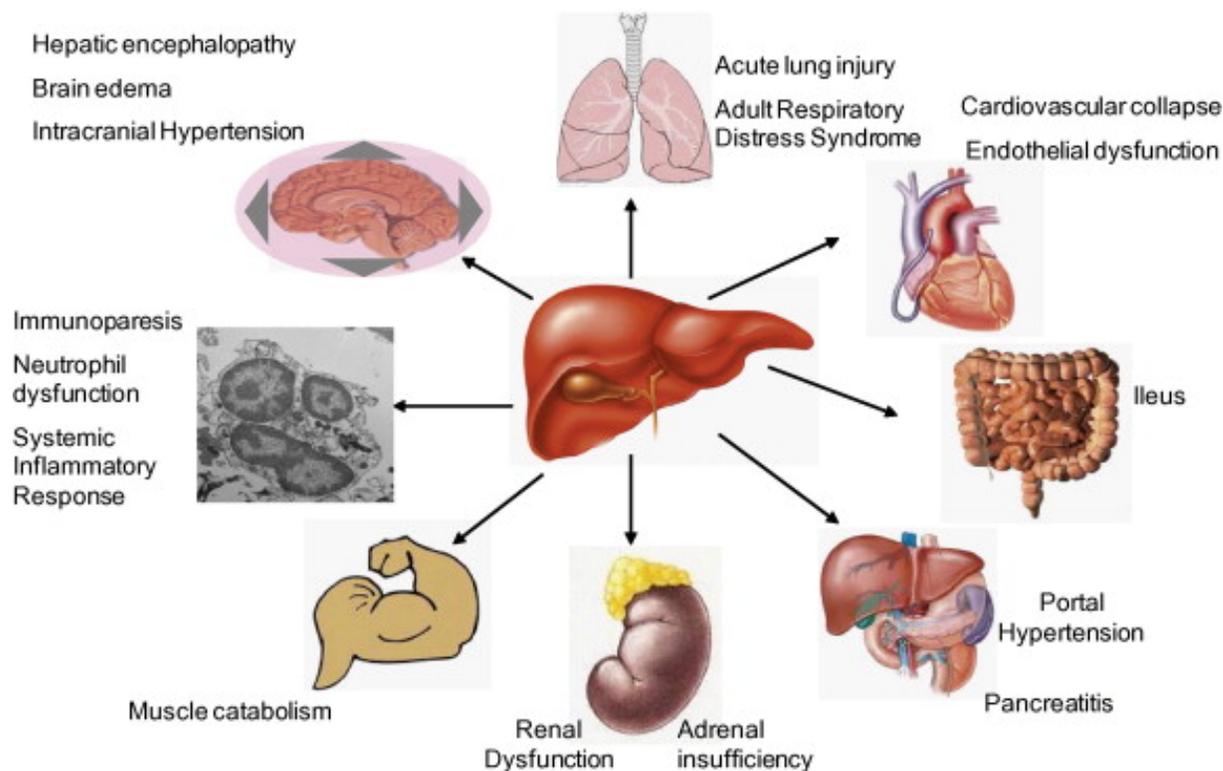

Additions to MELD such as MELD-Na (incorporates serum sodium) and MELD-ICG (incorporates indocyanine green clearance).

Variceal haemorrhage, especially from oesophageal varices, is the most common complication associated with portal hypertension. Almost 90% of patients with cirrhosis

develop varices, but only 30% of varices bleed. The first episode of variceal haemorrhage is estimated to carry a mortality rate of 30-50%.

ACUTE HEPATIC FAILURE

Systemic Manifestations of Acute Liver Failure

Acute liver failure (ALF) is a rare condition in which rapid deterioration of liver function results in altered mentation and coagulopathy in previously normal individuals.

U.S. estimates are placed at approximately 2,000 cases per year.⁴ The most prominent causes include drug-induced liver injury, viral hepatitis, autoimmune liver disease and shock or hypoperfusion; many cases (20%) have no discernible cause. Acute liver failure often affects young persons and carries a high morbidity and mortality.

Prior to transplantation, most series suggested less than 15% survival. Currently, overall short-term survival with transplantation is greater than 65%. Because of its rarity, ALF has been difficult to study in depth and very few controlled therapy trials have been

performed. As a result, standards of intensive care for this condition have not been established.

The most widely accepted definition of ALF includes evidence of coagulation abnormality, usually an INR 1.5, and any degree of mental alteration (encephalopathy) in a patient without preexisting cirrhosis and with an illness of 26 weeks duration. Patients with Wilson disease, vertically-acquired HBV, or autoimmune hepatitis may be included in spite of the possibility of cirrhosis if their disease has only been recognized for 26 weeks. A number of other terms have been used including fulminant hepatic failure and fulminant hepatitis or necrosis. Acute liver failure is a better overall term that should encompass all durations up to 26 weeks. Terms used signifying length of illness such as hyperacute (7 days), acute (7-21 days) and subacute (21 days and 26 weeks) are not particularly helpful since they do not have prognostic significance distinct from the cause of the illness. For example, hyperacute cases may have a better prognosis but this is because most are due to acetaminophen toxicity.

All patients with clinical or laboratory evidence of moderate to severe acute hepatitis should have immediate measurement of prothrombin time and careful evaluation for subtle alterations in mentation. If the prothrombin time is prolonged by 4-6 seconds or more (INR 1.5) and there is any evidence of altered sensorium, the diagnosis of ALF is established and hospital admission is mandatory. Since the condition may progress rapidly, with changes in consciousness occurring hour-by-hour, early transfer to the intensive care unit (ICU) is preferred once the diagnosis of ALF is made. History taking should include careful review of possible exposures to viral infection and drugs or other toxins. If severe encephalopathy is present, the history may be provided entirely by the family or may be unavailable. In this setting, limited information is available, particularly regarding possible toxin/drug ingestions. Physical examination must include careful assessment and documentation of mental status and a search for stigmata of chronic liver disease. Jaundice is often but not always seen at presentation.

Right upper quadrant tenderness is variably present. Inability to palpate the liver or even to percuss a significant area of dullness over the liver can be indicative of decreased liver volume due to massive hepatocyte loss.

An enlarged liver may be seen early in viral hepatitis or with malignant infiltration, congestive heart failure, or acute Budd-Chiari syndrome. History or signs of cirrhosis should be absent as such features suggest underlying chronic liver disease, which may have different management implications. Furthermore, the prognostic criteria mentioned below are not applicable to patients with acute-on-chronic liver disease.

Initial laboratory examination must be extensive in order to evaluate both the etiology and severity of ALF. In addition to coagulation parameters, early testing should include routine chemistries (especially glucose as hypoglycemia may be present and require correction), arterial blood gas measurements, complete blood counts, blood typing, acetaminophen level and screens for other drugs and toxins, viral hepatitis serologies (most prominently A and B), tests for Wilson disease, autoantibodies (anti-nuclear and anti-smooth muscle antibodies) and a pregnancy test in females. Plasma ammonia, preferably arterial,^{7,8} may also be helpful. A liver biopsy, most often done via the transjugular route because of coagulopathy, may be indicated when certain conditions such as autoimmune hepatitis, metastatic liver disease, lymphoma, or herpes simplex hepatitis are suspected. As the evaluation continues, several important decisions must be made: whether to admit the patient to an ICU, whether to transfer the patient to a transplant facility, and (if already at a transplant center) whether and when to place the

patient on the list for transplantation. For patients in a non-transplant center, the possibility of rapid progression of ALF makes early consultation with a transplant facility critical. Specific prognostic indicators may point toward the need for transplantation. For patients with acetaminophen-related ALF in particular, an arterial pH of 7.3 should prompt immediate consideration for transfer to a transplant center and placement on a transplant list.

Patients with altered mentation should generally be admitted to an ICU. Planning for transfer to a transplant center should begin in patients with grade I or II encephalopathy because they may worsen rapidly.

Early transfer is important as the risks involved with patient transport may increase or even preclude transfer once stage III or IV encephalopathy develops. Evaluation for transplantation should begin as early as possible. In these critically ill

patients with potential for rapid deterioration it is necessary to make treatment plans promptly. Social and financial considerations are unavoidably tied to the overall clinical assessment where transplantation is contemplated. It is important to inform the patient's family or other next of kin of the potentially poor prognosis and to include them in the decision-making process.

Table. Initial Laboratory Analysis

Prothrombin time/INR
Chemistries
sodium, potassium, chloride, bicarbonate, calcium, magnesium, phosphate
glucose
AST, ALT, alkaline phosphatase, GGT, total bilirubin, albumin
creatinine, blood urea nitrogen
Arterial blood gas
Arterial lactate
Complete blood count
Blood type and screen
Acetaminophen level
Toxicology screen
Viral hepatitis serologies
anti-HAV IgM, HBSAg, anti-HBc IgM, anti-HEV§, anti-HCV*
Ceruloplasmin Level#
Pregnancy test (females)
Ammonia (arterial if possible)
Autoimmune markers

ANA, ASMA, Immunoglobulin levels
HIV status‡
Amylase and lipase

**Done to recognize potential underlying infection.*

DETERMINING ETIOLOGIES AND SPECIFIC THERAPIES

Etiology of ALF provides one of the best indicators of prognosis, and also dictates specific management options.

LIVER BIOPSY

The characteristic finding on liver biopsy is a heavy deposit of hemosiderin granules in hepatocytes and bile duct cells. Fibrosis may range from minimal to well-established cirrhosis. At times, hereditary hemochromatosis is difficult to distinguish from cirrhosis with secondary iron overload. A preponderance of parenchymal iron relative to the amount of scar tissue and the presence of iron in the bile duct cells characterize hereditary hemochromatosis. Iron overload secondary to underlying cirrhosis is usually associated with advanced cirrhosis, relatively less stainable iron, and absence of iron in the bile ducts. When excess hepatic iron derives from an exogenous source, such as a series of massive transfusions for chronic hemolytic anemia, iron is prominent in the Kupffer cells. When the morphologic features of the liver biopsy do not clearly distinguish between hereditary hemochromatosis and secondary iron overload, quantitative analysis of the hepatic iron content may prove helpful. Patients with hemochromatosis typically have quantitative hepatic iron values ranging from 200 to 800 $\mu\text{mol/g}$ dry weight (normal, $< 35 \mu\text{mol/g}$), whereas patients with alcoholic siderosis have hepatic iron content ranging from 40 to 100 $\mu\text{mol/g}$. Another useful diagnostic test for hemochromatosis is calculation of the hepatic iron index; this value is usually

greater than 2 in homozygotes and less than 2 in patients with alcoholic siderosis. Finally, tissue obtained from the heart, pancreas, or skin of patients with hemochromatosis shows heavy infiltration of stainable iron.

ACETAMINOPHEN HEPATOTOXICITY

Acetaminophen hepatotoxicity is suggested by historic evidence for excessive ingestion either as an intended suicidal overdose or the inadvertent use of supra-therapeutic quantities of pain medications. Acetaminophen is a dose-related toxin; most ingestions leading to ALF exceed 10 gm/day. However, severe liver injury can occur rarely when doses as low as 3-4 gm/day are taken. Very high aminotransferases may be seen; serum levels exceeding 3,500 IU/L are highly correlated with acetaminophen poisoning and should prompt consideration of this etiology even when historic evidence is lacking. Because acetaminophen is the leading cause of ALF (at least in the

United States and Europe) and there is an available antidote, acetaminophen levels should be drawn in all patients presenting with ALF. Low or absent acetaminophen levels do not rule out acetaminophen poisoning since the time of ingestion may be remote or unknown, especially when overdose may have been unintentional and/or occurred over several days. If acetaminophen ingestion is known or suspected to have occurred within a few hours of presentation, activated charcoal may be useful for gastrointestinal decontamination. While it is most effective if given within one hour of ingestion, it may be of benefit as long as 3 to 4 hours after ingestion. Administration of activated charcoal (standard dose 1g/kg orally, in a slurry) just prior to administration of N-acetylcysteine does not reduce the effect of N-acetylcysteine. N-acetylcysteine (NAC), the antidote for acetaminophen poisoning, has been shown to be effective and safe for this purpose in numerous controlled trials. The standard acetaminophen toxicity nomogram¹⁹ may aid in determining the likelihood of serious liver damage, but cannot be used to exclude possible toxicity due to multiple doses over time, or altered metabolism in the alcoholic or fasting patient. Given these considerations, administration of NAC is recommended in any case of ALF in which acetaminophen overdose is a suspected or possible

cause. NAC should be given as early as possible, but may still be of value 48 hours or more after ingestion. 21 NAC may be given orally (140 mg/kg by mouth or nasogastric tube diluted to 5% solution, followed by 70 mg/kg by mouth q 4 h 17 doses) and has few side effects (occasional nausea, vomiting, rare urticaria or bronchospasm). In patients with ALF oral administration may often be precluded (for instance, by active gastrointestinal bleeding or worsening mental status), and NAC may be administered intravenously (loading dose is 150 mg/kg in 5% dextrose over 15 minutes; maintenance dose is 50 mg/kg given over 4 hours followed by 100 mg/kg administered over 16 hours). Allergic reactions may be successfully treated with discontinuation, antihistamines and epinephrine for bronchospasm.

WILSON DISEASE

Wilson disease is an uncommon cause of ALF (2%-3% of cases in the US ALFSG). Early identification is critical because the fulminant presentation of Wilson disease is considered to be uniformly fatal without transplantation.

The disease typically occurs in young patients, accompanied by the abrupt onset of hemolytic anemia with serum bilirubin levels 20 mg/dL. Due to the presence of hemolysis, the indirect-reacting bilirubin is often markedly elevated along with the total bilirubin. Kayser-Fleischer rings are present in about 50% of patients presenting with ALF due to Wilson disease.⁴⁰ Serum ceruloplasmin is typically low, but may be normal in up to 15% of cases and is often reduced in other forms of ALF; high serum and urinary copper levels as well as hepatic copper measurement may confirm the diagnosis. Very low serum alkaline phosphatase or uric acid levels are hints to suggest Wilson disease in the absence of other indicators. A high bilirubin (mg/dL) to alkaline phosphatase (IU/L) ratio (2.0) is a reliable albeit indirect indicator of Wilson disease in this setting.^{40,41} Renal function is often impaired as the released copper can cause renal tubular damage. Treatment to acutely lower serum copper and to limit further hemolysis should include albumin dialysis, continuous hemofiltration, plasmapheresis or plasma exchange. Initiation of treatment with penicillamine is not recommended in ALF as there

is a risk of hypersensitivity to this agent; acute lowering of the copper is more effectively accomplished using direct plasma copper reduction techniques, especially when renal function is impaired.⁴⁰ Although such copper lowering measures should be considered, recovery is infrequent without transplantation. Wilson disease is one of the special circumstances in which patients may already have evidence of cirrhosis and still be considered to have a diagnosis of ALF when rapid deterioration occurs. Please refer to the AASLD Practice Guideline on Wilson Disease for more detailed information regarding the diagnosis and management of patients with this condition.

BUDD-CHIARI SYNDROME

The Budd-Chiari syndrome (acute hepatic vein thrombosis) can also present as ALF. Abdominal pain, ascites and striking hepatomegaly are often present. The diagnosis should be confirmed with hepatic imaging studies (computed tomography, doppler ultrasonography, venography, magnetic resonance venography). In the presence of significant liver failure, transplantation may be required as opposed to venous decompression. As malignancy-associated hypercoagulability is one of the causes of Budd-Chiari syndrome, it is important to rule out underlying cancer prior to transplantation of these patients.

THERAPY: GENERAL CONSIDERATIONS

While patients with ALF represent a heterogeneous group, they have consistent clinical features, and share the common disease process of acute hepatocyte loss and its sequelae. Despite decades of research, however, no agent or therapy that is beneficial to all patients with ALF has been found. Systemic corticosteroids are ineffective in this condition.

Because most patients with ALF tend to develop some degree of circulatory dysfunction, agents that may improve hemodynamics have been of particular interest.

While prostacyclin and other prostaglandins have appeared promising in some reports, others have not supported their efficacy in ALF. NAC may improve systemic circulation parameters in patients with ALF, but this was not observed in all studies. NAC has been shown to improve liver blood flow and function in patients with septic shock. Use of NAC in all forms of ALF cannot be justified based on current evidence. A large, multi-center, randomized, double-blind controlled trial of intravenous NAC versus placebo for non-acetaminophen ALF is currently under way. Because there is no proven therapy for ALF in general, management consists of intensive care support once treatments for specific etiologies have been initiated. While some patients with evidence of acute liver injury but without significant coagulopathy or encephalopathy may be monitored on a medicine ward, any patient with altered mental status warrants admission to an ICU as the condition may deteriorate quickly. Careful attention must be paid to fluid management, hemodynamics and metabolic parameters as well as surveillance for and treatment of infection.

Maintenance of nutrition and prompt recognition and resuscitation of gastrointestinal bleeding are crucial as well. Coagulation parameters, complete blood counts, metabolic panels (including glucose) and arterial blood gas should be checked frequently. Serum aminotransferases and bilirubin are generally measured daily to follow the course of the condition, however changes in aminotransferase levels correlate poorly with prognosis.

Specific Issues. See Table.

Table. Intensive Care of Acute Liver Failure
<i>Cerebral Edema/Intracranial Hypertension</i>
Grade I/II Encephalopathy
Consider transfer to liver transplant facility and listing for transplantation
Brain CT: rule out other causes of decreased mental status; little utility to
identify cerebral edema
Avoid stimulation, avoid sedation if possible

Antibiotics: surveillance and treatment of infection required; prophylaxis possibly helpful
Lactulose: possibly helpful
Grade III/IV Encephalopathy
Continue management strategies listed above
Intubate trachea (may require sedation)
Elevate head of bed
Consider placement of ICP monitoring device
Immediate treatment of seizures required; prophylaxis of unclear value
Mannitol: use for severe elevation of ICP or first clinical signs of herniation
Hyperventilation: effects short-lived; may use for impending herniation
<i>Infection</i>
Surveillance for and prompt antimicrobial treatment of infection required
Antibiotic prophylaxis possibly helpful but not proven
<i>Coagulopathy</i>
Vitamin K: give at least one dose
FFP: give only for invasive procedures or active bleeding
Platelets: give for platelet counts $< 10,000/mm^3$ or invasive procedures
Recombinant activated factor VII: possibly effective for invasive procedures
Prophylaxis for stress ulceration: give H2 blocker or PPI
<i>Hemodynamics/Renal Failure</i>
Pulmonary artery catheterization
Volume replacement

Pressor support (dopamine, epinephrine, norepinephrine) as needed to
maintain adequate mean arterial pressure
Avoid nephrotoxic agents
Continuous modes of hemodialysis if needed
NAC, prostacyclin: effectiveness unknown
Vasopressin: not helpful in ALF; potentially harmful.
<i>Metabolic Concerns</i>
Follow closely: glucose, potassium, magnesium, phosphate
Consider nutrition: enteral feedings if possible or total parenteral nutrition

CENTRAL NERVOUS SYSTEM

Cerebral edema and intracranial hypertension (ICH) have long been recognized as the most serious complications of ALF. Uncal herniation may result and is uniformly fatal. Cerebral edema may also contribute to ischemic and hypoxic brain injury, which may result in long-term neurological deficits in survivors. The pathogenic mechanisms leading to the development of cerebral edema and ICH in ALF are not entirely understood. It is likely that multiple factors are involved, including osmotic disturbances in the brain and heightened cerebral blood flow due to loss of cerebrovascular autoregulation. Inflammation and/or infection, as well as factors yet unidentified may also contribute to the phenomenon. Several measures have been proposed and used with varying success to tackle the problem of cerebral edema and the associated ICH in patients with ALF. Some interventions are supported by more evidence than others; no uniform protocol has been established.

Prevention/Management of Elevated Intracranial Pressure (ICP). The occurrence of cerebral edema and ICH in ALF is related to severity of encephalopathy (Table). Cerebral edema is seldom observed in patients with

grade I-II encephalopathy. The risk of edema increases to 25% to 35% with progression to grade III, and 65% to 75% or more in patients reaching grade IV coma. A stepwise approach to management is therefore advised.

Grades I-II. Depending on the overall clinical picture, patients with only grade I encephalopathy may sometimes be safely managed on a medicine ward with skilled nursing in a quiet environment to minimize agitation, although management in an ICU is preferable. Frequent mental status checks should be performed with transfer to an ICU if level of consciousness declines. With progression to grade II encephalopathy, an ICU setting is indicated. Head imaging with computerized tomography (CT) is used to exclude other causes of decline in mental status such as intracranial hemorrhage. Sedation is to be avoided if possible; unmanageable agitation may be treated with short-acting benzodiazepines in small doses.

GRADES III-IV.

As patients progress to grade III or IV encephalopathy it is advisable to intubate the trachea for airway protection. Choice of sedation in this instance will vary according to clinician preference: propofol is often used because it may reduce cerebral blood flow; however, its effectiveness in this regard has not been shown in controlled studies. Small doses of propofol may be adequate, given its long half-life in patients with hepatic failure.

Patients in advanced stages of encephalopathy require close follow-up. Monitoring and management of hemodynamic and renal parameters as well as glucose, electrolytes and acid/base status becomes critical, and frequent neurological evaluation for signs of elevated intracranial pressure should be conducted. Patients should be positioned with head elevated at 30 degrees.⁸⁰ Efforts should be made to avoid patient stimulation. Maneuvers that cause straining or Valsalva-like movements in particular may increase ICP; it may be advisable to use endotracheal lidocaine prior to endotracheal suctioning.

Table 5. Grades of Encephalopathy
--

CLASSIFICATION according to

Child - Turcotte and Pugh

<i>Parameter</i>	Class A Compensation (5-6 points)	Class B Subcompensation (7-9 points)	Class C Decompensation (10 and >points)
Bilirubin, mcmol/l	<35	35-55	>55
Albumine, g/l	>35	30-35	<30
Prothrombin time	60-80%	40-59%	<40%
Ascites	absent	treatable	untreatable
Encephalopathy	absent	1-2 st.	3-4 st.
<i>Points:</i>	<i>1</i>	<i>2</i>	<i>3</i>

Seizures.

Seizures, which may be seen as a manifestation of the process that leads to hepatic coma and ICH, should be controlled with phenytoin. Use of any sedative is discouraged in light of its effects on the evaluation of mental status. Only minimal doses of benzodiazepines should be used given their delayed clearance by the failing liver. Seizure activity may acutely elevate ICP⁸¹ and may also cause cerebral hypoxia and thus contribute to cerebraledema. Some experts have advocated prophylactic use of phenytoin, especially as seizure activity may be inapparent.

A small randomized controlled trial of prophylactic phenytoin in ALF showed no difference in overall survival, but a striking diminution in cerebral edema at autopsy in the treated group. A recent clinical trial did not show beneficial effects on the prevention of seizures, brain edema or survival. Further studies may clarify the value of this treatment, but it cannot be recommended as a prophylactic measure at this time.

COMPLICATION

Infection.

All patients with ALF are at risk for acquisition of bacterial or fungal infection or sepsis, which may preclude transplantation or complicate the post-operative course. Prophylactic antimicrobial therapy reduces the incidence of infection in certain groups of patients with ALF, but no actual survival benefit has been shown, making it difficult to recommend antibiotic prophylaxis uniformly. Although often given, poorly absorbable antibiotics for selective bowel decontamination have not been shown to impact survival either. Deterioration of mental status in hospital, particularly in patients with acetaminophen toxicity, may represent the onset of infection. If antibiotics are not given prophylactically, surveillance for infection (including chest radiography and periodic cultures of sputum, urine and blood for fungal and bacterial organisms) should be undertaken, while maintaining a low threshold for starting appropriate anti-bacterial or anti-fungal therapy. There are no controlled trials available to confirm whether the use of prophylactic antimicrobials decreases the likelihood of progression of encephalopathy and/or development of cerebral edema in ALF. Recent studies have suggested an association between infection and/or the systemic inflammatory response syndrome (SIRS) and progression to deeper stages of encephalopathy. Given that prophylactic antibiotics have been shown to reduce the risk of infection, that later stages of encephalopathy are associated with increased incidence of cerebral edema, and that fever may worsen ICH, it is possible that antibiotic and antifungal prophylaxis may decrease the risk of cerebral edema and ICH. This hypothesis is yet to be proven, however.

SPONTANEOUS BACTERIAL PERITONITIS

Spontaneous bacterial peritonitis (SBP) develops in 10% to 25% of cirrhotic patients followed prospectively for at least a year. The cirrhosis is usually advanced and

active, as manifested by hepatic encephalopathy, esophageal varices, and jaundice. The incidence of SBP is substantially higher in patients with ascitic fluid protein levels below 1.0 g/dl and serum bilirubin levels above 2.5 mg/dl. These findings could explain the increased risk of ascitic fluid infection, because the antibacterial activity of the ascitic fluid, as measured by opsonic activity, is proportional to the level of ascitic fluid protein. The exact pathogenesis is unknown. Presumably, hematogenous seeding of the ascitic fluid, which functions as an ideal bacterial culture medium, serves as a major route of infection. Cirrhosis undoubtedly facilitates the process by allowing enteric organisms to enter the bloodstream via the portosystemic collaterals, thus bypassing the major reticuloendothelial system in the liver.

DIAGNOSIS

Clinical features The typical attack of SBP is heralded by fever, peripheral leukocytosis, abdominal pain, hypoactive or absent bowel sounds, and rebound tenderness. Most patients do not demonstrate all these symptoms, and some have none. Hence, ascitic fluid should be analyzed whenever the condition of a patient with cirrhosis suddenly deteriorates.

Laboratory tests.

The ascitic fluid is often turbid because of leukocytosis and bacterial growth. Leukocyte cell counts greater than 1,000/mm³ consisting of more than 85% granulocytes are common. Almost all patients have ascitic fluid cell counts greater than 300/mm³; more than half of these are polymorphonuclear cells. However, not all patients with ascitic fluid leukocytosis have SBP. In practice, it is wise to treat patients with antibiotics when the clinical picture is suggestive and the ascitic fluid contains more than 500 white blood cells/mm³. The ultimate criterion for infection is demonstration of organisms either by Gram stain of the fluid (one fourth of cases) or by culture. To maximize detection of the responsible infectious organisms, 5 ml of ascitic fluid should be injected at bedside into both aerobic and anaerobic blood culture bottles. Two thirds of the causative organisms are enteric; *Escherichia coli* and *Klebsiella* species are the

most common agents. *Pneumococcus* and *Streptococcus* organisms are responsible for as many as 20% of cases. In nearly half of cases, blood cultures are positive for the same organism found in the ascitic fluid.

TREATMENT

Cefotaxime administered intravenously at a dosage of 2 g every 6 hours is an appropriate initial treatment for an episode of SBP; in patients with renal insufficiency, the dosage is adjusted downward. On this regimen, 75% to 80% of treated episodes resolve. A few episodes resolve after a change in the antibiotic regimen. However, 20% to 25% of patients die before the infection resolves. Therapy is equally effective whether given for 5 days or 10 days. Patients should be monitored closely and ascitic fluid checked at least once (e.g., after 48 hours) to ensure that the infection is being effectively treated. Despite optimal therapy, 40% to 60% of patients with SBP die. Half of the deaths are a direct result of the peritonitis; the other half succumb to other complications of their severe liver disease. Long-term oral therapy with norfloxacin (400 mg/day) or ciprofloxacin (750 mg once a week) reduces the incidence of recurrent spontaneous bacterial peritonitis attributable to aerobic gram-negative bacteria and should be considered in patients at high risk for recurrence.

COAGULOPATHY.

Clotting abnormalities are uniform in patients with ALF as previously discussed, leaving patients at increased risk for bleeding complications. While synthesis of coagulation factors is decreased, consumption of clotting factors and platelets also may occur, so that platelet levels are often 100,000/mm.³ In the absence of bleeding it is not necessary to correct clotting abnormalities with fresh frozen plasma (FFP). An exception is when an invasive procedure is planned and perhaps in the setting of profound coagulopathy (e.g., INR 7). In addition to the risks associated with transfusion of blood

products, use of plasma supplementation limits the value of coagulation parameters as a means of following the progress of ALF patients and can also lead to volume overload which may exacerbate ICH. Vitamin K is routinely given in a dose of 5-10 mg subcutaneously, regardless of whether poor nutritional status appears to be contributing to the coagulopathy. Experts differ regarding prophylactic use of platelets in thrombocytopenic patients or use of FFP for evidence of severe coagulopathy. Platelet transfusions are not generally used until a low threshold value is observed. In the absence of bleeding, it is safe to use a threshold platelet count of 10,000/mm³, although some experts recommend more conservative levels of 15-20,000/mm³ especially in patients with infection or sepsis.¹²¹ Experience in other conditions of thrombocytopenia suggests that values 10,000/mm³ are generally well tolerated.¹²² When invasive procedures must be performed, platelet counts of 50-70,000/mm³ are usually considered adequate.¹²¹ Patients who develop significant bleeding with platelet levels below approximately 50,000/mm³ should generally be transfused with platelets provided no contraindication exists.

Likewise, bleeding in the setting of a prolonged prothrombin time (INR 1.5) warrants administration of FFP. Recombinant activated factor VII (rFVIIa) may be used in treating coagulopathy in patients with liver disease.

A recent small nonrandomized trial of fifteen patients with ALF found that administration of rFVIIa in combination with FFP produced more effective temporary correction of coagulopathy and thus might be useful in facilitating performance of invasive procedures in these patients particularly in the setting of renal insufficiency in which volume overload is a concern.⁹⁶ This agent will require further study and analysis of cost-benefit ratio (current cost for one dose is approximately \$4,000) before it can be broadly recommended, however.

GASTROINTESTINAL BLEEDING.

Gastrointestinal (GI) bleeding is a recognized complication of ALF. A large prospective multi-center cohort study found that mechanical ventilation for more than 48

hours and coagulopathy were the only significant risk factors for bleeding in critically ill patients of all types. Additional risk factors for bleeding reported in smaller studies have included hepatic and renal failure, sepsis, shock and others. Patients with acute liver failure are thus at high risk for gastrointestinal hemorrhage. Histamine 2 receptor (H2) blocking agents such as ranitidine have long been used in the prophylaxis of GI bleeding in critically ill patients; their efficacy has been supported in several trials. Sucralfate has also been found to be effective in many studies, and there have been smaller randomized trials and a meta-analysis which suggested that sucralfate may be as effective in preventing gastrointestinal bleeding and might be associated with lower risk of nosocomial pneumonia than H2 blockers which lower gastric pH. More recently, however, a much larger (1,200 patients), well-designed trial comparing ranitidine to sucralfate in mechanically-ventilated patients found that ranitidine but not sucralfate decreased the risk of clinically significant bleeding; the incidence of pneumonia was similar for the two groups. Limited studies of proton pump inhibitors (PPIs) as bleeding prophylaxis have demonstrated their effectiveness in maintaining elevated intragastric pH. Two trials found no significant bleeding in PPI-treated patients on mechanical ventilation, but study size may have precluded detection of significant bleeding. H2 blockers have been proven to be effective and PPIs are almost certainly effective as well. PPIs may provide superior protection but this remains to be proven. Sucralfate may be acceptable as second-line treatment.

TREATMENT OF RECURRENT VARICEAL BLEEDING

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

The placement of a transjugular intrahepatic portosystemic shunt (TIPS) is rapidly becoming an accepted technique for the treatment of bleeding esophageal varices refractory to endoscopic therapy. This procedure creates a shunt but avoids the complications of major surgery. The initial enthusiasm surrounding the introduction of TIPS has been tempered by recognition of the complications of encephalopathy, which

develops in 10% to 30% of patients and is refractory to medical therapy in approximately 5%, and shunt stenosis or occlusion, which develops in 30% to 50% of patients at 12 months. It seems reasonable to restrict this form of treatment to centers with experienced staff and to patients who are poor surgical candidates, are refractory to endoscopic therapy, or have bleeding from gastric rather than esophageal varices. A number of trials have compared TIPS with endoscopic therapy (either sclerotherapy or banding) after initial control of hemorrhage in patients with Child class A or B cirrhosis; several tentative conclusions can be drawn from these studies. Mortality associated with TIPS is not significantly different from that associated with endoscopic treatment. TIPS is superior to endoscopic therapy in the prevention of variceal rebleeding (19% versus 47%). TIPS may be particularly attractive for patients in whom compliance with follow-up endoscopy is in doubt. However, one must accept the increased risk of hepatic encephalopathy after TIPS (34%, versus 18% after endoscopic therapy). TIPS is less attractive for patients with advanced chronic liver disease and Child class C cirrhosis with poor synthetic function. The survival of patients after TIPS can be predicted by the Mayo Clinic endstage liver disease score, which includes the following four variables: serum bilirubin, serum creatinine, INR for prothrombin time, and cause of the underlying liver disease. The long-term utility of TIPS must also be evaluated in context of shunt stenosis or occlusion, which is a management problem after TIPS. Thus, for esophageal variceal bleeding, TIPS cannot be recommended as the first-choice treatment for prevention of variceal rebleeding.

SURGICAL PORTOSYSTEMIC SHUNT

Recurrent or continued bleeding may indicate a need for a surgical portosystemic shunt. This major operation carries a mortality of approximately 40% when performed on an emergency basis. If bleeding can be stopped and shunt surgery performed electively, mortality declines substantially. Although portosystemic shunting procedures do not appear to prolong survival, they do prevent subsequent bleeding. The major problem after surgery is intractable hepatic encephalopathy and hepatic failure. The

preferred shunt procedure is the one with which the surgeon is most experienced. A distal splenorenal shunt with concomitant gastroesophageal devascularization selectively decompresses esophageal varices while maintaining mesenteric blood flow to the liver. In most but not all studies, use of the distal splenorenal shunt reduced the incidence of severe encephalopathy as a late complication after surgery, compared with conventional shunts. The procedure is technically difficult; time will reveal if it possesses any long-term advantages.

PROPHYLACTIC TREATMENT FOR VARICEAL BLEEDING

Because the first episode of variceal bleeding can result in significant morbidity and mortality, there has been considerable interest in the prophylactic treatment of esophageal varices in persons who have never bled. Prophylactic portosystemic shunts decrease rebleeding but do not enhance survival. Prophylactic sclerotherapy has been studied in several centers with mixed results. In the largest study, which was restricted to alcoholic patients, this approach proved harmful. The experience with the beta-adrenergic antagonists propranolol and nadolol has been somewhat more encouraging because the drugs appear both to prevent the first episode of bleeding and to reduce mortality associated with bleeding in patients who have moderate or large esophageal varices.⁵¹ If a patient known to have large varices is well motivated and tolerates the medication, beta-adrenergic antagonists may be considered. Isosorbide-5-mononitrate, a long-acting nitrate, may also help prevent the first variceal hemorrhage.

HEMODYNAMICS/RENAL FAILURE

Hemodynamic derangements consistent with multiple organ failure occur in ALF; the underlying mechanisms are complex and incompletely understood. Management of hemodynamic balance becomes increasingly important and difficult in the face of elevated

ICP and/or compromised renal function. Preservation of renal function is imperative in this setting. In many ways patients with ALF resemble physiologically the patient with cirrhosis and hepatorenal syndrome. Intravascular volume deficits may be present on admission due to decreased oral intake resulting from altered mental status, transudation of fluid into the extravascular space, and possibly GI blood loss.

Most patients will require fluid resuscitation initially. Low systemic vascular resistance results in low blood pressures even in the fluid-resuscitated patient, and placement of a pulmonary artery catheter may aid in assessing volume status and guiding further management. Fluid replacement with colloid (such as albumin) is preferred rather than crystalloid (such as saline); all solutions should contain dextrose to maintain euglycemia.

While adequate fluid replacement and treatment of potential infection and sepsis may help to correct hypotension, inotropic or pressor support may be required in order to maintain mean arterial pressures of at least 50-60 mmHg. There has been debate over which agents are best used to support blood pressure in ALF and whether they are useful at all. Alpha-adrenergic agents such as epinephrine and norepinephrine have been thought to potentially worsen peripheral oxygen delivery. On the other hand, dopamine has actually been associated with increased systemic delivery of oxygen. In any case, the hypotension and vasodilatation associated with ALF will generally respond to these agents, and they should be used if needed to maintain perfusion of vital organs. Agents that promote vasoconstriction are generally avoided unless significant systemic hypotension is present, and therefore should not be used in the setting of decreased intracranial perfusion with normal systemic blood pressure.

Acute renal failure is a frequent complication in patients with ALF and may be due to dehydration, hepatorenal syndrome or acute tubular necrosis. The frequency of renal failure may be even greater with acetaminophen overdose or other toxins, where direct renal toxicity is seen. Although few patients die of renal failure alone, it often contributes to mortality and may portend a poorer prognosis. Every effort should be made to protect renal function by maintaining adequate hemodynamics, avoiding nephrotoxic agents such as aminoglycosides and non-steroidal anti-inflammatory drugs, and by the prompt identification and treatment of infection.

When dialysis is needed, continuous rather than intermittent modes of renal replacement therapy (e.g., continuous venovenous hemodialysis [CVVHD]) should be used, as they have been shown in randomized trials to result in improved stability in cardiovascular and intracranial parameters compared with intermittent modes of hemodialysis. Intravenous contrast agents are associated with nephrotoxicity in the setting of compromised hepatic function, and should be used with caution. If contrast must be administered, pretreatment with NAC may be of value, although this remains controversial. The potential utility of prostaglandins and NAC in improving hemodynamics and renal function was discussed previously; neither has sufficient evidence to be recommended as part of the management of hemodynamic derangements in ALF at this time, although NAC may have other benefits as discussed above. Evidence that terlipressin or vasopressin may be useful in patients with cirrhosis and hepatorenal syndrome has raised the question of whether this agent might benefit patients with ALF as well. A recent small study of terlipressin in patients with ALF found that even in very small doses, the drug was associated with increased cerebral blood flow and ICH. Such results indicate that at this time the risks associated with vasopressin use appear to outweigh its benefits in patients with ALF.

The observation that hemodynamic status as well as ICH tends to improve after removal of the native liver during transplantation for ALF led to a recommendation of hepatectomy as a “last resort” means of improving severe circulatory dysfunction in these patients. This option is based on uncontrolled studies and case reports, where successful outcomes have occasionally been reported even with patients who remained anhepatic for more than 48 hours. Despite these reports, hepatectomy to control hemodynamics cannot be recommended.

ASCITES

Occasionally, ascites presents as a right-sided pleural effusion. Portal hypertension, decreased serum albumin with consequent loss of oncotic force within the vascular and interstitial spaces, and renal retention of sodium and water contribute to

ascites formation. Although infectious, pancreatic, or neoplastic causes of ascites are infrequent, they should not be overlooked, because therapy and prognosis differ for each condition. To exclude such possible causes, a small amount of ascitic fluid should be removed from the abdominal cavity using a narrow-gauge needle. The gross appearance of the fluid may suggest an unusual etiology. For instance, cloudy fluid implies an infection; bloody fluid, a tumor; and milky fluid, lymphatic obstruction. Routine laboratory studies of the fluid should include white cell and differential cell counts, protein and albumin determinations, and culture. In ascites caused by cirrhosis, the serum-ascites albumin gradient is greater than 1.1, the total protein is less than 2.5 g/dl, the total white cell count is less than 300/mm³, the proportion of granulocytes is less than 30%, and cultures are negative. Approximately 5% of patients with ascites attributable to cirrhosis have ascitic fluid that has a total protein concentration greater than 2.5 g/dl.

PARACENTESIS

Large-volume paracentesis has become popular in the treatment of patients with ascites. In one study, paracentesis of 4 to 6 L/day was accomplished safely and resulted in shorter hospital stays and fewer complications than conventional diuretic therapy. Patients usually welcome paracentesis because it relieves considerable discomfort. It also provides the physician with the ascitic fluid necessary for diagnostic purposes. Subsequent work has shown that the administration of 6 to 8 g/L of intravenous albumin after 5 L or more prevents renal insufficiency and hyponatremia induced by paracentesis. In about 5% of patients, ascites do not respond to the usual dosages of conventional diuretic medication, or diuresis is achieved only at the expense of renal function. In these patients, insertion of the LeVeen peritoneovenous shunt has been considered. The shunt routes ascitic fluid subcutaneously from the peritoneal cavity to the internal jugular vein via a one-way valve. Compared with medical therapy alone, the peritoneovenous shunt results in speedier resolution of the ascites. However, placement of the shunt does not alter survival. Because most patients continue to require diuretics, although at lower doses, the shunt may produce benefit by increasing renal

blood flow. Serious complications of the shunt include bacterial infection of the peritoneum, disseminated intravascular coagulation, and rupture of esophageal varices. Because of these complications, the peritoneovenous shunt is seldom used.

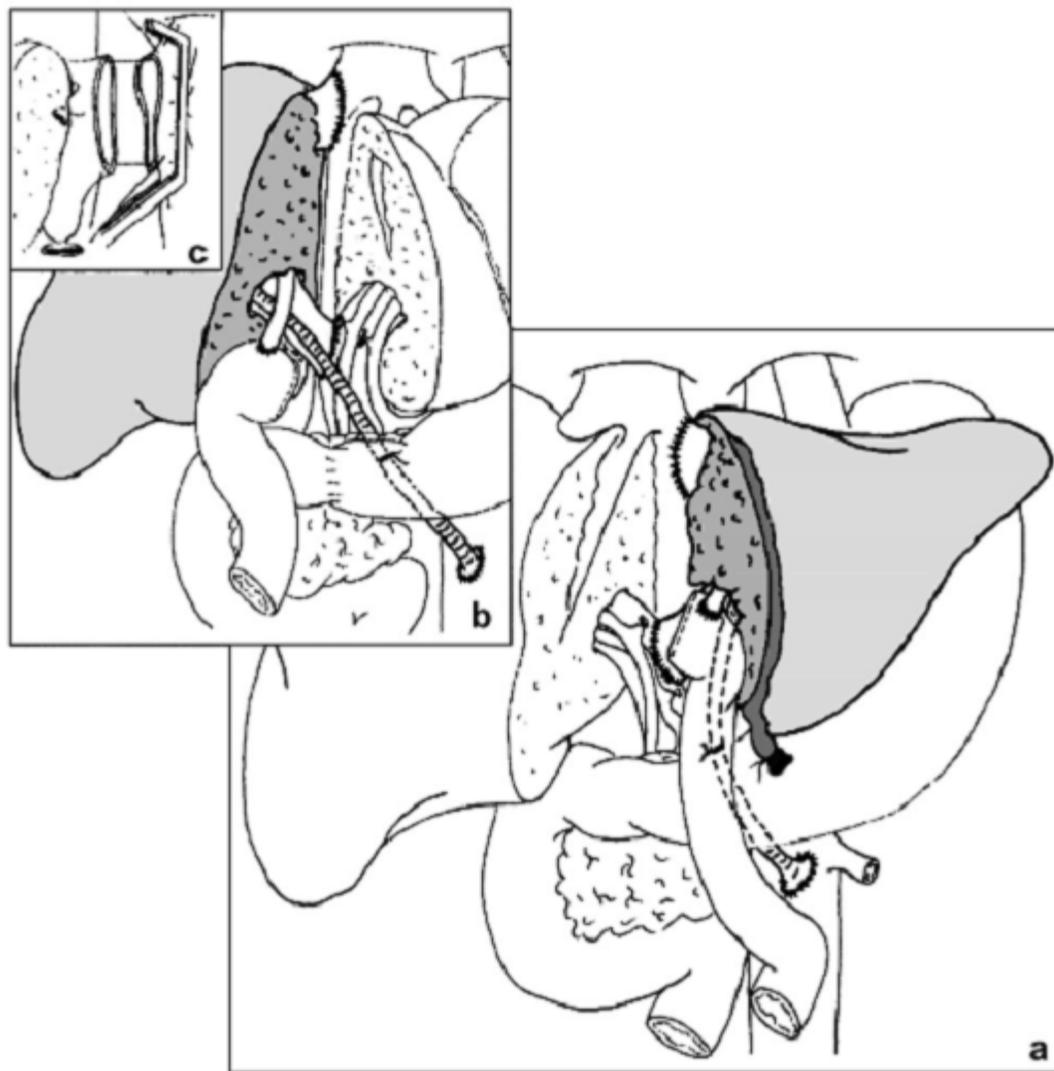

TREATMENT OF REFRACTORY ASCITES

Refractory ascites can also be effectively managed by placement of a TIPS. The majority of patients still require diuretic therapy, albeit at reduced dosages. The value of TIPS compared with repeated large-volume paracentesis for the management of refractory ascites awaits further study. However, TIPS is effective in the treatment of hepatic hydrothorax, which often accompanies refractory ascites.

TRANSPLANTATION AND PROGNOSIS

TRANSPLANTATION

Orthotopic liver transplantation remains the only definitive therapy for patients who are unable to achieve regeneration of sufficient hepatocyte mass to sustain life. As mentioned previously, the advent of transplantation has coincided with improvement in overall survival rates from as low as 15% in the pre-transplant era to 60% presently. Advances in critical care and changing trends toward more benign etiologies such as acetaminophen (having a better overall outcome) have likely helped. Spontaneous survival rates are now around 40%,⁵ compared to 15% in the pre-transplant era. Post-transplant survival rates for ALF have been reported to be as high as 80% to 90%,^{5,93} but accurate long-term outcome data are not yet available. In the largest U.S. study, only 29% of patients received a liver graft, while 10% of the overall group (1/4 of patients listed for transplantation) died on the waiting list.⁵ Other series have reported death rates of those listed for transplant as high as 40%,^{150,151} despite the fact that ALF remains the one condition for which the most urgent (UNOS status 1) listing is

LIVER SUPPORT SYSTEMS

A support device to replace the acutely failing liver seems a reasonable but elusive goal. The ideal replacement for the failing liver would detoxify, metabolize and synthesize; in short, perform all the liver's many functions. A variety of systems have been tested to date, with no certain evidence of efficacy. Sorbent systems embody only detoxification and no hepatocyte replacement. Such systems, employing charcoal or other adherent particles in a capsule or column device placed in an extracorporeal circuit, may show loss of platelets and worsening of coagulation parameters across the device. Transient improvement of hepatic encephalopathy may be observed but no improvement in hepatic function or long-term benefit has been shown. Hepatocytes, whether of human

or other mammalian origin, have been used in cartridges in extracorporeal circuits, either with or without sorbent columns.

Few controlled trials have been published, and some preliminary reports suggest no benefit to outcome, with or without transplantation. One recent multicenter trial did report improved short-term survival for a subgroup of patients with ALF who were treated with a porcine hepatocyte-based bioartificial liver, but corroboration of these results by further studies will likely be required before the true utility of this device can be established. All such trials are difficult to perform and to control properly due to the rarity of well-characterized patients, the heterogeneity of etiologies, varying levels of disease severity and varying access to transplantation. A recent meta-analysis, considering all forms of devices together, demonstrated no efficacy for bio-artificial liver devices for the treatment of ALF. A variety of other strategies have been employed including exchange transfusion, charcoal hemoperfusion, extracorporeal liver perfusions, and intra-portal hepatocyte infusions. To date, none can be recommended, and their use remains experimental. Efforts to improve hepatocyte regeneration have likewise been futile thus far.¹⁶⁰ When heterotopic or partial replacement transplantations have been performed it appears that the native liver can recover in some but not all situations, but this may require weeks or months to occur, underscoring the real challenge to liver replacement devices, that is, that liver assist devices might well be required for long periods of time.

PROGNOSIS

Table. Potentially Helpful Indicators* of Poor (Transplantfree)
Prognosis in Patients With ALF
Etiology
Idiosyncratic drug injury
Acute hepatitis B (and other non-hepatitis A viral infections)
Autoimmune hepatitis

Mushroom poisoning
Wilson disease
Budd-Chiari syndrome
Indeterminate cause
Coma grade on admission
III
IV
King's College Criteria:
Acetaminophen-induced ALF:
Arterial pH ≥ 7.3 (following adequate volume resuscitation) irrespective of
coma grade OR
PT ≥ 100 seconds (INR ≥ 6.5) \geq serum creatinine ≥ 300 μ mol/L (3.4 mg/
dL) in patients in grade III/IV coma
Non-acetaminophen-induced ALF:
PT ≥ 100 seconds irrespective of coma grade OR
Any three of the following, irrespective of coma grade:
– Drug toxicity, indeterminate cause of ALF
– Age ≥ 10 years or ≥ 40 years \ddagger
– Jaundice to coma interval ≥ 7 days \ddagger
– PT ≥ 50 seconds (INR ≥ 3.5)
– Serum bilirubin ≥ 300 μ mol/L (17.5 mg/dL)

Given limited organ availability, lack of good alternatives to transplantation, and potential complications of lifelong immunosuppression, accurate prognosis in ALF is a paramount goal. Prognostic scoring systems, although derived from data on relatively

large numbers of patients, still fail to achieve success, given the wide variety of etiologies that lead to this end stage syndrome. The traditional King's College Hospital criteria have been the most commonly utilized and most frequently tested of the numerous proposed prognostic criteria for ALF. Several studies evaluating these criteria have shown positive predictive values ranging from just below 70% to nearly 100% and negative predictive values ranging from 25% to 94%. Overall, such prognostic scores have proven to have acceptable specificity but low sensitivity to determine outcome. Criteria based on decreased levels of factor V in patients with encephalopathy predicted death in acute viral hepatitis cases with a positive predictive value of 82% and a negative predictive value of 98%, but subsequent studies in both acetaminophen and nonacetaminophen ALF have shown these criteria to be less accurate than King's College Hospital criteria in predicting outcome.

In a recent meta-analysis, Bailey et al. compared various prognostic criteria in patients with ALF due to acetaminophen, including King's College Hospital criteria, various combinations of elevated serum creatinine, encephalopathy, and prothrombin time elevations (both single and serial measurements), decreased factor V levels, the Acute Physiology and Chronic Health Evaluation (APACHE) II scores and Gc globulin (vitamin D binding protein, a liver-derived component of the actin-scavenging system [17]). The analysis found that King's College Hospital criteria and pH 7.30 alone were both fairly specific in predicting a poor outcome. While the King's College Hospital criteria were more sensitive than pH alone (69% versus 57% sensitivity), use of both criteria was still likely to miss many patients who would ultimately require transplantation. The authors also found that an APACHE II score of 15 on admission had a specificity of 92% (comparable to King's College Hospital criteria) with a much better sensitivity of 81%, but this measure was only examined in one limited study. Other factors such as age and the length of time between onset of illness and onset of encephalopathy have previously been proposed as important prognostic indicators in ALF, these parameters did not affect outcome in the largest U.S. multi-center study of ALF to date. Patients presenting in grade III or IV encephalopathy were less likely than those patients presenting in grade I or II encephalopathy to survive without receiving a liver graft. The most significant predictor of outcome in this study was etiology of ALF, as patients with ALF due to

acetaminophen, hepatitis A, shock liver, or pregnancy-related disease showed 50% transplant free survival, while all other etiologies showed 25% transplant-free survival. Other prognostic criteria have been proposed including severity of SIRS, Alpha fetoprotein (AFP) levels, ratios of factor VIII and factor V, liver histology, CT scanning of the liver, cytokine levels, serum phosphate levels, and adrenal insufficiency. Evaluations of these criteria have had varied results; while some appear promising, more research is needed to determine their reliability. The Model for Endstage Liver Disease (MELD) score, now widely used to predict mortality among patients with chronic liver disease who are under consideration for liver transplantation, cannot currently be recommended as applicable to ALF, a different condition from cirrhosis.

POSTCHOLECYSTECTOMY SYNDROME

The name a “postcholecystectomy syndrome” (PCES) is understood as a complex of pathological processes and states, that arose after cholecystectomy and are clinically connected with cholecystitis and conducted earlier operative treatment. It is needed to mention, that the term “postcholecystectomy syndrome” (PCES) is a collapsible concept and as a nosology form of disease can serve as a valuable diagnosis. Postoperative violations do not always mean the failure of cholecystectomy, because they can arise as a result of other different diseases which are masked under cholecystitis.

Classification

(by O.O.Shalimov, 1988)

PCES is distinguished:

1. PCES, related to the diseases of gall-bladder and changes in bilious ducts which were uncorrected at cholecystectomy (51 %):

- a) stenotic papillitis;
- b) stenoses of bilious ducts;
- c) tubular stenosis of choledochus on soil of chronic pancreatitis;
- d) residual choledocholithiasis;
- e) mechanical violations of patency of duodenum (chronic duodenojejunal obstruction and arteriomesenteric obstruction);
- f) cysts of bilious ducts;
- g) parasite diseases of bilious ducts.

2. PCES, conditioned by the changes which arose as a result of operative treatment concerning cholecystitis (19 %):

- a) iatrogenic damage of bilious ducts;
- b) scar stricture and deformation of bilious ducts with violation of outflow of bile;
- c) deformation of duodenum with violation of evacuation of its maintenance;
- d) remaining gall-bladder;
- e) strange bodies of bilious ways (filaments, needles, prosthetic appliances, fragments of drainages);
- f) reflux after transduodenal sphincteroplasty or choledochoduodenostomia;
- g) neurinoma of the cut nerves.

3. Disease of hepatopancreatoduodenal area, connected with protracted cholecystitis (17 %):

- a) chronic cholangiohepatitis;
- b) chronic pancreatitis;
- c) pericholedocheal lymphadenitis;
- d) intrahepatic and parahepatic abscesses;
- e) cholangiogenic sepsis;
- f) tumour of liver, bilious ducts and pancreas.

4. Organic and functional diseases of other organs and systems, not connected with the disease of gall-bladder and its deleting (7 %):

- a) hernia of the esophagus opening of diaphragm;
- b) ulcerous disease of stomach and duodenum;
- c) chronic gastroduodenitis, colitis;
- d) tumours of stomach and intestine;
- e) nephroptosis;
- f) kidney-stone disease and chronic pyelonephritis;
- g) solar plexitis;
- h) diencephalic syndrome;
- i) asthenovegetative syndrome, psychopathy, hysteria;
- j) Abdominal ischemic syndrome;
- k) deforming spondylarthrosis.

5. Nervously-kinetic violations of biliary ducts and duodenum (6 %):

- a) dyskinesia of biliary ducts and large papilla of duodenum (LDP);
- b) blood pressure LDP low;
- c) LDP hypertension;
- d) hypokinesia of duodenum;
- e) reflux-gastritis.

Symptoms and clinical passing

Clinical symptoms of postcholecystectomy syndrome, as a rule, show up in four basic complex symptoms: by a pain syndrome, mechanical icterus, cholangitis, internal and external biliary fistula.

Most patients continue to be disturbed by the attacks of “hepatic colic” or dull aching pain appears in right hypochondrium or in an epigastric area.

A leading role in the PCES (35–40 %) development belongs to “forgotten concretum”. There is a repeated formation of stone in rare cases.

An icterus which shows up by discoloration of skin, sclera, sky, by the positive reaction on biliary pigments, diminishment or absence of urobilin in urine and stercobilin in an excrement, by the increase of maintenance of bilirubin and alkaline phosphatase in a blood, is the important sign of PCES. As a rule, such patients are disturbed by the itch of skin and general weakness. The increase of temperature of body and fever are the important sign of cholangitis, which arise after the pain attack of “hepatic colic”. Such attacks, as a rule, are accompanied by the changes in blood (leucocytosis, appearance of young and stab neutrophil) test and functional violations of liver.

During intravenous cholangiography on sciagrams dilatation ducts can be seen and their emptying from the contrasting matter is slow. Retrograde pancreatocholangiography (Pic. 3.4.32) can set a level and character of obstruction of ducts (stone, tumour, indurative pancreatitis and others like that). In the PCES diagnostics ultrasonic examination occupies

important place by which it is possible to verify the sizes of bilious ways and expose concrement (Pic. 3.4.33).

The presence of external bilious fistula or drainpipe in biliary passings enables to contrast both intrahepatic and external bilious ducts (Pic. 3.4.34). External fistula are localized in the area of postoperative scar. Thus bile and pancreatic juice cause maceration of skin, rashes and infiltrate are formed. External fistula periodically can be closed and opened, accompanied by icterus and cholangitis, presence of gases in bilious ways and contrasting mass during the roentgenologic inspection of patient.

Variants of clinical passing

PCES engulfs different types of pathology, which differ by both the reasons of origin and clinical signs. At the PCES development conditioned by the uncorrected changes at cholecystectomy, a leading role belongs to concrement forgotten in a general bilious duct during cholecystectomy (35–40 %).

The real relapse of cholelithiasis is met seldom, only in 5–7 % and, as a rule, in people with the protracted anamnesis of gallstone disease, after choledocholithotomy and previous choledocholithiasis. Both the first and the second variants of pathology (forgotten stone or recurrent cholelithiasis), can cause pain of a different character in the area of liver, icterus and cholangitis. Distinguishing the real relapse of choledocholithiasis from unreal is difficult, therefore acquired concrement cholegraphy, sonography, retrograde pancreatocholangiography have the decisive value in diagnostics.

Scar stricture of large duodenal papilla (LDP) is met in 30 % cases. They are divided into primary and secondary. Under the concept of “scar of LDP stricture” the damage of distal part of general bilious duct by length from 5 to 10 mm is understood, the most widespread reason of which can be a gallstone disease. This complication usually shows up the attacks of hepatic colic or permanent aching pain in right hypochondrium. At intravenous cholegraphy contrasting of all parts of bilious ways is marked in such patients, expressed ectasia and delay of selection of contrast. Retrograde pancreatocholangiography has the decisive value in diagnostics of this complication.

It is needed to mark that except for the organic stenoses LDP, occasionally there are undiagnosed before operation functional, transitional forms of defeats of bilious ways which can be accompanied by high blood pressure or low blood pressure of sphincter. Operating trauma of nervous branches, formation of connections and scars always negatively influence the LDP function. Violation of function of sphincter is accompanied by pain and dyspepsia disorders.

Scar strictures of distal part of choledochus on soil of chronic pancreatitis (tubular stenosis) are considered to be a difficult type of pathology of bilious ways (15–16 %). The first signs of this disease, as a rule, arise during 2–3 months after operation and show up by

permanent dull pain in right hypochondrium, dyspepsia disorders, cholangitis and mechanical icterus. Valuable information in diagnostics of tubular stenosis can be got from retrograde pancreatocholangiography and percutaneous transhepatic cholangioduodenography.

The frequent reason of origin of pain after cholecystectomy is an inflammatory process in regional lymphatic knots. The so called pericholedocheal lymphadenitis can squeeze a general bilious duct, cause violation of function of the Oddi sphincter and predetermine development of pancreatitis.

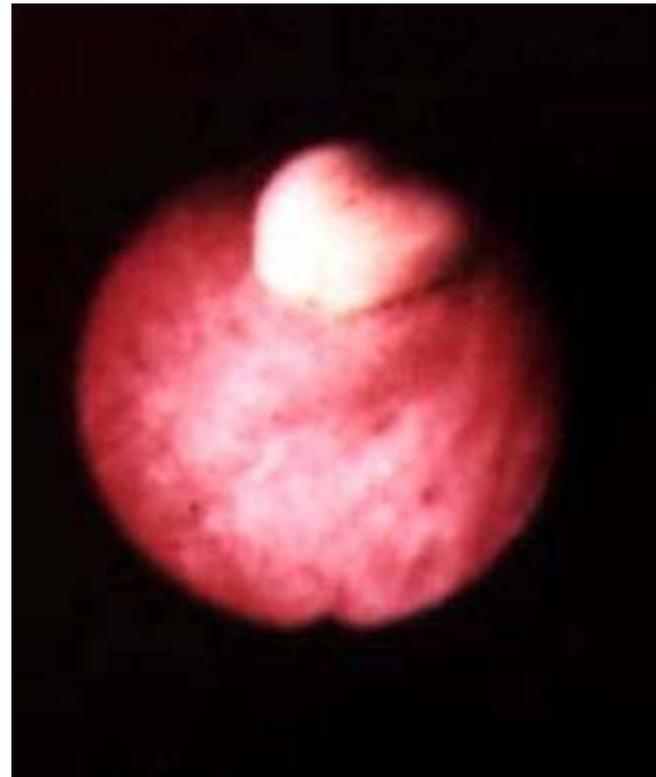

Pancreatitis, which is connected with cholecystectomy, can be met in 30–40 % patients with PCES. Similar pancreatitis arises up as a result of the undiagnosed stenosis of the Oddi sphincter and distal part of Wirsung's duct during operation on bilious ways. It results in violation of outflow of bile and pancreatic maintenance and provokes acutening of existing or origin of acute pancreatitis.

In 20–25 % cases the reason of PCES is duodenostasis undiagnosed before operation. Nausea, bitter taste in the mouth, periodic vomiting and loss of weight are the basic signs of this disease. Facilitation, as a rule, comes, when patients occupy knee-elbow position or lie down on the right side. Duodenomanometry is the basic method of diagnostics of duodenostasis (CDS) (normal pressure in a duodenum is 100–120 mm of col. or 1,17 kPa). During roentgenologic examination (tube relaxation duodenogram) violation of duodenal patency is exposed. The last can be conditioned by high duodenojejunal corner, arteriomesenteric compression, cicatricial periduodenitis, lacks of development of duodenum and others. Uncorrected during cholecystectomy such changes of duodenum can be the reason of unsatisfactory results of operative treatment of patients with cholecystitis.

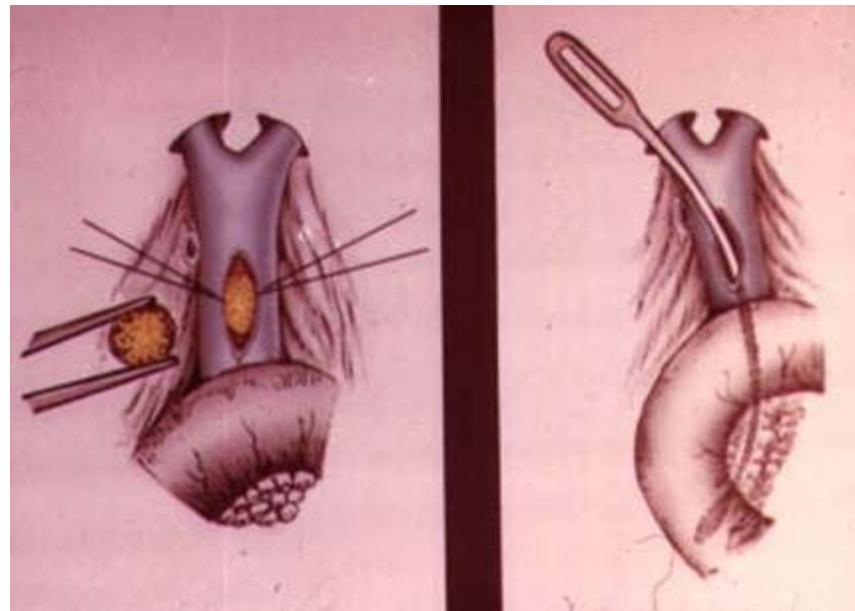

The organic and functional diseases of other organs and systems (hernia of diaphragm, ulcerous disease of stomach, duodenum and others like that), which are not connected with the disease of gall-bladder and its deleting, always require their preoperative diagnostics and previous treatment.

Diagnosis program

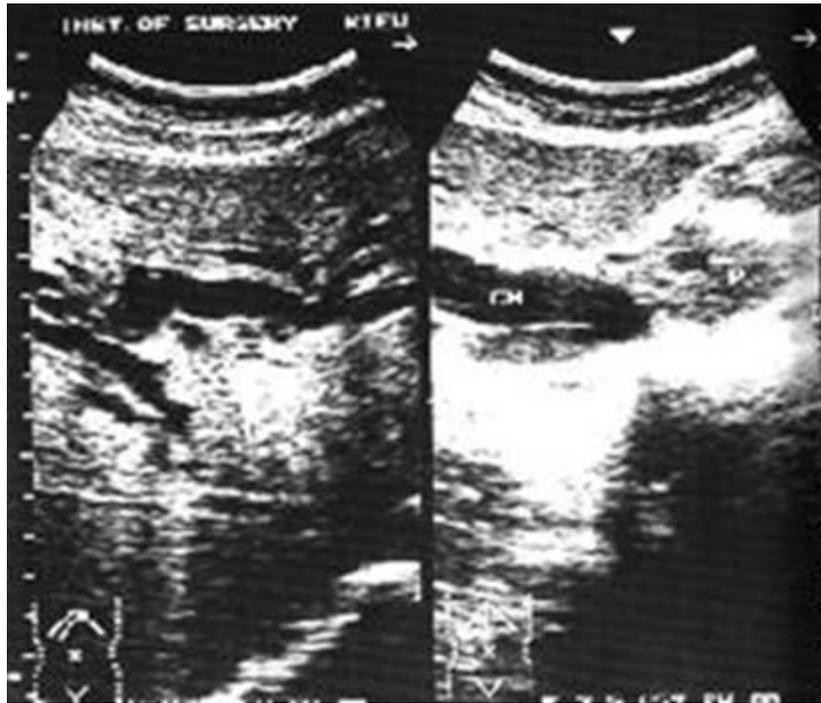

1. Anamnesis and physical methods of inspection.
2. Laboratory inspections (general analysis of blood, urines, biochemical blood test: bilirubin, cholesterol, creatinine, urea, amylase and others like that).
3. Duodenal intubation, duodenomanometry.
4. Roentgenoscopy and roentgenography of the stomach and duodenum, bilious ways.
5. Intravenous infusion cholegraphy.
6. Retrograde pancreatocholangiography.
7. Percutaneous transhepatic cholangioduodenography.
8. Computer tomography.
9. Scanning of livers.

Choledohoscopia. Choledochitis.

Supraduodenal choledochotomy

Sonography. Mechanical jaundice.

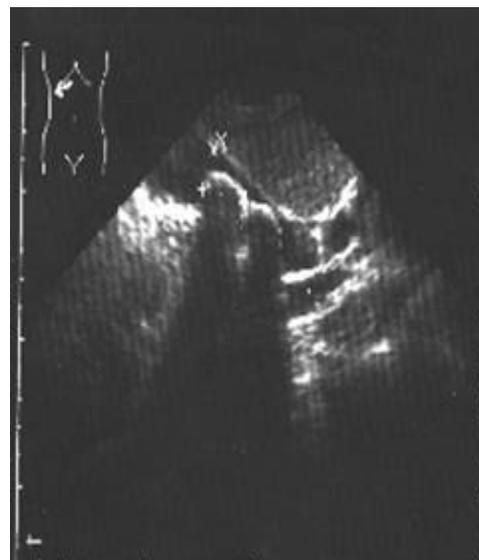

Choledocholithiasis. Retrograde cholangiopancreatography.

Choledocholithiasis on the terminal part of the choledochus. Transcutaneous transhepatic cholangiography.

Choledocholithiasis, ERCP

Sonography. Dilatation of the common bile duct.

Choledocholithiasis, fistulocholangiography.

Retrograde cholangiopancreatography. Choledocholithiasis.

Differential diagnostics

Chronic pancreatitis. Everyday medical practice testifies that in patients with the diseases of biliary ways the symptoms of damage of pancreas appear very often. Actually biliary pancreatitis is the most widespread form of chronic pancreatitis. For this disease belting pain and positive Mayo-Robson's symptom are characteristic. Thus, pain can be of “hepatic colics” character, accompanied by icterus or cholangitis. By palpation patients feel painfulness in the overhead half of abdomen.

At acutening of chronic pancreatitis there is growth of diastase activity in urines and amylase in blood. Ultrasonic examination, computer tomography have the important value in diagnostics of chronic pancreatitis.

Ulcerous disease of stomach and duodenum. Considerable difficulties can arise during conducting of the differential diagnostics of PCES with ulcerous disease, especially at its complications by penetration.

For diagnostics of this pathology character of pain, its intensity, time of origin and periodicity of appearance have the important value. In all doubtful cases it is necessary to conduct the x-Ray examination of both biliary ways and gastro-intestinal tract. Final confirmation of diagnosis can be got by endoscopy.

Tactics and choice of treatment method

Patients with a postcholecystectomy syndrome must be hospitalized in permanent surgical establishments, where after the inspection it is needed to define the character of treatment (conservative or operative).

Conservative treatment is conducted for:

- 1) patients with dyskinesia of bilious ways, with different diseases of gastro-intestinal tract, diabetes and other pathology of therapeutic type;
- 2) patients who are indicated to endoscopic papillosphincterotomy or surgical interference, but they renounce its conducting;
- 3) patients who need operative treatment, however, impossible it is to execute it because of difficult accompanying pathology.

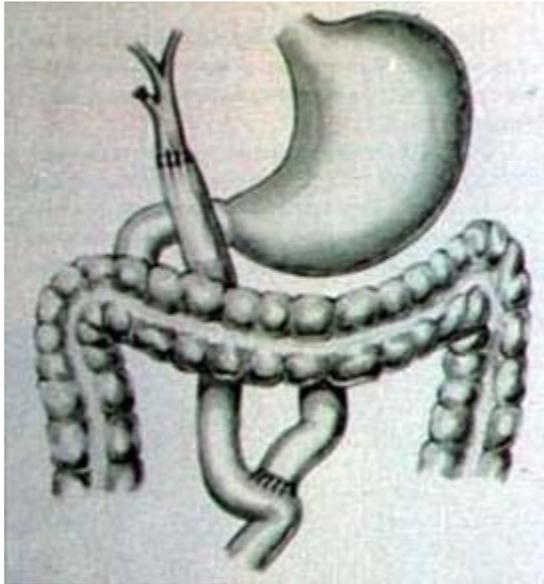

Conservative treatment is provided for:

- 1) removal of pain syndrome;
- 2) improvement of outflow of bile;
- 3) fight against an infection;
- 4) correction of exchange violations;
- 5) treatment of accompanying pathology.

Actually, taking into account the exposed reasons of PCES tactics of treatment can be chosen effectively. At residual choledocholithiasis, endoscopic papillosphincterotomy the stenotic papillitis method of choice with extraction of concrement must be chosen.

A diet is appointed to maximally spare the biliary system and gastro-intestinal tract, to foresee diminishment of calorie content, considerable limitation of fats and products which contain surplus of cholesterol.

From medicinal devices which normalize the function of sphincters of bilious ducts and duodenum (reglan, cerukal, sulperid, motillium, liquiriton, aprogen and others) preparations are used, they adsorb unconjugated bilious acids (fosfalugel, cholestyramin, bilignin), diminish inflammation of mucus shell (de-nol, vikair, venter) and repress activity of pathological microbe flora (furazolidon, biseptol, erytromicine and others).

Choledohejunostomy by Roux.

If the process spreads on liver or pancreas, correction is brought in medicinal therapy. The uneffectiveness of the conducted conservative therapy is an indication to the repeated operative treatment on bile-excreting ways.

Indication to operative treatment

1. Tumours of duodenal papilla, scar stricture of biliary duct, large stump of cystic duct and tubular stenosis of choledochus.
2. Mechanical icterus, internal and external fistula, expressed with the frequent relapses of cholangitis.

In argumentation of method of operative treatment of postcholecystectomy syndrome the intraoperative revision of biliary ways is of important value. In this plan of expansion of general biliary duct more than 10 mm is considered as a sign of biliary hypertension.

Considerable methods of the PCES diagnostics are also intraoperative cholangiography, choledochoscopy, cholangiomanometry and debitometry.

The choice of method of surgical treatment of postcholecystectomy syndrome, first of all, depends on character of pathology. Basic of them at postcholecystectomy syndrome are: 1) choledochoduodenostomy (by Finsterer, Flerken, Jurash, Kirschner); 2) choledohejunostomy (on the eliminated loop for Roux and after the Brawn method with choke by O.O. Shalimov); 3) transduodenal papillosphincteroplasty and wirsungoplasty.

[Biliary-enteric anastomosis: Running technique \(Video 2\)](#)

SYNDROME OF PORTAL HYPERTENSION

LIVER TRANSPLANTATION CHRONIC PANCREATITIS

Syndrome of portal hypertension is a complex of diseases, which predetermine the origin of violations of outflow of blood from the system of portal vein. The increase of pressure of blood in the pool of portal vein, which is accompanied by specific symptoms and complications, is the basic display of pathology.

Classification

According to the causal factors the syndromes of portal hypertension are divided into three kinds:

1. Intrahepatic, that arises at different forms of cirrhosis of liver.
2. The suprahepatic arises at the thrombosis of hepatic veins (the Badda-Kiari syndrome).
3. Pre-hepatic is thrombosis of basic trunk of portal vein.

Stages of development of portal hypertension.

1. Preclinical.

2. Expressed clinical signs.
3. Complications.

Cirrhosis of liver. Intrahepatic portal hypertension

The cirrhosis of liver is a chronic progressive disease, the characteristic signs of which are the defeats of parenchymatous and interstitial tissue of organ, necrosis and dystrophy of hepatic cells, with the subsequent node regeneration as diffuse excrescence of connecting tissue. All this finally results in a different degree of insufficiency of functions of liver and origin of syndrome of portal hypertension.

[video](#)

Etiology and pathogenesis

Acute and chronic hepatitis, alcoholism, tuberculosis, malaria, syphilis, brucellosis, helminthiasis, lacks of heart, gallstone disease, exchange violations are considered the reasons of pathology (hemochromatosis, hepatolenticular degeneration, albuminous starvation and vitamin insufficiency (B6, B12, E), collagenosis (rheumatoid arthritis, lupus erythematosus), thireotoxicosis, toxic factors (industrial poisons, medicines).

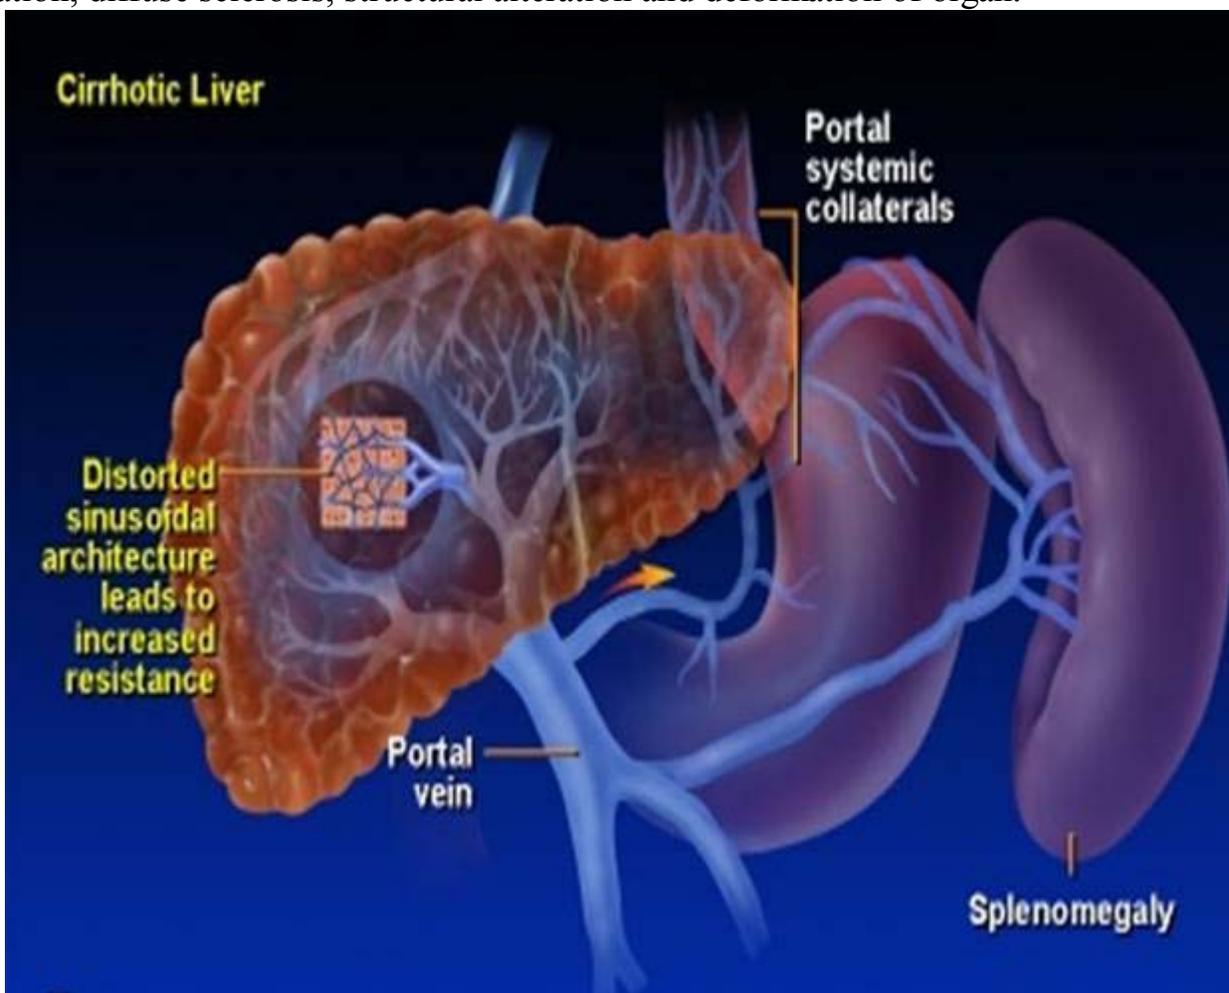

As a result of the influence of harmful factors there is a destruction of hepatocytes (cytolysis) and subsequent excrescence of connecting tissue. Thus there are violations of transhepatic bloodflow, which is the principal reason of portal hypertension. The increase of pressure in the system of portal vein results in expansion of natural portocaval anastomosis: 1) between the veins of cardial part of stomach and esophagus (porto-esophageal way); 2) between paraumbilical veins and umbilical (portoabdominal way); 3) between superior, middle and inferior rectal veins (portorectal way). Of less importance are other groups of anastomosis: portoileocecal, lumbal, rectal, pulmonary.

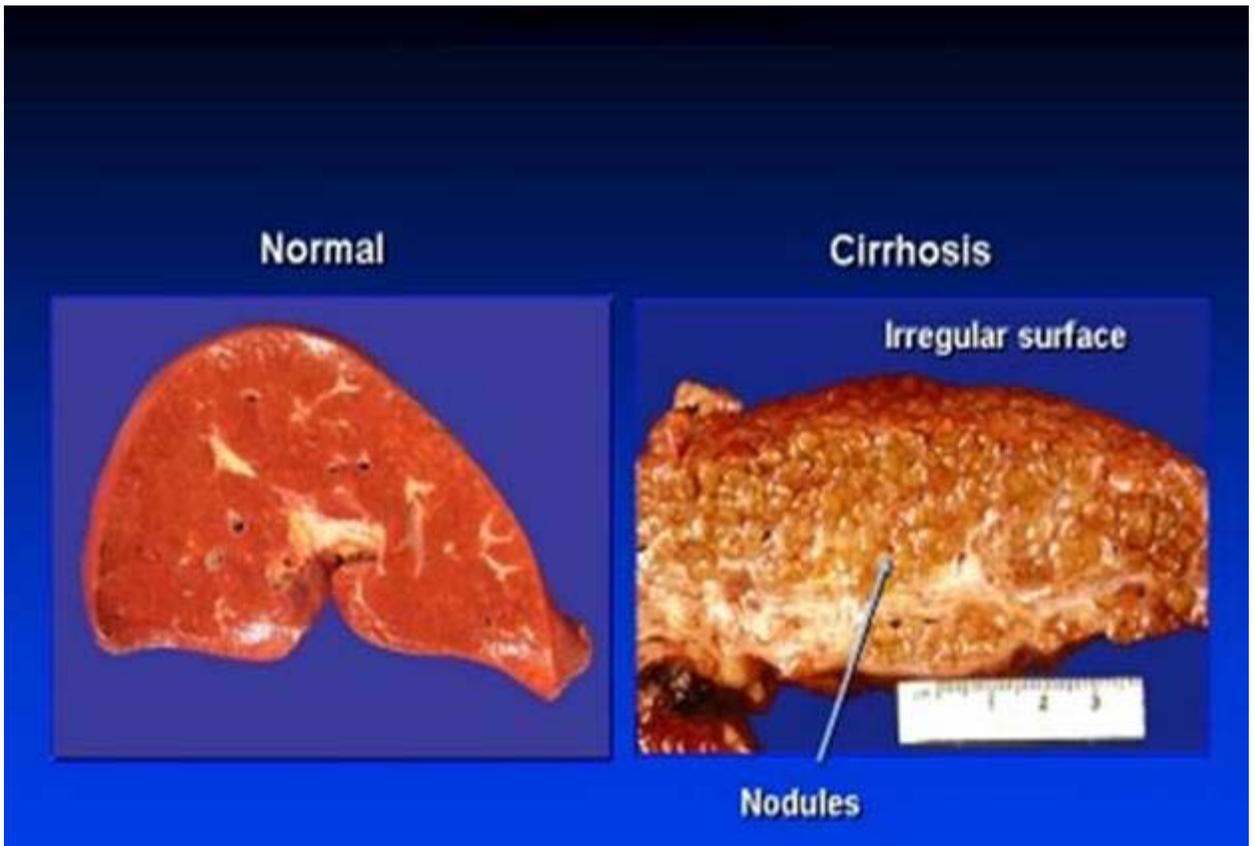

Pathomorphology

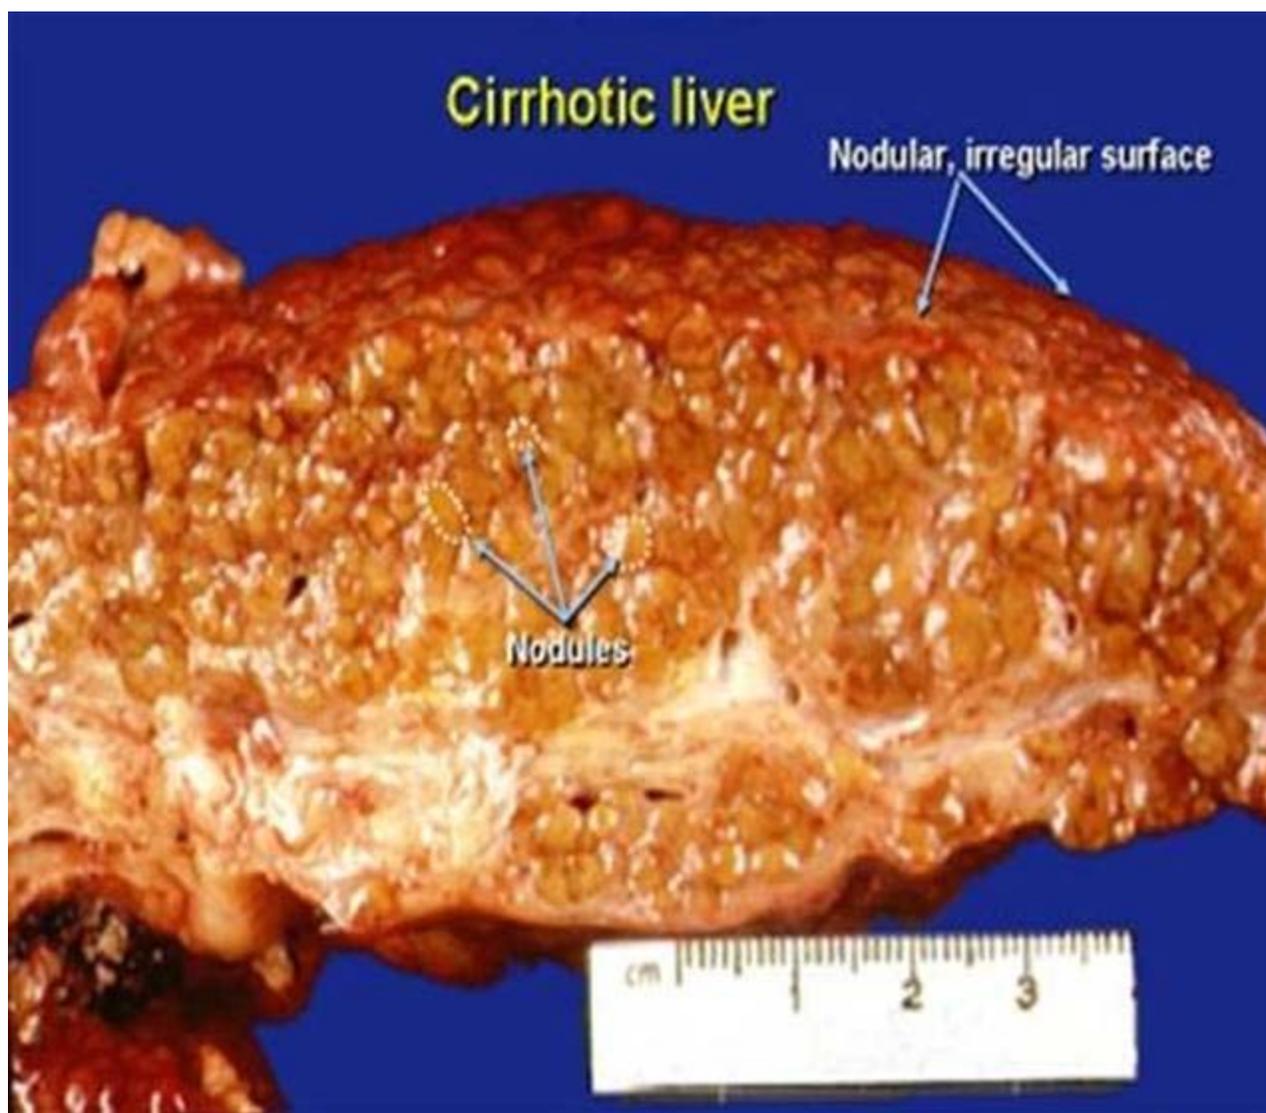

The liver at cirrhosis is dense macroscopically, knotted, diminished in size, rarely is increased. Depending on the size and character of knots, the macroscopic forms of cirrhosis are distinguished: small-nodular, large-nodular, mixed.

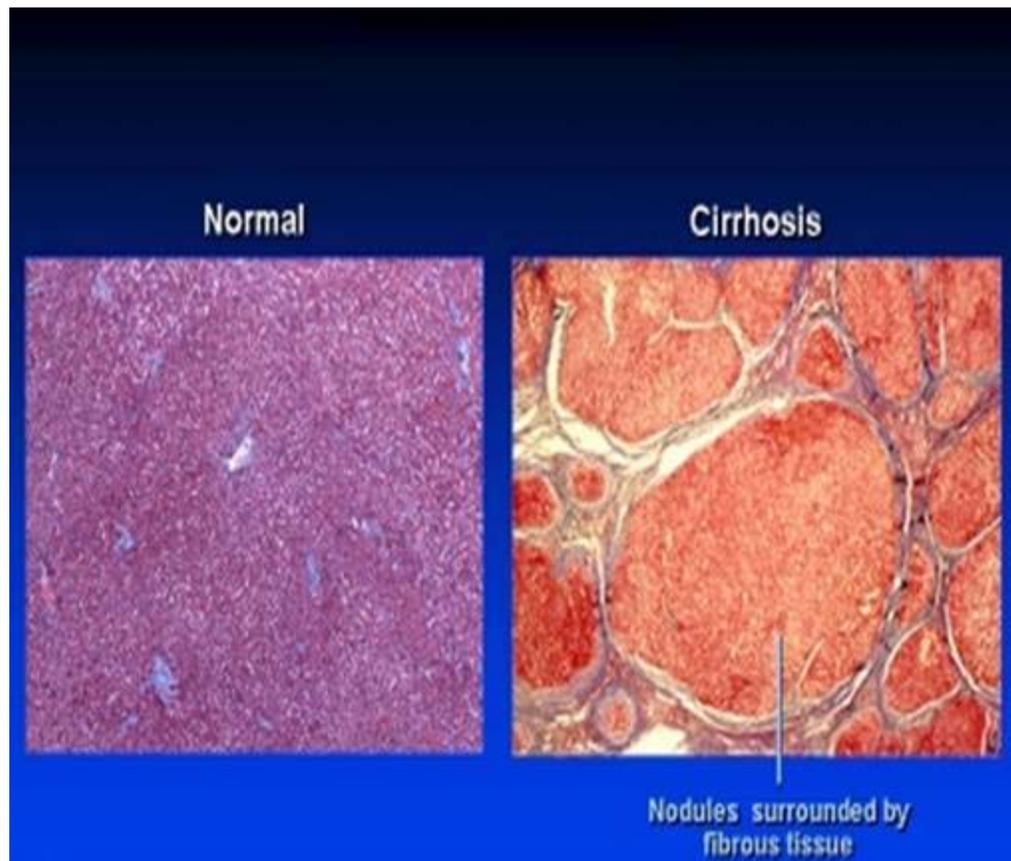

Postnecrosis cirrhosis — large-nodular or mixed; portal — small-nodular; initially bilious — small-nodular or with a smooth surface; second time bilious — small-nodular. At the first two types of cirrhosis the surface of cut is of red colour, at bilious — grey-green.

The histological signs of cirrhosis are: dystrophy and necrosis of hepatocytes, disfigured regeneration, diffuse sclerosis, structural alteration and deformation of organ.

Classification

According to Havana classification (1956), cirrrosises are divided into:

- 1) portal;
- 2) bilious;
- 3) postnecrosis;
- 4) mixed.

According to the stages of development:

- 1) initial;
- 2) formed cirrhosis;
- 3) dystrophic.

According to the degree of weight:

- 1) easy;
- 2) middle;
- 3) heavy.

According to passing:

- 1) progressive;
- 2) stable;
- 3) regressing.

Symptoms and clinical passing

Pain syndrome. It is characterized by permanent aching, sometimes intensive, pain in right hypochondrium with an irradiation in the right shoulder-blade and back.

To the dyspepsia syndrome is characterized by loss of appetite, nausea, vomiting and weight loss.

Syndrome of cholestasis. The colour of skin of patients with this type of pathology can be from insignificantly yellow to earthily-grey. The presence of icterus specifies the activity of inflammatory process in the liver.

In cases of asthenovegetative syndrome, as a result of progress of encephalopathy, the inversion of sleep comes (somnia in the day-time and insomnia at night). General weakness, rapid fatigueability, irritates and headache are characteristic.

Syndrome of endocrine violations. Patients with this syndrome are characterized by the gynecomastia and decline of potency for men, for women — disorders of menstrual cycle.

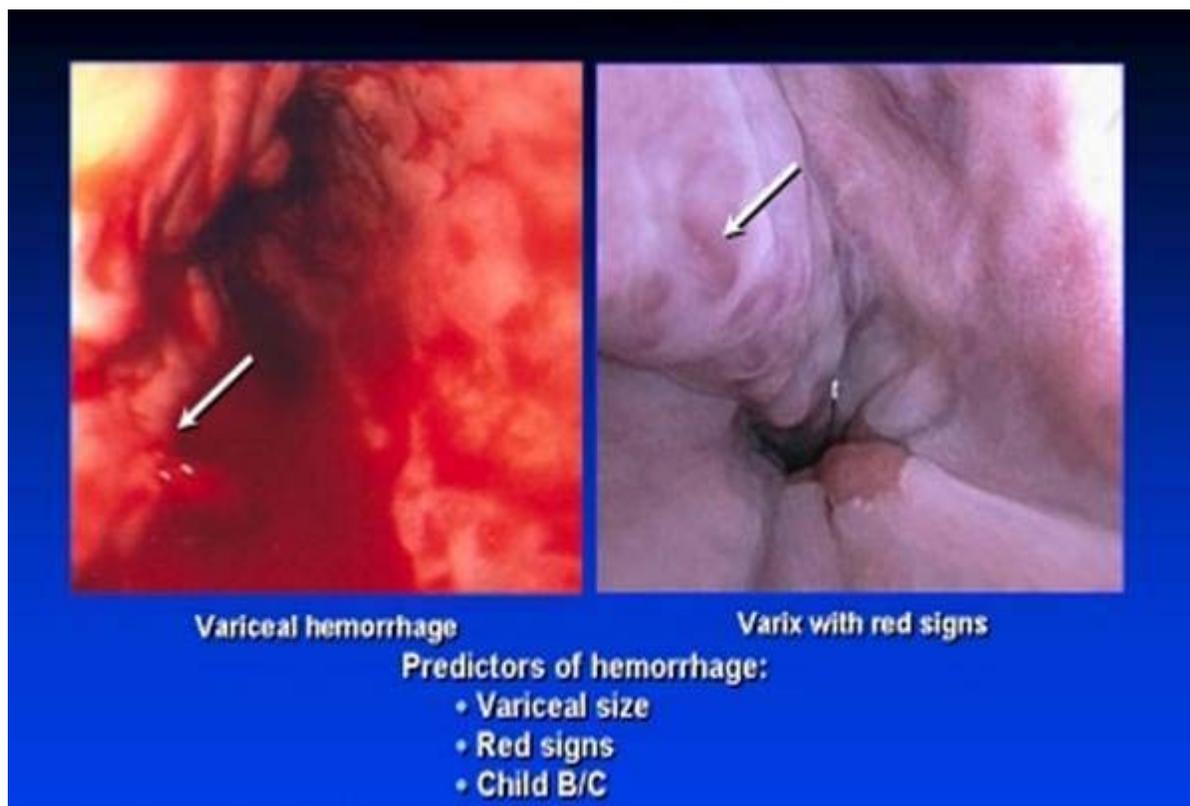

Syndrome of portal hypertension. Expansion of veins of oesophagus stomach, haemorrhoid veins, veins of front abdominal wall, splenomegalia, hypersplenism (anaemia, leucopenia, thrombocytopenia) and ascites are considered basic signs.

Objective data: at the observation patients display the icteric of skin and mucus, vascular “asterisks” on face, neck, brushes, breasts, “hepatic hands” (rose marble of skin), increased in sizes, as a result of ascites, stomach (“frog stomach”), varicose expansion of veins of abdominal wall (“head of jelly-fish”).

During palpation of abdomen the liver is increased, dense, with acute edge and fine-grained surface. At the atrophy cirrhosis it is impossible to palpate it. Spleen is increased, ascites is marked.

Laboratory information. Anaemia, leucopenia, thrombocytopenia, hypoproteinemia, relative hyperglobulinemia and hypoglobulinemia are characteristic signs of cirrhosis. The increase of level of alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, positive reaction of Takata-Ara; change of coagulate ribbon to the right (the Veltmann test), hypoprothrombinemia and increase of immunoglobulin A, C are observed also.

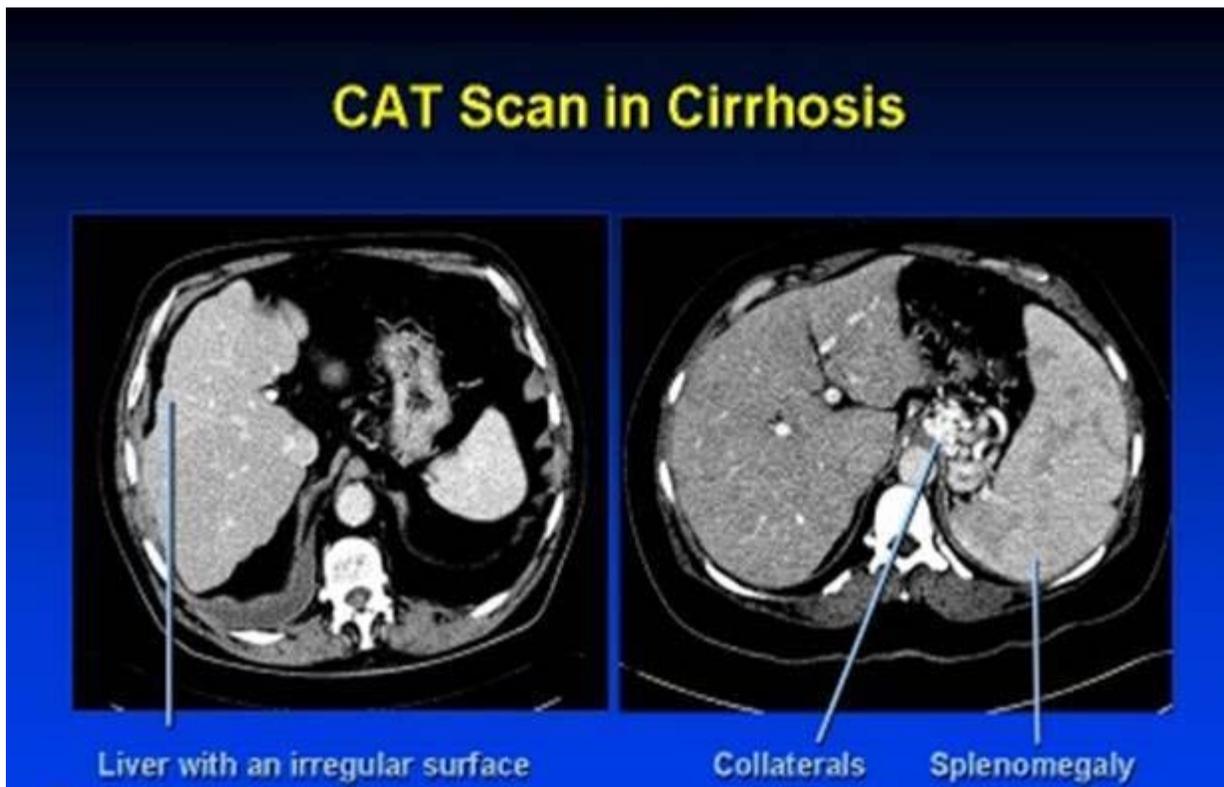

By endoscopy it is possible to expose varicose expansion of veins of oesophagus and cardial part of stomach.

Under roentgenoscopy, roentgenography of oesophagus and stomach the characteristic picture of varicose expansion of veins of oesophagus is observed.

Sonography enables to estimate sizes, structure of liver and spleens, to visualise a portal vein and its influxes, and also to expose ascites.

Computer tomography more precisely than sonography, allows to investigate the changes in the liver and neighbouring organs.

Hepatoscintigraphy gives information about position, sizes, degree of accumulation to nuclide in the liver and spleen.

Intravenous radiohepatography (albumen marked I131) can characterize arterial and portal bloodflow in liver and spleen.

Reohepatography enables to find out the state of bloodflow of liver.

Splenoportography visualises the vessels of the portal system, exposing thrombosis or considerable expansion of portal vein and its influxes, poverty of hepatic vascular picture (cirrhosis of liver). During this manipulation portal pressure which in such patients usually is higher 250 mm (2,45 kPa) of waters is measured.

By *celiacography and mesentericography* expansion and sinuosity of splenic artery and poverty of hepatic vascular picture are exposed. Expansion of splenic and gate veins is observed in the vein phase.

Application of laparoscopy can give valuable information about the state of liver, spleens and presence of ascites. Clinical passing of cirrhosis of liver depends on etiologic factors, activity of process, degree of functional insufficiency of liver, presence of complications and accompanying diseases.

Variants of clinical passing and complication

At *slow progressive passing* the symptoms of disease periodically either increase or become less expressed. Characteristic are the damage of parenchyma of liver and protracted

passing.

Together with that, quick progressive passing is a transitional form from subacute atrophy of liver to the cirrhosis. Death of patients at such passing of pathology, as a rule, comes as a result of hepatic insufficiency during a few months from the beginning of disease.

Most characteristic for the alcoholic cirrhosis of liver after the absolute exception of reception alcohol and adjusting of valuable nutrition is *regressive passing*.

Protracted periods of remission which come on the early stages of cirrhosis after adequate conservative treatment are inherent to *stable* character of passing.

Complications: bleeding from the varicose extended veins of esophagus and stomach, haemorrhoidal veins, choleic bleeding, thrombosis of portal vein, hepatogenic gastric ulcers, hepatic insufficiency, hepatic comma, transition of cirrhosis in cancer and encephalopathy.

Complication of portal hypertension by bleeding from the varicose extended veins of esophagus carries the instant danger for life of patient, if portal pressure grows over 250–300 mm of waters (2,45–2,94 kPa). Lethality of patients after the first bleeding makes 25 %, after the second — about 50 % and after the third — over 75 %. Such complications can arise both during complete rest and after the physical loading. Bleeding, as a rule, is profuse, and is accompanied by vomiting by “coffee-grounds” and grume of fresh blood. Thus patients often have collapse with the acute falling of arterial pressure and eclipse of consciousness. The frequent liquid emptying of black can also take place (melena).

Diagnosis program

1. Anamnesis and physical examination.
2. General analysis of blood and urine.
3. Biochemical blood test (albuminous factions, bilirubin, glucose, AlAT, ASAT, alkaline phosphatase, cholesterol, reaction of Takata-ara, the Veltmann test; electrophoresis albumens).
4. Coagulogram.
5. Endoscopy.
6. Contrasting sciagraphy of oesophagus, stomach.
7. Sonography.
8. Scanning of livers.
9. Splenoportography.
10. Laparoscopy.

Differential diagnostics

Insufficiency of circulation of blood after the right ventricle type can be accompanied by an increased painfulness of liver. It can be the reason of such symptomatic complex as rheumatism, atherosclerotic cardiosclerosis, innate lacks of heart and chronic pulmonary heart. However, for this pathology edemata on lower extremities which arises long before development of ascites is characteristic. It is needed to remember, that ascites well responds to

treatment by cardiac glycoside and diuretic. And yet, except for anasarca, for insufficiency of circulation of blood the shortness of breath is characteristic, acrocyanosis and the stagnant phenomena in lungs, changes of ECG. The icterus in such patients is very rarely, and the functional tests of liver change insignificantly.

Pericarditic pseudocirrhosis. This pathology develops at squeezing pericarditis. Except for development of ascites, that can be observed, for this pathology symptoms of constructional pericarditis are characteristic also: increase of vein pressure over 200 mm of waters. item (1,96 kPa), paradoxical pulse (disappearance during inhalation) and decline of amplitude of pulsation of heart on roentgenokymography. Roentgenologicly, laying of salts of calcium in a pericardium, “little” and “quiet” heart are found in patients. For this disease characteristic are the typical changes at ECG and phonocardiography.

Tactics and choice of treatment method

Conservative treatment. Patients with non-active compensated or minimum activity by cirrhosis, as a rule, do not need special medicinal treatment. Mainly the shown base therapy (principle of maximal medicinal and functional spare of liver, providing of the optimum dietary mode and employment, dynamic clinical supervision with correction of the mode and setting of vitamins, enzymes and other preparations) is applicable here. In relation to patients with subcompensated non-active or minimum activity by cirrhosis of liver, they are expedient to apply the medicinal course of treatment: daily intravenous in drops inflowing of Neohemodesis (200 ml) or solution of glucose (5 % — 200–300 ml), use of Esenciale (2 capsules three times on a day) or Legalon (Karsil) (2–3 drops three times on a day). 2 courses of the noted treatment are conducted for a year. At hypoalbuminemia it is rationally to connect anabolic steroid — Retabolil (50 mg 1 time per two weeks intramuscularly, course — 4–5 injections) also, transfusion 2–3 times per a week of solution of the albumen 10–20 % (10–20 g) or plasma (100–200 ml).

Patients with the active phase of cirrhosis, need to be hospitalised when they have expressed portal hypertension and presence of ascites, bed rest, limitation in day's feed of salt to 5 g and to conduct correction of water-electrolyte exchange are appointed to them.

It is possible also to recommend potassium-sparing diuretic: Veroshpiron (0,025 g 3–4 times per a day) or Triamteren (0,3 g 2 times per a day), Uregid or Oxodoline (0,05–0,1 g 1 time per 2–3 days).

At presence of ascites the concentrated plasma (125–150 ml 1 time per a week, course — 4–5 inflowing) and 20 % solution of albumen (100 ml 1 time per a week, course — 8–10 inflowing) is applied.

Abdominal paracentesis and deleting of liquid is conducted in case of proof ascites, that does not respond to adequate treatment, and also at hepatorenal syndrome or threat of the oesophagus bleeding.

At hepatic comma:

1. Through subclavian catheter the inwardly-vein introduction 5 % solution of glucose (1000–1500 ml on days) with cocarboxylase (300 mg) is put, by the vitamin B12 (500 mcg), by

lipoic acid (180 mg) — 20–30 drops for a minute.

2. Prednisolone (150 mg intravenously, by stream and then in each 4 hours for 90 mg).
3. Arginine (25 g intravenously, in drop, and then in that dose in every 8 hours), 20–25 g Ornacetil intravenously for the day long.
4. Kanamicine (0,5 g) or Polymixine of M (150 000 ODES) or ampicillin (1,0 g) — each 4 hours through a stomach-pump.
5. Washing of intestine is 1 time per days.
6. Exchange blood transfusions — daily, during 7–10 days.
7. Introduction of oxygen through a nasal catheter (2–4 л/min).
8. At development of metabolic acidosis — 200–600 ml 4 % solution of hydrogen carbonate of sodium.
9. In case of expressed metabolic alkalosis there are preparations to potassium (to 10 g on days).

All adopted measures are continued to taking the patient from comma.

It is thus needed to mark that from data of practice conservative treatment of patients with the cirrhosis of liver reverse development of cirrhosis or prevent progress of disease can not be provided. Without regard to it, medicinal therapy, however, can improve the general condition of patient.

However, in all patients with the disease of liver it is needed to look for possibility of transplantation of this organ, and by an indication it is needed to count appearance of hepatargia.

Surgical treatment. Operative treatments are divided into two groups:

- 1) radical, that can liquidate portal stagnation;
- 2) palliative, which are able only to level the separate signs of this pathology.

Contra-indication to operation: 1) decline of albumens of blood to the level of 2,5 % and below; 2) falling of albumin-globulin coefficient less than 0,7; 3) diminishment of prothrombin index below 30 %; 4) presence of symptoms which specify active destructively-inflammatory process in liver (hectic temperature of body, leukocytosis, acute increase of level of transaminase and globulin faction and positive reaction on a C- reactive albumen).

Radical operations

Among them most widespread are:

1. Direct portacaval shunt: a) latero-lateral; b) termino-lateral. (Fig. 1) Bleeding is considered an indication for application of this operative treatment from the varicose veins of esophagus (in anamnesis) on soil of intrahepatic block.

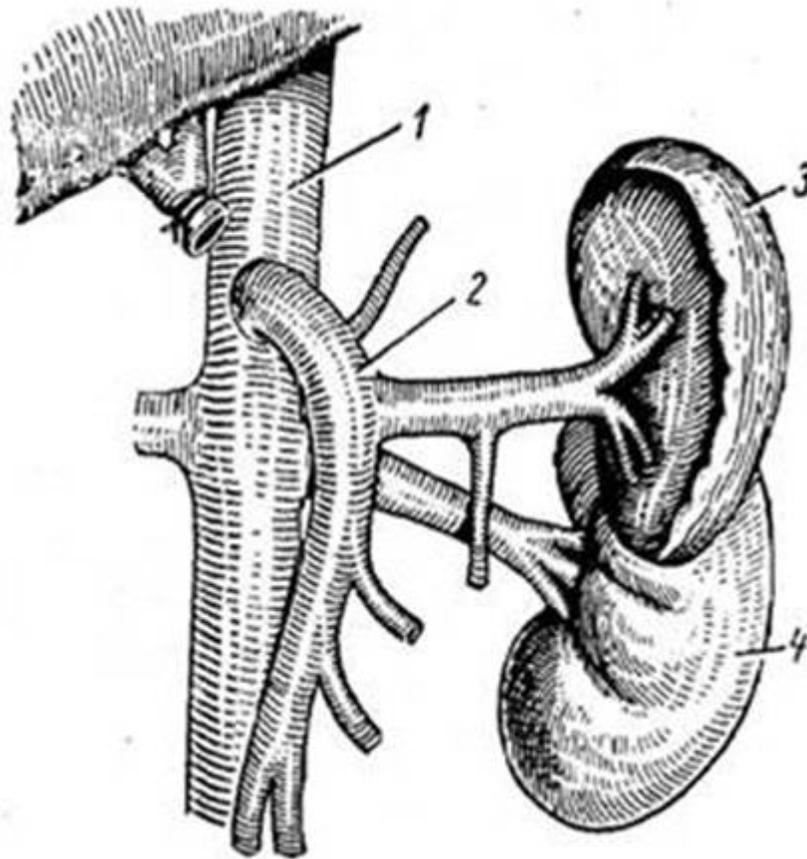

Fig. 1. Direct termino-lateral portocaval anastomosis

1-inferior vena cava

2-portal vein

3- spleen

4- left kidney

2. Splenorenal anastomosis: a) termino-lateral;(Fig.2) b) termino-terminal; c) H-shaped (by autovein or alloprosthesis). An indication is bleeding from the varicose veins of esophagus (in anamnesis) on soil of intrahepatic and suprahepatic blocks.

5-superior mesenteric vein

6- spleen

7- left kidney

4. Anastomosis of shallow veins is ineffective and is not presently used.

Palliative operations

Among them the widespread are used:

1. Operations directed on stimulation of regeneration of liver: a) partial (regional) resection of liver; b) electro-coagulation of surface of liver; c) cryogenic and laser destructions of surface of liver; d) periarterial neurectomy of general hepatic artery; e) bandaging of splenic artery and splenectomy; f) endovascular embolization of splenic artery.

2. Organoanastomosis:

a) omentopexy;

b) omentodiaphragmopexy;

c) omentohepatopexy.

3. Operations at ascites:

- a) laparocentesis; [VIDEO](#)
- b) taking of ascites liquid in preperitoneal, retroperitoneal and hypodermic cellulose, in urethra;
- c) lymph-venous anastomosis (between a pectoral lymphatic duct and internal or external jugular vein);
- d) peritoneovenous shunting by the synthetic tube with a valvular device, taken in an abdominal wall;
- e) extraperitonization of the livers (formation of vascular communications between a liver and diaphragm).

Tactics at bleeding from the varicose veins of esophagus

Treatment of patients at bleeding from the varicose veins of esophagus needs to be begun with the tamponade internal surface of esophagus and cardial part of stomach by the special double-balloon Sengstaken-Blakemore tube. Some other conservative measures directed on the stop of bleeding without the use of this probe are considered ineffective and tactically wrong.

The Sengstaken-Blakemore tube has three ducts, two of which are connected with rubber bulbs, one — with the cavity of stomach. (Fig.4)

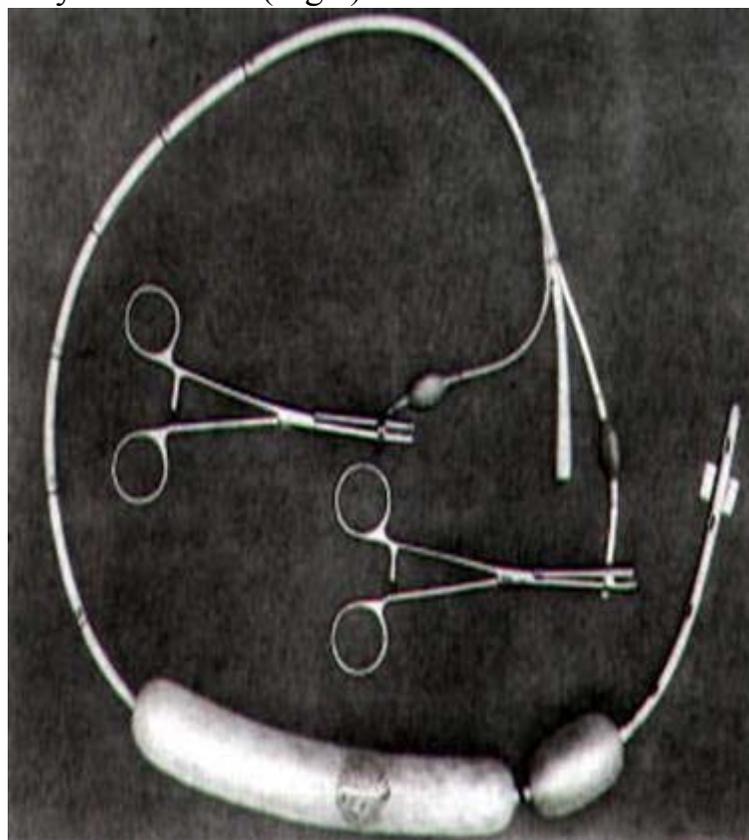

Fig.4 Sengstaken-Blakemore tube

Before application of probe by introduction of air the volume of bulbs is measured. Probe through a nose and in a distal (gastric) bulb is inserted, the necessary amount of air is forced (about 150,0 ml). After this by drawing out of it a round (distal) gastric bulb is pinned outside against cardia. Farther prolonged esophagus bulb is inflated to appearance at the patients feeling of arching (volume about 120,0 ml) and it is obturated. Then to the proximal end of

probe through the block, the load is suspended weighing about 1 kg. It warns reverse advancement of probe in stomach and by this provides stability of compression of the varicose extended veins. The control after hemostasis is carried out through the third, connected with stomach, duct of probe. By such method it can be succeeded to attain to hemostasis in 80–90 % cases. The probe in such position is held 2–3 days. After this decompression of repeated bleeding can come almost in half of patients. Therefore deleting the probe is not needed. Taking this into account, it is expedient to carry out decompression of bulbs in the light intervals of days and inflate bulbs at night, when the control after the possible bleeding is complicated.

Conservative treatment is reasonable: 1) at the easy degree of loss of blood and I degree of hepatic insufficiency (basic biochemical indexes either are not changed or with insignificant deviations from a norm; ascites and encephalopathy are absent);

2) at the III degree of hepatic insufficiency, progressive ascites and encephalopathy, regardless of degree of loss of blood.

Conservative therapy of bleeding from the varicose veins of esophagus must engulf the whole volume of medical measures, as at similar pathology of ulcerous genesis (hemostatic therapy, antacid, H₂- blocker histamine receptors).

For the decline of portal pressure pituitrin is entered. The endoscopic methods of stop of bleeding are applied also (imposition of clips on veins, sclerosis therapy — 76 % ethyl alcohol, Varicocide, 66 % solution of glucose, endovascular occlusion of veins, laser coagulation of veins). It is needed to count setting of preparations for stimulation of regeneration of liver (esenciale, lif-52 and others like that), application of disintoxication therapy.

Surgical treatment is considered applicable at bleeding of middle and heavy degrees with the I and the II degrees of hepatic insufficiency (general bilirubin not more large 50 $\mu\text{mol/L}$, general albumen not more small 60 g/L , prothrombin index not more low 60 %, present transient ascites) in the cases when the valuable conservative treatment directed on the stop of bleeding is not effective during 24–48 hours.

Types of operations

I. Operations directed to disconnection of gastroesophageal vein way.

1. The Taner's operation:

a) transversal cutting and sewing together of stomach in subcardial part;

b) cutting with the next sewing together of esophagus in supradiaphragmatic segment.

2. Operation by O.O. Shalimov is cutting and sewing together of esophagus by the device for circular anastomosis.

3. Sewing of cardioesophageal transition circular by U-shaped stitches after V.M.

Korotkyy.

4. Operation developed by M.D. Paciora, is sewing and bandaging by separate ligatures of bleeding veins of cardial part of stomach and esophagus from the side of mucus shell.

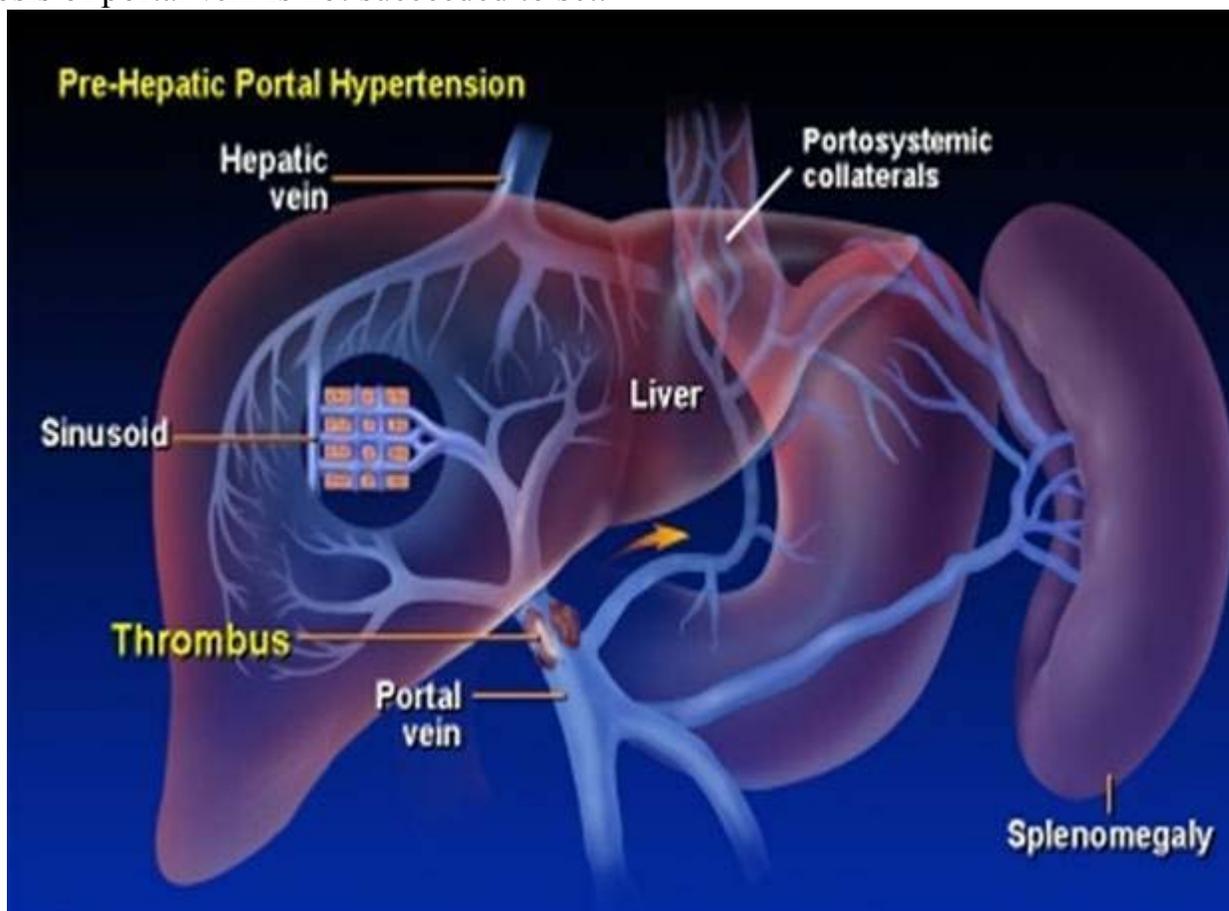

5. Resection of distal part of esophagus and proximal part of stomach.

II. Operations which reduce portal pressure: portocaval anastomosis (direct and selective), splenectomy.

Thrombosis of portal vein. Subhepatic portal hypertension

Etiology and pathogenesis

In children the basic etiologic factor which predetermines the thrombosis of portal vein, is infectious aggression. Inflammatory processes of abdominal cavity (acute appendicitis, cholecystitis traumas), the getting wet belly-button of new-born are those principal reasons which predetermine the origin of pylephlebitis and thrombopylephlebitis. In adults the most frequent reasons of thrombosis of portal vein are the cirrhosis of liver and hepatoma. Similar pathology can develop after splenectomy or operations on bilious ways. The reason of thrombosis can be the cardiovascular anomalies of development, in particular, innate defect of portal vein. However, it is needed to mark that in the half of patients reason of origin of thrombosis of portal vein is not succeeded to set.

Symptoms and clinical passing

In patients with portal hypertension, that arose on soil of thrombosis of portal vein, acute symptoms, as a rule, are absent. However, it is possible to observe the dyspeptic phenomena in them: nausea, bad appetite, flatulence. Moderate pain is felt in right hypochondrium, that is multiplied after acceptance of meal.

At this pathology appearance of early ascites which mainly carries temporal, transitional character is characteristic, sometimes it takes out chronic shape. On more late stages hypersplenism can develop and bleeding arise from the varicose extended veins of esophagus and cardia.

The general condition of patients here can remain satisfactory, the relapses of bleeding from the varicose extended veins of esophagus and cardia are seldom. If they arise, they are carried by patients relatively well. It can account for favourable passing of portal hypertension by development of collateral circulation of blood. Together with that, productively unfavourable passing of disease is observed on the background development of chronic ascites and portocaval encephalopathy.

The diagnosis is usually confirmed by sonography and splenoportography. Valuable information about such patients can be given by computer tomography on the background rapid introduction of contrasting matter to the portal system (computerized axial tomography).

Tactics and choice of treatment method

Effective preparations of conservative treatment of portal hypertension caused by the thrombosis of portal vein for modern medicine so far are unknown. However, as bleeding from the varicose extended veins of esophagus and cardia seldom are profuse and it is comparatively well added to conservative therapy, it is expedient to apply, even on an early stage, unoperative methods of treatment. Moreover, possibilities of surgical treatment at this pathology are limited. In fact in this situation technically adequate portocaval decompression is difficult to execute in connection with the thrombosis of basic branches of the portal system. However, in default of effect from conservative therapy in patients with complication by much bleeding, dissociative operations are to be applied to the type of Taner's or sewing of vessels on verge of esophagus and cardial part of stomach. Together with that, it is needed to mark that this operative treatment gives only a temporal effect.

Thrombosis of hepatic veins (the Budd-Chiari disease).

Suprahepatic portal hypertension

Etiology and pathogenesis

In most patients etiology of disease is unknown. Application of oral contraceptives, and also presence of intrahepatic and anhepatic tumours, is instrumental in the origin of pathology. The process can be accompanied by the thrombosis of lower hollow vein (the Budd-Chiari syndrome). This syndrome can arise also at thrombosis or stenosis of lower hollow vein at the level of hepatic veins. Portal hypertension, usually, develops early, and the cirrhosis of liver is formed after some time.

Symptoms and clinical passing

For the clinic of disease, as a rule, stormy passing is peculiar. Thus patients feel great pain in stomach, liver is increased, painful. Increasing ascites is often observed. As experience shows, development and expression of symptoms of disease depend on the depth of damage by the thrombosis process of hepatic veins and joining of thrombosis of lower hollow vein.

The disease is also accompanied by development of polycythemia, which is the second and conditioned, from one side, by concentration of blood, and from other — investigation of increased products of erythropoietin, that is selected by a regenerating liver.

At endoscopy the varicose extended veins of esophagus and cardial part of stomach are exposed.

In some patients it is possible to observe acute passing of the Budd-Chiari syndrome, that usually has bad prognosis and is often closed lethally. Portal hypertension in these patients, as a rule, develops early and has the expressed character, sometimes arriving at maximal numbers (390–400 mm of waters). Bleeding which arise on this background carries difficult profuse character.

Tactics and choice of treatment method

Conservative therapy in such cases is ineffective. At acute passing of disease lethal end can be warned only by forming of direct or selective portocaval anastomosis. The protracted (chronic) passing of disease is also accompanied by early and expressed portal hypertension, that can be complicated by bleeding from the varicose extended veins of esophagus. In such cases, as well as at acute forms, although not so quickly, the operative treatment directed on decompression of the portal system is possibly conducted.

LIVER TRANSPLANTATION

History

Canine liver grafts were shown to function after transplantation to the pelvis by Welch in 1955. Orthotopic liver transplantation in dogs was attempted by Cannon in 1956 and performed successfully by Moore in 1959. The first attempt at liver allotransplantation in man was made

by Starzl at the University of Colorado on March 1, 1963. The 3-year-old recipient with extrahepatic biliary atresia died of hemorrhage on the day of transplantation. Ensuing attempts in Denver, Boston, and Paris were unsuccessful until 1967, when the first extended survival of a human liver allograft recipient was achieved by Starzl. The addition of cyclosporine immunosuppression by Calne in 1978 and then combination therapy with cyclosporine and prednisone by Starzl in 1980, as well as better liver preservation and surgical techniques, improved the prospects for clinical liver transplantation

INDICATIONS FOR TRANSPLANTATION

The specific indications for liver transplantation have become more standardized owing to the better knowledge of the natural history of a number of liver diseases and concomitant improvement in short- and long-term results of orthotopic liver transplantation (OLT). As with most aspects of this topic, however, significant controversy remains about several disease states leading to end-stage liver failure.

Cholestatic Liver Diseases. Cholestatic diseases, including primary biliary cirrhosis (PBC), secondary biliary cirrhosis, and primary sclerosing cholangitis (PSC), are the diseases most successfully treated by liver transplantation. Operative survival is greater than 90%, and 5-year survival is approximately 80%. This rate is due mostly to the slow onset of illness, which allows for preoperative preparation of the recipient and appropriate timing of the procedure, as well as absence of recurrence of the disease in the graft. As a result of this success, cholestatic disease is one of the most frequent indications for transplantation, accounting for 22% of all transplants performed in the United States. Clearly, the timing of operation is critical, and a substantial literature has addressed the rate of disease progression.

The indications for transplantation in patients with PSC are based on refractory symptoms resulting from recurrent cholangitis or impaired synthetic function. The risk of cholangiocarcinoma, approximately 15% in these patients, is an additional relative indication for OLT. A current trend toward earlier intervention with liver transplantation in PSC is underway, with retrospective comparisons of transplant versus nontransplant therapy weighing heavily in favor of the transplant approach. Clearly, however, some patients, particularly those with predominantly extrahepatic biliary strictures do well with conventional bypass or endoscopic procedures. Thus, timing remains a matter of clinical judgment, with most patients benefiting from allotransplantation.

Several models of survival have been established to predict outcome in patients with PBC. All prognostic scores are based in part on the rise in serum bilirubin. In general, transplantation is recommended when the bilirubin level exceeds 15 mg./100 ml., although earlier transplantation for severe associated symptoms such as pruritus or fatigue, refractory ascites, or variceal bleeding is appropriate. Although close monitoring of asymptomatic patients is reasonable, it is important not to delay intervention until the clinical status of the patient deteriorates, because OLT is the only definitive treatment.

Alcoholic Liver Disease. Nineteen percent of all liver transplants performed in the United States have been for alcoholic cirrhosis. Although the procedure was originally avoided

because of fears of high postoperative recidivism and a tendency toward medical noncompliance, the national trend has been to transplant in this setting more frequently, and in 1993 it was the most common indication reported by the United Network for Organ Sharing (UNOS) registry. Experience has demonstrated that graft and patient survival are not significantly different from those of other favorable indications and that disease recurrence (return to heavy alcohol use) is approximately 12%. Given these results, combined with the extraordinary prevalence of alcohol-related liver disease compared with other transplantable diseases (36,000 deaths per year), transplantation for alcoholic cirrhosis could easily exhaust the already scarce supply of donor organs. Selection is clearly needed to exclude comorbidities, alcohol-associated organ failure such as cardiomyopathy, and patients with continued dependence on alcohol. Even so, the need far outpaces the supply. Considerable philosophical debate addresses the use of scarce resources for individuals with self-inflicted disease. At this point, the decision to transplant should be based on a thorough preoperative medical evaluation supplemented by involvement in alcoholic rehabilitation and abstinence for at least 6 months. Patients presenting *too sick to drink* must be evaluated individually with an estimate of recidivism made to optimize long-term results. Palliative procedures are appropriate when possible. The recent development of the transjugular intrahepatic portosystemic shunt (TIPS) procedure has allowed many of these patients to be stabilized without extensive surgical intervention, for more thorough evaluation in a nonemergent setting.

Hepatitis C and Cryptogenic Cirrhosis. Another rapidly increasing indication for OLT is hepatitis caused by the hepatitis C virus (HCV). This is frequently discussed in tandem with cryptogenic cirrhosis. Transplantation is pursued for symptomatic infection only. Since the discovery of reliable methods for detecting HCV, this pathogen has been identified as the etiologic agent for liver failure in an increasing number of recipients. In 1996, it was associated with more than 25% of transplants in most centers. Cryptogenic disease accounted for an additional 12%. Excellent short-term results have been achieved with a 3-year survival of 70% (63% nonretransplant survival). These results have been tempered, however, by reinfection at almost 90%, with active recurrent hepatitis at 50%. Recurrent hepatitis has led to few deaths, although a fourth of the reinfected patients have converted to a chronic state. More deaths from recurrent disease can be expected in this group, and longer follow-up is required to determine whether results will remain acceptable. Disease recurrence has also been seen in cryptogenic cases, again suggesting a viral infection. Several treatments have been studied for HCV infection, with the most promising being parenteral therapy with interferon alfa.

Metabolic Diseases. Several metabolic diseases have been successfully cured with OLT, including alpha₁-antitrypsin deficiency, Wilson's disease, hemochromatosis, Crigler-Najjar syndrome, tyrosinemia, primary hyperoxaluria, and familial homozygous hypercholesterolemia. Survival is uniformly excellent. The recipient hepatectomy is usually simple, and the preoperative state of the patient is stable. Timing of transplantation should be such that secondary effects of the disease are not extensive.

Fulminant Hepatic Failure. In the absence of pre-existing liver disease, rapid loss of hepatic function culminating in jaundice and coma is termed *fulminant hepatic failure* (FHF). The etiologic agent can vary. The time course relates inversely to the prognosis, with those

progressing to coma in less than 2 weeks having a 36% survival and those progressing in 2 to 8 weeks having a 7% survival. Despite the dramatic rate of progression of disease, these patients have very acceptable results from OLT (about 60% 5-year survival). Predictably, survival after OLT improves with improved health of the patient at the time of transplant. Survival for all etiologies of FHF has doubled in the past decade, primarily due to great strides in supportive intensive care. Unlike chronic viral diseases, recurrence of disease for viral causes of FHF is unusual.

Care of patients with FHF is complex, and OLT should be considered early. Thus, prompt transfer to a liver transplantation center is critical. In patients with rapid deterioration, supportive care (e.g., hyperventilation, diuresis) should be supplemented with monitoring of intracranial pressure (ICP) for best results. Subdural ICP monitors have obviated the need for intraventricular devices and have thus reduced the bleeding risks of this approach. Perfusion pressures (mean arterial pressure minus ICP) of less than 40 mm. Hg, especially when combined with pupillary fixation, suggest that irreversible brain injury has occurred, and OLT should be avoided. Patient decompensation can be rapid and unpredictable. In the absence of a suitable donor, several aggressive maneuvers can successfully delay the onset of brain death from intracranial pressure. These include hepatectomy with end-to-side portacaval shunt, xenogeneic *ex vivo* perfusion, and bioartificial hepatic support (see later). Donor criteria may be liberalized to achieve timely hepatic replacement, and ABO incompatibility is acceptable.

Chronic Hepatitis B. Transplantation for chronic hepatitis B virus (HBV) cirrhosis remains a controversial topic. The discouraging reinfection rate of over 80% of recipients associated with a high rate of clinical hepatitis recurrence (60% at 1 year) and high related mortality (30% at 1 year and 52% at 5 years) raises questions about the procedure. Although generally contraindicated, transplantation may be appropriate in certain settings. Recent intense investigation in this area has identified several factors affecting reinfection. In general, the state of viral replication at the time of transplantation is critical in establishing reinfection. Identification of active viral replication (serum HBV DNA and HBeAg detection) at the time of transplantation clearly worsens the prognosis. Immunoprophylaxis with anti-HBV antibodies improves outcome for replication-negative patients, but long-term results for patients so treated remain to be seen. In general, OLT in the presence of HBV infection should be reserved for patients enrolled in specific viral prophylaxis protocols.

Intrahepatic Malignancy. Predictably, transplantation for primary and metastatic cancer has been associated with a high recurrence of tumor and a poor 5-year survival. Thus, there is little indication for OLT in a patient with known malignancy. Liver transplantation is no longer an accepted therapy for hepatic metastasis except perhaps in some patients with rare neuroendocrine tumors. Today, liver transplantation is usually limited to patients with nonresectable hepatoma fulfilling the following criteria: asymptomatic hepatoma (i.e., not associated with recent weight loss, ascites, or constitutional symptoms); tumor less than 5 cm. in diameter; and fewer than or equal to three intrahepatic tumors. If feasible, liver resection should always be considered first. Extensive evaluation is required to exclude the presence of extrahepatic spread. Transplantation for cholangiocarcinoma is even more controversial and should probably be performed only under the guidance of specific protocols. The role of

adjuvant chemotherapy or chemoembolization in patients undergoing transplantation for cancer remains unknown.

Pediatric Indications. The most common indication for liver transplantation in children is biliary atresia. This diagnosis accounts for 55% of the pediatric recipients in the UNOS registry. Although the creation of a portoenterostomy (Kasai procedure) remains the standard initial treatment, long-term survival without eventual hepatic failure is uncommon. Five-year survival remains under 50%. For this reason, many have proposed that early intervention with OLT be considered. The results of liver transplantation in infants have been somewhat better, with 5-year patient survival of 64%. Thus, a reasonable course of action appears to be neonatal nontransplant surgical intervention, with transplantation reserved for those children developing hepatic insufficiency despite a Kasai procedure. The interim growth improves the donor pool substantially and decreases the technical difficulties inherent in the management of small children. Five-year survival improves to 74% at 3 to 5 years and 79% from 5 to 15 years. However, multiple reoperations and revisions after an initial portoenterostomy should be avoided because they rarely provide long-term disease-free survival and substantially hinder efforts to transplant the patient. The remaining usual indications for pediatric transplantation also occur in the adult population, with 13% performed for metabolic diseases (see above) and 10% associated with fulminant hepatic failure secondary to hepatitis of various etiologies.

SPECIFIC PATIENT SELECTION AND PREOPERATIVE CONSIDERATIONS

Patient Selection. The success of liver transplantation is closely related to the rational selection of patients most likely to benefit from the procedure. In fact, the single most important prognostic factor affecting survival is the medical condition of the recipient at the time of OLT. As with the recipients of other organs, patients should be without additional end-organ failure (other than that clearly related to hepatic insufficiency) and should be candidates for a major operative intervention. In general, dependence on alcohol or other harmful substances should be resolved for at least 6 months. Extrahepatic malignancy, sepsis, and diffuse mesenteric venous thrombosis represent absolute contraindications. Isolated portal vein thrombosis is a relative contraindication. The patient's liver function should be such that complications of dysfunction are emerging, with the predicted life span of the patient managed medically less than 2 years. With the improvements in survival after allotransplantation realized in the past decade, it is also appropriate to consider patients with metabolic diseases or moderately advanced liver disease with significant alterations in quality of life such as extreme fatigue, refractory pruritus, or encephalopathy.

Preoperative Preparation. Once advanced liver disease is identified, efforts to proceed with transplantation should be initiated, because the preoperative health of the recipient greatly affects the chance for success. Early evaluation by a multidisciplinary team schooled in the specific requirements for liver transplantation is critical. In addition to surgical evaluation, the selection of appropriate candidates for transplantation should be based on input from medical colleagues, including a hepatologist and infectious disease specialist. Evaluation by a social worker and psychiatrist to establish the ability of the patient and family to manage themselves postoperatively is important. Immediate efforts should optimize the candidate's nutritional

status and overall medical condition. Finally, education of the patient must be initiated early to ensure that complications of medical noncompliance are avoided postoperatively.

For all liver recipients, thorough preoperative evaluation to determine the antibody titer directed against hepatitis A, B, and C as well as cytomegalovirus, human immunodeficiency virus, Epstein-Barr virus, and herpes simplex is mandatory. In addition, viral antigen detection is required to identify active infection. The role of transplantation for primary viral hepatitis was discussed previously. Active infection with cytomegalovirus or herpesvirus requires clinical resolution before transplantation, but viral carriers can receive transplants given appropriate antiviral prophylaxis. Human immunodeficiency virus infection contraindicates OLT. In addition to the recipient's status, the donor's status for these viruses should be ascertained before implantation, again to allow for antiviral prophylaxis when indicated.

Several alternative therapies should be considered in the candidate for transplantation, not necessarily to obviate the need for transplantation but to improve the medical condition before transplantation. Patients with good synthetic function (normal bilirubin, normal coagulation, normal albumin), such as an individual with Child's A cirrhosis and recurrent variceal bleeding, may benefit from nontransplant surgical palliation such as a Warren shunt. The TIPS procedure is also a useful palliative step for refractory complications of portal hypertension. Stabilization of disease with these interventions gives more time to evaluate patients and optimize preoperative conditions. It allows for a more thorough evaluation of a patient's ability to comply with the posttransplant medical regimen, particularly alcoholic patients who present abstinent because they are *too sick to drink*. This compliance alone may stabilize the disease in an alcoholic patient with Child's A cirrhosis and avoid the need for transplantation. Reduction in the degree of portal hypertension may also minimize intraoperative bleeding during the recipient hepatectomy. Problems with these palliative procedures are frequent and require surveillance with particular attention to portal vein patency. Identified candidates should be treated at a center with transplant expertise to facilitate palliation that does not jeopardize future transplantation. Alternative treatment should not delay transplantation.

SELECTION OF DONORS

Immediate function of a transplanted liver is imperative. Unlike kidney, pancreas, or, to some extent, heart transplantation, no artificial means is readily available to support an anhepatic patient in the event of graft failure. Without a rapid restoration of synthetic function, death from bleeding or cerebral edema generally ensues within 72 hours. The single most important factor determining the early function of a liver allograft is the viability of the donor liver. Although this seems obvious, determining the state of the liver in a heart-beating cadaver remains imprecise, so careful attention to the conditions of the donor's death, the morphology and function of the organ before harvest, and the specifics of the extirpation is critical. Failure of a graft to function at all after a technically successful transplantation is known as primary nonfunction (PNF). The only treatment for PNF is retransplantation within 24 to 72 hours. Factors contributing to the development of PNF include parenchymal insufficiency unrecognized at the time of harvest, graft injury during the harvest or cadaver resuscitation,

preservation injury or prolonged cold ischemia, prolonged rewarming time, and reperfusion injury after implantation.

Several factors have been investigated to aid in the prediction of PNF. The most widely noted is the estimated parenchymal fat content. Donor liver biopsy specimens that show a 40% or greater parenchymal replacement by fat have a higher chance of PNF, and in some settings this is a reasonable indicator of the adequacy of a donor organ. This must, however, be balanced against the severity of the recipient's disease and the urgency of the planned operation. Other factors used to evaluate the donor's status include the age of the donor, the level of inotropic support, the mechanism of the donor's death, the level of hepatic or intra-abdominal trauma, the presence of hypernatremia, and the biochemical studies of liver function. No single parameter has been established absolutely governing the acceptance of a donor for organ harvest. Rather, combinations of risk factors are generally responsible for discarding a potential donor liver. In case of doubt about the quality of an organ, the personal inspection of the liver by an experienced transplant surgeon is often critical for decision about the use of an organ.

Donor use has been improved with the introduction of UW preservation solution as mentioned earlier. Until 1987 the outer limit for cold storage of the liver using EuroCollins solution was about 8 hours. Use of UW solution has extended the time to about 24 hours, allowing for better allocation of the organ and preparation of the recipient. The specifics of this and other preservation solutions are detailed in Part VII of this chapter.

The considerations of ABO typing and other immunologic concerns are discussed later. An additional issue is size compatibility. Smaller organs are easily adapted to a large recipient, but the converse is not true. One advance has been the use of reduced-size allografts, particularly in children. Usually the left lateral lobe (segments 2 and 3) or left lobe (segments 2, 3, and 4) is used, allowing up to 1/10 weight mismatch. This has been the most important factor in the success of transplantation in small children. This technique is sometimes used in adults when an emergency transplantation is required. Finally, male recipients of female organs have 10% worse survival than other sex-match combinations, according to the 1994 UNOS registry.

OPERATION ON THE DONOR

Harvest of the donor organ should be performed by an experienced surgeon, with particular care taken to optimize the preharvest resuscitation of the heart-beating cadaver. Because immediate hepatic function after transplantation is required, there is no room for error. Errors in resuscitation include injudicious use of vasopressors, prolonged acidosis, and hypoperfusion from hypovolemia. Visual inspection and palpation of the liver with knowledge of the potential recipient's status and size aid in the assessment of the appropriateness of a donor liver.

The liver is generally procured through a midline incision from jugular notch to pubis, including median sternotomy. Harvest is coordinated with the harvest teams for other organs. Complete mobilization of the liver is required, including division of both triangular ligaments and the falciform ligament. The hepatogastric ligament is divided. Particular attention is paid to the vascular supply, including preservation of aberrant hepatic arteries (20% aberrant right from

the superior mesenteric artery, 15% aberrant left from the left gastric artery). Unlike the relative impunity associated with arterial ligation in nontransplanted livers, failure to complete the arterial revascularization due to an unrecognized arterial supply is poorly tolerated after cold storage. PNF, late biliary stricture, or intrahepatic abscess may result. Additional care must be taken when simultaneous pancreas harvest is performed to avoid hepatic artery injury or portal vein transection. The suprahepatic vena cava should be preserved for the hepatic graft, and care should be taken to avoid caval injury during cardiac retrieval. The gallbladder is removed either *in situ* or after explantation.

Once mobilization is completed, perfusion with UW solution is initiated through the distal aorta or common iliac arteries with ligation of the supraceliac aorta. The inferior mesenteric vein or splenic vein is used for portal perfusion. When pancreatic harvest is performed, some surgeons prefer to use the portal vein for cold perfusion. UW solution is also flushed into the biliary tree. Topical slush is rapidly applied. Hepatic extirpation is performed after cardiopulmonary retrieval and before harvest of the pancreas and kidney. The iliac artery and vein should be harvested in the event that vascular reconstruction is required.

IMMEDIATE PREOPERATIVE MANAGEMENT

Patients awaiting liver transplantation are prioritized on a national waiting list based on severity of disease as defined by the UNOS. Status 4 patients are at home and functioning normally, status 3 patients can be at home but require continuous medical care. Status 2 patients are continuously hospitalized in an acute care unit for at least 5 days or are in the intensive care unit. Status 1 patients are in the intensive care unit because of acute or chronic liver failure with a life expectancy without a liver transplant of less than 7 days. Status 7 is reserved for patients taken from the active list for a temporary medical contraindication such as sepsis. These patients can accrue points for time on the list despite not being able to accept an organ. Strict adherence to guidelines for proper categorization is required to allow for ethical allocation of organs. As soon as a donor is identified, the organ is paired with a potential recipient, who is called to the hospital for preoperative evaluation before organ harvest.

Appropriate perioperative management of a transplant recipient begins with a thorough preoperative physical examination (including rectal and dental examinations) to rule out the possibility of ongoing infection or malignancy. Routine screening includes a complete blood cell count, electrolyte and metabolic profile, urinalysis, and chest film. Blood is crossmatched. Intravenous lines, including arterial lines and pulmonary artery catheters, should be placed with strict attention to aseptic technique because cutaneous contamination with bacteria or fungi can cause serious postoperative complications in the transplant patient. Selective decontamination of the gut and mechanical preparation of the bowel are advocated at many centers, as is a shower with an antimicrobial soap.

For patients in the intensive care unit, supportive measures are continued as needed. Of specific concern is the potential for neurologic recovery in patients with advanced encephalopathy and cerebral edema. A recent advance has been the use of intracranial pressure monitoring in the perioperative period. This was once shunned as a prohibitive risk for cerebral

bleeding in the coagulopathic fulminant hepatic failure patient, but routine assessment is now possible through minimally invasive techniques. Small-gauge catheter pressure monitors can be placed into the subdural space without the need for parenchymal puncture, thus decreasing the risk of the intervention substantially. Greatly elevated intracerebral pressures, especially in association with signs of transtentorial herniation in a Grade 5 coma patient, suggest an irreversible lesion that is unlikely to resolve after transplantation.

OPERATION ON THE RECIPIENT

Few surgical procedures require the fastidious attention to technical detail required in liver transplantation. Technical errors are translated directly into infectious complications or marginal biliary function. Thus, transplantation should be performed only by surgeons proficient in the procedure. In addition, the operative environment should include experienced nursing and ancillary support.

Intraoperative management by a knowledgeable anesthesiologist with experience in liver transplantation is critical for a successful technical result. The procedure presents the challenge of maintaining homeostasis of temperature, circulation (including oxygen-carrying capacity and coagulation competence), gluconeogenesis, and electrolyte concentration while establishing adequate anesthesia and paralysis with agents not requiring hepatic function for degradation. Intraoperative ICP monitoring is appropriate for patients with severe encephalopathy. In procedures using a venovenous bypass, a perfusionist is required, and procedures performed without bypass require adequate maintenance of preload during caval occlusion and correction of metabolic abnormalities after release of the congested portal circulation. After the initial function of the allograft, the most important factor predictive of technical success is the stability of the patient intraoperatively and his or her delivery to the intensive care unit normothermic with adequate circulatory competence.

Successful engraftment of the organ begins with a controlled recipient hepatectomy. This can be a formidable task in patients with severe portal hypertension and extensive collateral formation or in those with multiple operative interventions. In general, extirpation follows the basic surgical guidelines of establishing proximal and distal vascular control combined with lysis of all ligamentous attachments. Specific technical concerns include retaining maximal length on all vessels. Mobilization of the common bile duct depends on the planned biliary reconstruction (choledochocholedochostomy versus choledochojejunostomy). Care to avoid injury to the right adrenal vein during caval dissection is important. If venovenous bypass is planned, cannulation of the left axillary, femoral, and portal veins is performed.

The decision to place the recipient on bypass is routine at a number of centers; and liberal use of this technique, originally developed by Shaw and colleagues, has clearly led to improved operative mortality. Bypass avoids mesenteric congestion and minimizes the release of lactate and other by-products of hypoperfusion into the portal circulation. In addition, it improves venous return to the heart during implantation and thus improves hemodynamic stability during the period of caval occlusion. Bypass also diverts the portal flow during difficult recipient hepatectomies to minimize blood loss, particularly during dissection of the retrohepatic cava and bare spot. Despite these benefits, it is now clear that many patients tolerate OLT without

the additional manipulation required by bypass. It has thus become policy at many centers to employ this technique selectively after an intraoperative trial of portal vein and vena caval occlusion.

The implantation procedure begins with the suprahepatic vena caval anastomosis followed by the infrahepatic caval anastomosis. Alternatively, the donor vena cava can be anastomosed side to side with the recipient vena cava if it is left *in situ* during the recipient hepatectomy (piggyback technique). The operation then proceeds to the portal anastomosis. After all venous connections, the liver is reperfused with the suprahepatic vena cava temporarily occluded and the infrahepatic vena cava vented to allow washout of the hyperkalemic and adenosine-rich UW solution. The hepatic artery anastomosis is the final vascular step in the procedure. Some groups perform simultaneous arterial and venous reperfusion.

The biliary reconstruction remains an additional area of debate. Options include choledochocholedochostomy with or without externalized T-tube stents. This has the advantage of easy access for subsequent biliary manipulations or evaluation of bile, as well as preservation of the sphincter mechanism. Unfortunately, the anastomosis is particularly sensitive to ischemic injury of the common duct, and complications of leak when the T tube is removed remain vexing. The incidence of technical complications related to this method ranges from 12% to 50% in published series, with the cumulative average being 25%. These problems are obviated for the most part by use of a Roux-en-Y choledochojejunostomy at the expense of convenient biliary access. Leak or stricture is still observed in 4% to 30% of cases (mean 14%). This method is frequently used in pediatric transplants. One report of 300 transplants performed with a side-to-side choledochocholedochostomy technique has reported a remarkable 2.2% technical complication rate. This technique awaits confirmation in other centers.

POSTOPERATIVE MANAGEMENT

Management in the postoperative intensive care unit is similar to that after any major procedure. Ventilatory support and volume replacement are standard. Isolation is not required beyond standard universal precautions. No sedation is given until extubation. For unclear reasons, postoperative pain is usually mild, and any major discomfort should alert one for possible complications. Close monitoring of serologic liver enzymes is critical because increasing enzymes or a failure of enzyme values to correct rapidly suggests PNF or technical complications such as hepatic artery thrombosis. Liberal use of the Doppler ultrasonography and rapid return to the operating room are mandatory in these situations because early detection is the only factor separating a return to normal liver function from complete graft necrosis and patient death.

Use of drains and antibiotics is no different in this operation from that in any other major abdominal procedure. Closed-suction drains should be used and removed early after the threat of postoperative hemorrhage is over. Brief antibiotic prophylaxis is appropriate with an agent with adequate skin and biliary organism coverage. Prolonged use of prophylactic antibiotics is contraindicated. A protocol for decontaminating the small bowel can be used but is usually discontinued within a few weeks of transplantation. At Duke University Medical Center,

decontamination (colistin, 100 mg./10 ml.; gentamicin, 80 mg./10 ml.; nystatin, 2 Ч 10⁶/10 ml.) is discontinued at the time of normal enteral feeding, often within the first postoperative week).

If a T tube is used in the biliary reconstruction, a T-tube cholangiogram is obtained within a week with internalization contingent on a normal result. Patients are discharged when they are familiar with their medications. Patients living more than 2 hours from the transplant center generally stay in the vicinity for an additional 2 to 4 weeks. Close monitoring of hepatic function and medical compliance is continued twice a week for 4 weeks and weekly for an additional 4 weeks. After this outpatient evaluation, patients are returned to their referring community for chronic follow-up. It is important to establish open lines of communication between the community physician and the transplant center to ensure prompt recognition and referral of postoperative complications.

IMMUNOLOGIC MANAGEMENT

The liver must be considered separately from other solid organs with regard to immunologic management. Many well-established concepts of donor-host interaction after kidney or heart transplantation do not apply after hepatic transplantation, and failure to recognize the unique properties of this situation can lead to detrimental perioperative treatment.

HLA Typing. HLA matching is not feasible before liver transplantation. However, because new techniques have been developed that allow donor HLA data to be provided in a timely manner, the future use of these data is pertinent. Although matching donors and recipients with regard to HLA type clearly improves outcome after kidney, heart, and pancreas transplantation, no such correlation exists with liver transplantation. Indeed, matching may, in fact, reduce overall survival. The reasons for this lie in the dualistic nature of HLA in the pathophysiology of liver disease. T-cell-mediated rejection of the organ is mechanistically the same as with other organs, so rejection is reduced with improved HLA compatibility. However, the physiologic role of HLA is to present viral peptides to T cells to initiate destruction of virally infected cells. Thus, HLA compatibility potentiates the inflammation during viral reinfection after transplantation for viral hepatitis and increases the chance for clinical recurrence of the original disease. Similarly, T-cell-mediated autoimmune diseases (e.g., PBC) are etiologically based on T-cell recognition of HLA presented peptides. Therefore, recurrence of autoimmune diseases may be potentiated as well. Further knowledge regarding specific disease states worsened by certain HLA matches may be useful in selective typing in the future.

Crossmatch and ABO Matching. The lymphocytotoxic crossmatch is not used prospectively before liver transplantation. Again, temporal concerns are most pressing; but in this case, the value of a positive crossmatch in predicting subsequent poor outcome from hyperacute rejection is minimal. Indeed, hyperacute rejection is rarely seen even in the face of documented preformed antibodies and ABO incompatibility. The reasons for this remain controversial because hyperacute rejection can be readily produced experimentally. Although preformed antibodies reduce long-term graft survival somewhat, early results appear to be minimally affected. Grafts unmatched for ABO antigens can cause antibody-mediated graft-versus-host disease with mild hemolytic anemia and fever occurring between postoperative days

5 and 12. This is the result of intrahepatic B cells that secrete antibody directed against the recipient ABO antigens. Although it is usually self-limited, increased immunosuppression may be required. Alternatively, some groups suggest a decrease in immunosuppression to allow for a limited rejection of the offending B cells. It is preferred that rules for ABO compatibility be followed for elective transplantation. In the emergent setting, however, ABO-incompatible grafts can be used with acceptable results. The 5-year survival for grafts that are ABO incompatible is approximately 15% lower than that for grafts without ABO discrepancy. This not only reflects some immune preference but also the patient population that receives ABO mismatched grafts, that is, emergent transplants for FHF and PNF.

Acute Rejection. As with other allografts, T-cell-mediated destruction of the liver is inevitable without immunosuppressive therapy. The primary targets for T-cell recognition are HLA antigens on the biliary epithelium and vascular endothelium. The characteristics of this rejection, termed *acute rejection*, are similar to those of kidney or heart in that it develops in most of the cases during the first 6 months after transplantation, usually within the first 4 postoperative weeks. More than half of patients develop at least one episode of rejection. Symptoms are nonspecific, often including mild intermittent fever and general malaise with alteration in liver tests. The diagnosis should be confirmed by liver biopsy. Most episodes are readily reversible (90%), given prompt recognition and initiation of antirejection therapy. This contrasts sharply to chronic rejection, discussed later.

Monitoring for acute rejection is a continuous process. Needle-core biopsy of the allograft is the best diagnostic test. Histologically it appears as a predominantly T-cell and monocyte infiltrate in the portal tracts, with subendothelial (endotheliitis) and biliary epithelial aggregates. Eosinophils and polymorphonuclear leukocytes are present to a lesser degree but are more prevalent in hepatic rejection than in infiltrate seen in other organs. Although protocol biopsies are performed in some centers, most groups rely on monitoring of the liver function studies and/or the serum beta₂-microglobulin value, with biopsy used to clarify detected abnormalities. Because a primary target in acute rejection is biliary epithelium, it often presents initially as a cholestatic process with rapid increases in the alkaline phosphatase and bilirubin values. However, changes in hepatic biochemical parameters are nonspecific and can also indicate technical or infectious complications where alterations in the immunosuppressive regimen would be ineffective or even detrimental. Thus, liberal use of biopsy and Doppler ultrasound evaluation of hepatic blood flow and bile duct integrity is critical. Once acute rejection is diagnosed, rescue immunosuppression is initiated as described later.

Chronic Rejection. The development of liver allograft dysfunction over a period of months to years is termed *chronic rejection* and, like other allografts, is controversial and multifactorial in its etiology, and is usually not reversible. Histologically it appears as a paucity of bile duct epithelium without conspicuous lymphocytic infiltration and has thus been described as the “vanishing bile duct syndrome”. Additionally, an obliterative vasculopathy can occur with parenchymal fibrosis. The time course, histology, and refractory nature of chronic rejection suggest that direct cell-mediated destruction is not a primary mechanism. It is likely that the cumulative effects of mild subclinical immune recognition by several limbs of the immune

system, and the resulting exposure to soluble factors including fibrogenic cytokines, eventually take their toll on the fragile epithelium. Chronic rejection often requires retransplantation.

Immunosuppressive Pharmacology. Manipulation of the immune system is required to avoid graft loss from rejection. Identifying a safe, effective, and minimally immunosuppressive regimen requires a careful balance aimed at reducing infectious and neoplastic complications without a resultant increase in allograft rejection and/or dysfunction. Thus, rational, selective use of several immunosuppressive agents is required to manage successfully the broad array of patients who are transplanted. Three general classifications of immunosuppression are used: (1) induction therapy, a relatively intense initial conditioning of the newly transplanted recipient; (2) maintenance therapy, drugs given at minimal doses required to maintain graft function; and (3) rescue therapy, heightened immunosuppression given to reverse an episode of acute rejection. Most transplant centers have specific protocols for each situation.

Several issues specific to liver transplantation should be mentioned. Of major importance is that the liver appears to have less immunostimulatory antigenicity than other organs. The specifics of this perceived resistance remain somewhat controversial but may relate to several peculiarities of hepatic physiology. First, the portal circulation is exposed regularly to enteric pathogens and, more importantly, to absorbed peptides, which have potential antigenicity. A generalized perihepatic anergy has been postulated as protective in this setting to prevent vascular thrombosis and inappropriate hepatic inflammation. Clearly the reticuloendothelial system of the liver—the Kupffer cells—is important in establishing appropriate versus inappropriate presentation of portal antigen. Most of the Kupffer cells of the liver are replaced with those of recipient HLA type within a few weeks after transplantation. In addition, the Kupffer cells of the donor have been described as migrating to other recipient tissues and establishing a state of chimerism. Whether this chimerism creates specific tolerance or is the result of it remains to be seen. From a practical standpoint, maintenance immunosuppression after liver transplantation can be comparatively low, and many patients have been weaned to little or no immunosuppression for years. Also of importance in this regard, the liver can tolerate brief periods on immunosuppression withdrawal if it becomes necessary to combat a potentially lethal infection.

A recent issue of particular importance in liver transplant immunosuppressive pharmacology has been the development of the drug tacrolimus (FK 506). This agent has been suggested as having particular efficacy in the setting of liver transplantation, with truly remarkable results in early, uncontrolled trials performed at the University of Pittsburgh.⁴⁸ Tacrolimus has a mechanism of action similar to that of cyclosporin A and it has been used as a replacement for this drug. A possible benefit is the potential steroid-sparing effect of tacrolimus, exceeding that of cyclosporine. Single-drug maintenance therapy is being actively investigated. Multicenter, randomized, prospective trials comparing cyclosporine to tacrolimus are underway, with the initial 1-year follow-up demonstrating a significant reduction in rejection episodes and a lower need for rescue therapy with OKT3 in the tacrolimus group. No graft or patient survival advantage has been demonstrated. The side effect profile for tacrolimus differs from that of cyclosporine in that the cosmetic complications of hirsutism, acne, and gingival hyperplasia are not present but the potential for neurologic abnormalities, diabetes mellitus, and renal

impairment appears to be more prevalent. An important consideration is that the combination of cyclosporine and tacrolimus drastically increases the incidence and severity of side effects. Thus, therapy must be limited to one or the other, and limiting the use of either in the early postoperative setting may benefit renal function. Clearly, both cyclosporine and tacrolimus have proven efficacy for maintenance immunosuppression after liver transplantation. The specific selection of either remains to be established by randomized investigation. As a rescue agent during established acute rejection, neither tacrolimus nor cyclosporine is particularly efficacious compared with glucocorticosteroids or antilymphocyte antibody preparations.

Another practical issue unique to liver transplant immunosuppression relates to the absorption of cyclosporine and, to a lesser degree, tacrolimus. Drug uptake depends on the availability of enteric bile salts. Thus, with decreased production of bile in the initial posttransplant period or during a rejection episode, or biliary diversion through a T tube, cyclosporine should be administered intravenously to maintain adequate plasma levels. A new cyclosporine formulation (Neoral), which is bile salt independent for absorption, is now available.

Antiviral Immunity and Immunosuppression. The importance of viral infection in liver transplant patients cannot be overstated. *De novo* infection or latent virus reactivation of pathogens, including cytomegalovirus, herpes simplex virus, and Epstein-Barr virus, and reinfection of hepatotropic viruses, including hepatitis B and C, remain serious sources of posttransplant morbidity and mortality and are directly related to the intensity of the immunosuppressive regimen employed. In particular, the use of antilymphocyte antibody preparations, particularly OKT3, have been implicated in increasing the likelihood of viral infection and associated complications such as lymphoproliferative disorders. In response to this association, most transplant centers have incorporated antiviral prophylaxis into their immunosuppressive protocols, with the specific agents, duration of therapy, and dosages governed by the viral status of the recipient and the donor organ. The relationship between the pathophysiology of acute T-cell-mediated rejection and the physiologic function of T cells in viral immunity is underscored in the transplant patient on T-cell-directed immunosuppression.

OUTCOMES

Clearly, liver transplantation is the most significant advancement in the treatment of end-stage liver disease this century. Diseases treated by OLT are by definition terminal with few exceptions, and as such are lethal without hepatic replacement. Survival of a patient with no other hope for survival is the most obvious positive outcome. Operative survival now exceeds 90% for first grafts. Retransplant-free survival has improved steadily in the past 10 years and is now 73% at 1 year for all transplants reported to the UNOS registry. The 5-year survival reflecting transplantation before ganciclovir became available is approximately 60%, and improvements of 2% to 3% per year have been made each year since 1987. Predicted actuarial survival for transplants performed in 1995 is over 75%.

Survival and retransplant rates have been the principal, if not the only, measures of outcome in the transplant literature until recently. The technical issues of survival in the first decade of widespread transplantation have overshadowed other outcome measures to the point of their exclusion from the literature. Critical evaluation of costly health care interventions has become

a fundamental priority in our society. Outcomes can be defined either from a physician's, patient's, payer's, or society's perspective. The medical perspective is in the traditional purview of the clinician and clinician investigator, who use objective and quantifiable medical parameters, whereas the patient's perspective involves a more subjective assessment of quality of life. Today, survival has become the norm after OLT, and thus the next decade should clearly define outcome with regard to each of these perspectives.

Medical Perspective. Despite the recent advances in all aspects of liver transplantation, the procedure remains one with considerable morbidity. Most patients have some complications that deviate from an ideal recovery, and all patients accept the trade of their liver disease for the *disease* of immunosuppression. These negative outcomes are generally remedied by prompt recognition of problems and aggressive corrective intervention. It is, therefore, critical that the potential obstacles arising postoperatively are thoroughly understood. The authors have recently categorized negative outcomes under three headings: negative sequel, complications, and failure to cure.

A *negative sequel* is an adverse effect inherent to the transplant procedure. Transplantation in general carries with it the risk of lifelong immunosuppression. Patients must adapt their lifestyle to ensure that medications are taken as prescribed and that the immune system and organ function are monitored when necessary. The risk of opportunistic infection and malignancy that accompanies chronic immunosuppression persists for life. These factors, however, are less intrusive for liver transplant patients than for recipients of other solid organs because of their reduced need for immunosuppression, especially after the first transplant year.

Failure to cure refers to pre-existing conditions that remain unchanged or recur after the transplant procedure. The likelihood of cure reflects the primary disease. Metabolic and cholestatic diseases are generally resolved, as are the physiologic disorders of alcoholic cirrhosis. Unfortunately, viral infections remain generally uncured by liver replacement. As mentioned earlier, clinically significant recurrence of hepatitis B and hepatitis C may limit long-term cure. The cure for these illnesses remains in more potent antiviral therapeutics. Practically, however, viral reinfection that creates a clinically insignificant carrier state is viewed as a cure by the patient. Obviously, no extrahepatic malignancy can be cured by OLT, and the potential for cure in patients with intrahepatic malignancy is solely related to the presence or absence of metastatic disease at the time of recipient hepatectomy.

A *complication* is any other negative outcome that does not fit clearly into the definition of negative sequel or failure to cure. Complications of some kind occur in almost all patients, but the significance of these setbacks varies greatly. For example, acute rejection must be considered a complication of sorts, but most episodes are treated without significant alteration of a patient's comfort or residual disability. Conversely, PNF at best leads to retransplantation and at worst to death. The lack of uniform reporting of complications makes interpretation of the results of OLT difficult. The authors have presented a classification of complications stratified by severity. With the heightened requirement for outcomes-based research in the current economic environment, standardized evaluation of transplant programs with regard to complication rates will likely increase.

Several common complications, such as acute and chronic rejection, have been discussed.

Some complications deserve particular attention because of their seriousness and requirement for prompt intervention. PNF presents as a complete lack of synthetic function from the time of reperfusion. The patient develops encephalopathy, increased intracranial pressure, coagulopathy, hyperbilirubinemia, and hypertransaminasemia. Aggressive supportive therapy and prompt retransplantation are required within 72 hours. Total transplant hepatectomy with portacaval shunt can improve the hemodynamic and metabolic status of the patient for 24 to 36 hours if a suitable liver is not found immediately.

Hepatic artery thrombosis remains a complication, especially in the pediatric population. This presents as a rapid rise in serum transaminase levels. The transplanted liver does not tolerate loss of arterial flow, and failure to restore flow produces graft loss. Hepatic artery stricture or stenosis generally presents as a lesser degree of metabolic change later in the postoperative course. An alternative presentation of dearterialization is bile leak resulting from hepatic duct necrosis. An additional vascular complication that is less frequent but equally devastating is early portal vein thrombosis. Given the rapid and serious but reversible nature of these vascular complications, any suspect change in hepatic function requires immediate evaluation of the hepatic vasculature by Doppler ultrasonography, followed by either re-exploration or a confirmatory arteriogram.

Biliary complications, which occur in 15% to 30% of patients, suggest vascular compromise. Both leaks and strictures can occur regardless of the method of reconstruction. Percutaneous or endoscopic management is generally considered an acceptable first alternative, but reoperation should not be avoided for appropriate lesions at the expense of hepatic function or cholangitis.

Patient Perspective. Today, increasing emphasis is given to patient-oriented subjective outcomes such as quality of life and well-being. Subjective outcomes have inherent limitations, but they are arguably more relevant to individual patients. Well-being represents a composite of several different aspects, including mental, physical, and social criteria.

Due to the initial formidable technical issues of OLT, analyses of quality of life have been almost absent from the literature. With improved results these past few years, researchers in numerous centers are evaluating the effects of OLT on quality of life. Successful transplantation allows a return to an active lifestyle free from the metabolic and hematologic complications of hepatic failure or portal hypertension. Preliminary studies have already shown that self-image, functioning ability, and perception of health status are significantly improved after OLT. Currently, about 60% of patients undergoing OLT return to work within the first year,⁴ a figure that continues to increase long term.

Payer's Perspective. Once therapy has been shown to be effective, it is necessary to determine whether the treatment is cost-effective in order to compare it with other competing technologies. Analysis of cost-effectiveness is difficult to apply to liver transplantation because there is no alternative therapy with which the results of the procedure can be compared. Thus, the cost issue becomes one of establishing a monetary value for one's life. There is no doubt that OLT is expensive. The total first-year expenses for a new liver average \$200,000, with an additional \$10,000 to \$20,000 per year required thereafter. Cost for patients in the intensive care unit at the time of transplant are 3 to 5 times higher than those called in from home for the

procedure. With current health care reform underway, these amounts are falling somewhat. In addition, consolidation of transplant centers in the United States is likely to improve efficiency and reduce costs. As new immunosuppressive agents are introduced, competition is also likely to drive the cost down. Nonetheless, the extent to which physicians should go to return patients to health and to work is a matter of great societal debate. As with all other aspects of liver transplantation, rational selection of patients is the most important factor affecting cost.

EMERGING TECHNIQUES

Split and Reduced-Size Transplantation. The remarkable ability of the liver to regenerate and support the metabolic needs of an individual despite major resection has allowed for correction of most conditions with partial hepatic transplantation.¹⁰ This is useful for major size mismatches, especially in children, and can also help address the growing donor organ shortage. Anatomic division of the lobes of the liver with preservation of hepatic venous and arterial, portal, and biliary branches has become increasingly successful but remains technically formidable. The anatomic boundaries are based on the segmental anatomic system of Couinaud and Bismuth.¹⁷ Left lateral segments 2 and 3 or left lobe grafts (segments 2, 3, and 4) can be placed in recipients who are substantially smaller than the donor. Because of the anterior to posterior dimensions of the right lobe (segments 5 through 8), placement of this graft requires a recipient similar in size to the donor.

Several major centers have initiated protocols for split and reduced-size transplantation with excellent results. Predictably, biliary complications are increased in this procedure, but in children the problem of hepatic artery thrombosis is improved, owing to the comparatively large vasculature present in the graft when an adult liver is reduced for use in a child. Patient survival is as good as or better than full-size grafts in children. Use of reduced-size grafts has decreased the mortality of pediatric recipients on the waiting list to approximately 3%.

Living-Related Transplantation. Arising from the success of reduced-size grafting, living-related transplantation has been initiated at selected centers. This involves a reduced-size graft usually derived from a donor left lobe (segments 2 and 3 or 2, 3, and 4). Technically, this has been quite successful and has the benefits of reduced ischemic time, better HLA match, and better timing of transplantation, producing excellent graft survival. Because most of the transplants are performed for congenital anomalies, the negative aspects of HLA typing have not been problematic. The most pressing concern with this procedure is ethics. Although hepatic resection is generally safe, the mortality is not zero. One donor perioperative death has been reported, and many argue that with the success of reduced-size cadaveric allografts, a procedure that places a healthy parent at risk is not necessary. The concept of informed consent is difficult to establish because most parents disregard personal safety when the life of their child is at risk. One consensus hearing on the matter has approved this procedure, with the caveat that only centers with established success in reduced cadaveric grafts, pediatric transplantation, and adult hepatic surgery be involved.

Heterotopic Liver Transplantation. Placement of an allograft in an anatomically altered site has the advantages of avoiding the recipient hepatectomy (often the most morbid portion of the procedure) and preserving the orthotopic position for future use in the event of graft

failure. Metabolic abnormalities are correctable by this approach. Obviously, however, disorders leading to portal hypertension are not amenable to this mode of therapy.

ALTERNATIVE THERAPIES

The development of artificial support devices has revolutionized perioperative management in all areas of transplantation except hepatic. Renal dialysis, ventricular assist and intra-aortic counterpulsation devices, total parenteral nutrition, and insulin have all helped optimize the condition of solid organ recipients to some degree, making emergent transplantation unusual for any organ other than the liver. The importance of preoperative condition is clear from the survival statistics presented in this chapter. Thus, great effort has been directed toward finding adequate hepatic replacement.

Xenogeneic Support. Xenotransplantation, the use of organs from other species, has many theoretical advantages. A renewable supply of organs subject to genetic manipulation available on an elective basis would greatly alter the course of patients with liver failure. In addition, the hepatotropic viruses responsible for most hepatitis are generally specific for human hepatocytes, so the specter of reinfection would be abolished. Unfortunately, the immune barriers to transspecies transplantation remain formidable. Organs from discordant species, those phylogenetically distant animals to which preformed natural antibodies exist, are hyperacutely rejected. Organs from these animals also produce plasma proteins that are similar but not identical to their human homologues, thus raising the possibility of antigenic proteins subject to immune clearance. Concordant species, namely primates, are rejected in a more conventionally acute manner, but antibody-mediated rejection occurs. Although the immune barrier is less daunting, primates are slow-breeding animals that could quickly become extinct if widespread use were initiated. Of additional concern is the potential for introducing new viruses from primates to man.

Several efforts in xenogeneic organ use have been made in the past 5 years. Baboon livers were used to treat two patients with hepatitis B at the University of Pittsburgh. Both livers functioned well enough to carry out the major physiologic functions of the liver. Interpretation of the immune implications of these procedures, however, is difficult because one patient was infected with the human immunodeficiency virus with an inverted T4:T8 ratio pretransplant and the other received a concurrent baboon bone marrow transplant. An orthotopic pig liver transplant performed at Cedars Sinai Hospital in Los Angeles was hyperacutely rejected (L. Makowka, personal communication, 1994).

Ex vivo perfusion with porcine livers has been successfully employed as a bridge to orthotopic allotransplantation by the authors' group. Biochemical improvement in all measured parameters, including reversal of cerebral edema and reduction of coma, has been demonstrated by the authors' group and others. This approach has the advantage of being reversible without requiring a surgical procedure. It is, however, logistically difficult and temporary.

Bioartificial Liver. The ability of porcine hepatocytes to perform many of the functions of human hepatocytes has been exploited by several investigators by development of an *ex vivo* apparatus for hepatic support consisting of porcine hepatocytes attached to a hollow-fiber dialysis cassette. Early clinical trials have shown promise in reducing cerebral edema as well as

mild improvement in biochemical parameters. Additional investigation in this field will determine whether the volume of the liver can be reproduced in cellular form and whether temporary support will allow recovery of hepatic function, thus avoiding transplantation for some patients with viral or toxin-induced acute liver failure.

SUMMARY

Liver transplantation has evolved in the past decade from an experimental procedure to an accepted, effective therapy for end-stage diseases of the liver. Extended survival of over 75% in appropriately selected patients is now commonplace with return to an excellent quality of life. Continued improvements in perioperative management and operative technique are being realized. The most important predictors of success are the state of the patient at the time of transplantation and the disease being transplanted. Early intervention once end-stage disease is diagnosed is preferable. A critical shortage of suitable donor organs remains the single most important barrier to transplantation

CHRONIC PANCREATITIS

Chronic pancreatitis is a progressive inflammation of pancreas with the periodic acutening and remission, related to the process of autolysis, that shows up by pain, by violation of exocrine and endocrine functions of gland with the eventual result of fibrosis of organ and high risk of malignization.

Etiology and pathogenesis

A gallstone disease is considered the most frequent reason of chronic pancreatitis. Pathogenesis of cholangiogenic pancreatitis acted in pancreatic ducts (theory of general duct) is in part of difficulty of outflow of pancreatic secret and reflux of infected bile or maintenance of duodenum. Dyskinesia, spasms and stenosis of the Vater's papilla of duodenum are instrumental in reflux. Bile or duodenal maintenance, that gets Wirsung's duct, activates the enzymes of pancreas and is instrumental in the origin of its inflammation. Development of pancreatitis potentiates infection. The last can penetrate pancreas not only due to reflux but also in a hematogenic or lymphogenic way.

Thus, chronic pancreatitis develops as a result of functional violations of pancreas, which with the flow of time pass to organic. The reasons of such violations are the attack of acute pancreatitis suffered the in past, alcoholism, traumas of gland, pathology of its vessels, gastroduodenal ulcers, gastritis or duodenostasis.

Pathomorphology

The morphological changes in pancreas at chronic pancreatitis are mainly taken to development of passionately-degenerative processes and atrophy of parenchyma. Connecting tissue in such cases develops both in the particles of gland and between them. In one case the process has diffuse character, in the other it is limited. Thus pancreas becomes dense as a result of excrescence of connecting tissue. It can be multiplied, taking shape of chronic hypertrophy pancreatitis. Atrophy of gland comes in other cases, besides, not evenly in different parts.

The inflammatory edema of parenchyma is exposed in case of acutening of process. Hemorrhages, fatty necrosis and pseudocysts are exposed on the surface of cut.

Classification

(by O.O. Shalimov)

1. Chronic fibrous pancreatitis without violation of patency of main pancreatic duct.
2. Chronic fibrous pancreatitis with violation of patency of main pancreatic duct, dilatated

ducts of pancreas and hypertension of pancreatic juice.

3. Chronic fibrous-degenerative pancreatitis.

Taking into account clinical passing of chronic pancreatitis, classification of O.O. Shelagurov (1970) can have some changes. Such forms are selected:

1. Chronic recurrent pancreatitis.
2. Chronic pain pancreatitis.
3. Chronic painless (latent) pancreatitis.
4. Chronic pseudo tumor-like pancreatitis.
5. Chronic cholecystocholangiopancreatitis (cholangiogenic pancreatitis).
6. Chronic indurative pancreatitis.

Symptoms and clinical passing

As passing of disease has cyclic character with the periodic changes of remission and acuteening, the clinic of chronic pancreatitis depends on the phase of development of inflammatory process. Violation of excretory and incretory functions of pancreas influences polymorphic of symptoms which remission is especially determining in the phase.

Pain, dyspepsia phenomena and progressive loss of weight of body are the basic signs of chronic pancreatitis. Besides, pain, is permanent, changes only its intensity, mainly in epigastric region, sometimes on the left, burning, squeezing or prickly, comes forward the unique symptom of disease, complaints about it precede other symptoms. In some patients the pain feelings increase in lying position. Therefore patients occupy forced sitting position. Intensity of pain can change throughout a day. Patients explain it by acceptance of rich, fried food, boiled eggs, coffee. The last is the principal reason of acuteening of process with acute pain syndrome.

It is needed to mark, that occasionally passing of chronic pancreatitis can take hidden, smooth shapes, with the moderately expressed pain syndrome or pain, that has atypical character, for example, stenocardia. In such patients the symptoms related to violations of exogenous function of pancreas come forward. They complain about absence of appetite, nausea, belch, sometimes vomiting and diarrhea with putrid smell. Thirst, general weakness and progressive loss of weight is observed also.

At palpation of abdomen pain does not arise, or it is quite insignificant. It is sometimes succeeded to palpate horizontally placed pancreas as dense, moderately painful tension bar. The transmission of pulsation of aorta at palpation in a epigastric area count characteristic for pathology.

During intervals between the attacks the feeling of patients remains satisfactory.

Development of saccharine diabetes is the basic sign of endocrine insufficiency, hypoglycemia is rarer. The feature of this form of saccharine diabetes consists in the fact that it shows up in a few years after the beginning of disease, runs easier and often carries latent character. There can be hypoglycemia at the insufficient products of glucagon.

The syndrome of biliary hypertension with development of mechanical icterus and

cholangitis determining it can develop in some patients. The reasons for such cholestasis more frequently are tubular stenosis of choledochus, choledocholithiasis or stenotic papillitis. There is duodenal obstruction in some cases.

Important information about it can be given by the laboratory and instrumental methods of examination.

Examination of excretory function of pancreas is based on establishment of level of amylase in the whey of blood and urine. In acutening period of chronic pancreatitis this level of amylase rises, the numbers of tripsin and lipase grow.

Coprologic examination. Macroscopic picture of excrement gets greyish color, in large masses — with unpleasant smell. Steatorrhea (increase of amount of neutral fat) and creatorrhea are characteristic for it (a plenty of muscular fibres).

Examination of incretory function of pancreas includes: 1) determination of sugar in blood and urine (characteristic is hyperglycemia and glycosuria);

2) radioimmunoassay of hormones (insulin, C-peptide and glucagon).

Sciagraphy survey of organs of abdominal cavity in two projections enables to expose existent concrement in ducts and calcificat in parenchyma of pancreas.

Relaxation duodenography. Thus the development of “horseshoe” of duodenum and change of relief of its mucus can be seen.

Cholecystocholangiography with the purpose of diagnostics of gallstone disease and second damaging of bilious ways is conducted.

Ultrasonic examination (sonography) is one of the basic methods of diagnostics. With the help of symptoms of chronic pancreatitis it is possible to expose inequality of contours of gland, increase of closeness of its parenchyma, increase or diminishment of sizes of organ, expansion of pancreatic duct and wirsungolithiasis or presence of concrement of parenchyma. Thus it is necessary to inspect gall-bladder, liver and bile-excreting ways for diagnostics of gallstone disease and choledocholithiasis.

Scintigraphy of pancreas. On early stages strengthening of scintigraphic picture is observed, on later ones — defects of accumulation to radionuclide (symptom of “sieve” or “bee honeycomb”).

Computer tomography allows to expose the increase or diminishment of sizes of gland, presence of calcificats, concrement, inequality of contours of organ, focuses or diffuse changes of its structure .

Endoscopic retrograde cholangiopancreatography (ERCPG). Expansion of pancreatic duct its deformation, wirsungolithiasis is marked.

It is expedient to apply laparoscopy in the phase of acutening of chronic pancreatitis at development of fatty and hemorrhagic pancreatonecrosis (“stearin name-plates”, exudation).

The puncture biopsy of pancreas under sonography control can have an important value for differential diagnostics of pancreatitis and cancer.

Percutaneous transhepatic cholangioduodenography and -stomy. This method is used both for differential diagnostics of pseudo tumor-like form of chronic pancreatitis and cancer of pancreas and with the purpose of preoperative preparation at presence of icterus. During it there is a possibility to expose expansion of intra- and out-of-hepatic ducts, localization and

slowness of their stricture.

Variants of clinical passing and complications

Chronic recurrent pancreatitis. The changes of periods of acuteening and remission are characteristic for it. The first period shows up by the attacks of pain of different frequency and duration, and during remission patients feel satisfactory.

Chronic pain pancreatitis. Intensive pain in the overhead half of abdomen with an irradiation in loin and region of heart is inherent for this form. Also belting pain often appears.

Chronic painless (latent) pancreatitis. In patients with this form of pathology for a long time the pain is either absent in general or arises after the reception of spicy food rich and can be insignificantly expressed. Violation of excretory or incretory function of pancreas come forward on the first plan.

Chronic pseudo tumor-like pancreatitis. Dull pain in the projection of head of pancreas, dyspepsia disorders and syndrome of biliary hypertension are clinical its signs.

Chronic cholangiogenic pancreatitis. Both clinic of chronic cholecystitis and cholelithiasis and clinic of pancreatitis are characteristic for this form.

Chronic indurative pancreatitis. In patients with this diseases symptoms of excretory and incretory insufficiency of pancreas are present. The low indexes of amylase in blood and urine are characteristic. At the expressed sclerosis of head of pancreas the with including process of general bilious duct, development of mechanical icterus is possible.

Among complications of chronic pancreatitis, fatty dystrophy and cirrhosis of liver, stricture of terminal part of general bilious duct, ulcers of duodenum, thrombosis of splenic vein, saccharine diabetes, pseudocysts of pancreas, exudation pleurisy and pericarditis and heart attack of myocardium are observed.

Diagnosis program

1. Anamnesis and physical methods of inspection.
2. General analysis of blood.
3. Biochemical blood test (amylase, bilirubin, glucose).
4. Analysis of urine on diastase.
5. Coprograma.
6. Sonography.
7. Relaxation duodenogram.
8. Cholecystocholangiography.
9. Retrograde cholangiopancreatography.
10. Computer tomography.

Differential diagnostics

Disease of gall-bladder and biliary ways (gallstone disease, dyskinesia of biliary ways). For these diseases pain in right hypochondrium is inherent, that irradiates in right shoulder-blade and shoulder. At chronic pancreatitis pain is localized in epigastric area, left hypochondrium, often is of belting character. One of the basic additional methods of inspection for confirmation of diseases of gall-bladder and ducts is sonography.

Ulcerous disease of stomach and duodenum. Pain at ulcerous disease is seasonal (relapses more frequent in spring and autumn), unites with heartburn and has tendency to diminishment after vomiting. In patients with chronic pancreatitis pain arises after faults in a diet, often is of belting character. Frequent vomiting is determining, that does not bring facilitation to the patient. Also violations of excretory and incretory functions of pancreas can take place.

Abdominal ischemic syndrome. Patients with this pathology complain about pain, that arises at once after the reception of meal, somewhat diminishes after application of spasmolytics. For the disease considerable weight loss and waiver of meal in connection with dread of pain attack can be characteristic. The basic method of examination, with a necessity for differential diagnostics, celiacography is useful, which enables to expose occlusion of abdominal trunk or its compression. During conducting of differential diagnostics with two last nosologies it is necessary to state a possibility of origin of secondary pancreatitis.

Cancer of pancreas. Mechanical icterus and presence of Courvoisier's symptom are considered the clearest and most important displays of cancer of head of pancreas, and carcinoma of body and tail is a proof pain syndrome. For the cancer the damage of pancreas, rapid progress of symptomatology are characteristic, and for chronic pancreatitis the protracted passing with proper clinical symptomatology and changes which can be exposed by the laboratory, roentgenologic and instrumental methods of examination are characteristic. The most informative among methods of diagnostics of cancer of pancreas are sonography (echo-producing formations in parenchyma of pancreas), computer tomography (tumor knots) and puncture biopsy of gland with the histological examination (reliable diagnostics of cancer).

Heart attack of myocardium. In anamnesis of patients with the heart attack of myocardium it is possible to expose pain behind breastbone, that arises at the physical activity and emotional stress, it is irradiated in left shoulder-blade and left shoulder, unrelated with the reception of meal and disappears as a result of action of coronarolytics. The typical changes of ECG confirm the diagnosis of heart attack of myocardium. In addition, no violations of external and incretions of pancreas are characteristic. The roentgenologic and instrumental methods of examination can help in differential diagnostics.

Tactics and choice of treatment method

Treatment is conducted in the phase of acutening of chronic pancreatitis, as well as at its acute form. In the first days the bed rest and medical starvation is prescribed without limitation of alkaline drink (mineral water). The fight against pain syndrome includes application of

anaesthetic preparations and spasmolytics (promedol, analgin, baralgin, papaverine, no-shparum, platyphyllin). Preparation action is directed on the decline of pancreatic secretion (atropine, methacin, sandostatine, dalargin, stilamine, somatostatine) or on oppression of gastric secretion: H₂-blockers (hystodil, cimetidine, hastrocepin, ranisan, tagamet and others like that), antiacides (almagel, gastropan). Appoint, next to it, and antihistaminic preparations (diphenhydramine hydrochloride, suprastine, fenkarol, tavegil). Antienzymic therapy is also important: a) inhibitor of protease (contrical, trasilol, hordox, antagosan), the dose of which must depend on the level of hyperenzymeemia; b) cytostatic agent (ftorafur, 5-fluorouracil); c) chemical inhibitor of tripsin (aminocapronic acid, pentoxil). For the improvement of microcirculation at this pathology heparin, reopolyhlucline and reohluman are applied. The ponderable value is achieved by disintoxication therapy (hemodes, hluconeodes, enterodes). With the purpose of parenteral feed 5–10–40 % glucose with insulin, plasma, albumen, alvesyn, polyamin and lipofundine are used. Normalization of agile function of organs of digestion is achieved by settings of cerucal and reglan. In complex treatment it is necessary to include vitamins (C, B1, B6, B12) and anabolic hormones (retabolil, nerobol).

At calming down of the inflammatory phenomena a diet № 5 is prescribed in pancreas and conduct correction of excretory insufficiency of pancreas (festal, pansinorm, pancceosymin, digestal and others like that). With the purpose of stimulation of function of pancreas it is possible to apply secretin.

Correction of endocrine insufficiency of pancreas. At development of the secondary saccharine diabetes of easy degree a diet is recommended with limitation of carbohydrates, bukarban, maninil and other peroral preparations, at middle and heavy degrees — insulinotherapy.

Physical therapy procedures. Except medical treatment it is possible to apply inductothermy, microwave therapy (high frequency) and electro-stimulation of duodenum. For spa treatment visiting of Morshyn, Husjatyn, Shidnytsja is recommend.

Surgical methods of treatment of chronic pancreatitis

Indication to operation and its volume depend on the form of pancreatitis. Acutening of chronic cholangiogenic pancreatitis at presence of gallstone disease must be examined as indication to operation in first 24 hours since disease's beginning. Operative treatment is done in case of:

- 1) calcinosis pancreas with the expressed pain syndrome;
- 2) violation of patency of duct of pancreas;
- 3) presence of cyst or fistula of resistance to conservative therapy during 2–4 months;
- 4) mechanical icterus on soil of tubular stenosis of distal part of general bilious duct;
- 5) compression and thrombosis of portal vein;
- 6) gallstone disease complicated by chronic pancreatitis;
- 7) ulcerous disease of stomach and duodenum complicated by secondary pancreatitis;

8) duodenostasis, complicated by chronic pancreatitis;

9) impossibility of exception to operation tumors or violations of arterial circulation of blood of pancreas.

Cholecystectomy at presence of calculous cholecystitis and secondary pancreatitis, acute destructive cholecystitis or hydropsy of gall-bladder.

Choledocholithotomy is executed for patients with cholangiolithiasis: a) with the deaf stitch of general biliary duct (use rarely); b) with its external draining for taking of infected bile (cholangitis), decline of biliary hypertension (at the edema of head of pancreas); c) with internal draining (at tubular stenosis of distal part of general biliary duct, acute expansion of choledochus with the complete loss of elasticity of its wall (execute one of variants of choledochoduodenostomy).

Papillosphincterotomy: a) execute transduodenal with papillosphincteroplasty; b) endoscopic is recommended at the isolated or connected with choledocholithiasis stenosis of large duodenal papilla, fixed concrement of large papilla of duodenum.

Wirsungoplasty is scission of plastic arts of narrow part or distal part of main pancreatic duct (apply at patients with stricture of proximal part of duct by a slowness no more than 2 cm). Lately at the isolated stenosis of bee-entrance of main pancreatic duct endoscopic wirsungotomy is executed.

Pancreatojejunostomy:

a) longitudinal (it is executed at considerable expansion of pancreatic duct)(Fig.5);

b) caudal (by Duval) with the resection of distal part of pancreas.

Resection of pancreas: a) distal or caudal;

b) distal subtotal;

c) pancreatoduodenal (PDR);

e) total duodenopancreatectomy heads or bodies of gland (execute in case of fibrous-degenerative pancreatitis).

Occlusion of ducts of pancreas by polymeric connections (cianocrylat, prolamine, neopren and others like that) results in atrophy of exocrine parenchyma, but keeps to the islet of tissue.

Operations on the nervous system are used in case of the pain forms of chronic indurative pancreatitis, resistant to conservative therapy, in default of rough morphological changes of parenchyma, stroma of gland and deformation of main pancreatic duct: a) left-side splanchnicectomy; b) bilateral pectoral splanchnicectomy and sympathectomy; c) postganglionic neurotomy of pancreas. [video](#)

Cysts of pancreas

Cyst of pancreas is a cavity, filled by liquid (pancreatic juice, exudation, pus), intimately soldered with head, body or tail of organ, is limited by capsule, which has epithelium on internal surface.

Pseudocyst (unreal cyst) is a cavity in pancreas which appears as a result of its destruction,

limited by capsule, that does not have epithelium on internal surface.

Etiology and pathogenesis

The reasons of pseudocysts are destructive pancreatitis, traumas of pancreas, oklusion of Wirsung's duct by parasite, concrement, tumors, innate anomalies of development.

To the real cysts belong: innate (dysontogenetic) cysts which are anomalic in development; acquired retention cysts which develop as a result of difficult outflow of pancreatic juice, cystadenoma and cystadenocarcinoma (by mechanism the origins belong more frequently to proliferative, sometimes — degenerative cysts).

The mechanism of development of pseudocysts consists in the focus necrosis of gland, difficult normal outflow of its secret, there is a destruction of walls of pancreatic ducts with overrun of pancreatic juice gland that causes reactive inflammation of peritoneum of surrounding organs which form the walls of pseudocyst.

Pathomorphology

Morphologically the cysts of pancreas are divided into: pseudocysts retention to the duct are innate, single and multiple.

Pseudocysts are fresh and old. The internal surface of fresh pseudocyst is rough, granulating, grey-red. The table of contents is alkaline, grey or with a brown tint. In an old pseudocyst the wall is smooth and shiny, pale-grey. The table of contents is lighter. Epithelium pseudocysts is absent. More frequently they are met in body and tail of gland and are not connected with ducts.

Retention cysts connected with an obturated duct. The cavity has smooth, grey-white surface, maintenance is transparent, watery or mucous-like. Innate cysts are mainly multiple and shallow. A simple retention cyst differ from those that are always connected with the anomalies of development of ducts and are unite with polycystosis buds and liver.

Rarely there are echinococcus cysts, which have a clear chitinous shell, liquid in cavity and daughter's blisters. They are localized in the area of head of pancreas.

Classification

(by A.N. Bakulev and V.V. Vinogradov, 1952)

I. Innate cysts of pancreas:

1. Dermoid cysts.
2. Teratoid cysts.

3. Innate adenomas.
4. Fibrocystic degeneration.
5. Polycystic degeneration.

II. Inflammatory cysts:

1. Pseudocysts.
2. Retention cysts.

III. Traumatic cysts:

1. As a result of direct damage of gland.
2. As a result of indirect damage of gland.

IV. Parasite cysts:

1. Echinococcosis glands.
2. Cysticercosis glands.

V. Neoplasty cysts:

1. Cyst-adenoma.
2. Cyst-adenocarcinoma.
3. Cavernous hemangioma.
4. Cystic epithelioma.

Pathomorphologyo cysts are divided on:

1. The true cyst.
2. Pseudocysts.

According to clinical passing pseudocysts are divided into acute, subacute and chronic.
According to weight of passing — into simple (uncomplicated) and complicated.

Symptoms and clinical passing

In patients with the cystic damaging of pancreas there can be pain of different character and intensity (dull, permanent, cramp-like and belting). It is localized more frequently in right hypochondrium, epigastric area (cyst of head and body of gland), left hypochondrium (cyst of tail of pancreas). Pain is irradiated in the back, left shoulder-blade, shoulder and spine.

Dyspepsia violations are characteristic. Nausea, vomiting and belch are observed.

The syndrome of functional insufficiency of pancreas shows up by disorders of exocrine and endocrine insufficiency and depends on the degree of damage of organ. The unsteady emptying, replacement of diarrhea of constipation, steatorrhea and creatorrhea, development of the second diabetes are marked.

Compression syndrome. Arises as a result of compression of neighbouring organs. Clinically the compression of organs of gastro-intestinal highway shows up by complete or partial obstruction of general bilious duct (mechanical icterus), vein (portal hypertension) gate, splenic vein (splenomegaly).

During the examination patients with large cysts are marked by asymmetry of abdomen in epigastric and mesogastric areas. At palpation of abdomen tumular formation of elastic consistency with an even, immobile surface is found.

Sonography examination shows echo-free formation with a clear capsule, determines localization and sizes of cyst.

Contrasting roentgenologic examination of stomach and duodenum with the sulfate of barium at the cyst of head of pancreas exposes moving of pyloric part of stomach upwards and breeding of „horseshoe” duodenum (at relaxation duodenography in the conditions of low artificial blood pressure). If a cyst is localized in the area of body of gland, displacement of stomach is marked forward and upwards or downward, rapprochement of its walls, moving of duodenal transition and loops of thin bowel downward and to the right; at lateral projection the distance between stomach and spine is increased. The cyst localized in the area of tail of gland, displaces the stomach forward and upwards, to the left or to the right.

Cholecystocholangiography exposes calculous cholecystitis and cholelithiasis.

Retrograde pancreatocholangiography exposes the changed and deformed, infrequently extended pancreatic duct, occasionally there can be filling of cavity of cyst by the contrasting matter.

Computer tomography shows accumulation of liquid limited by the capsule of different closeness and thickness.

Laboratory examinations exposes hyperamylasemia, steatorrhea and creatorrhea, sometimes — hyperglycemia and glycosuria.

Clinical passing of cysts of pancreas depends on their kind, localization, size, stage of forming and complications.

Four stages of forming of pseudocyst are distinguished (P.G. Karaguljan, 1972).

I stage (1–1,5 months last) — in the center of inflammatory process the cavity of disintegration, which takes surrounding tissue, appears in an omentum bag.

The II stage (2–3 months) is characterized by the beginning of forming of capsule of pseudocyst. Cyst is magnificent, unformed, acute inflammatory phenomena calms down.

The III stage (3–12 months) is completion of forming of capsule of pseudocyst. Last accretes with surrounding organs.

The IV stage (begins an in year from the origin of cyst) is a separated cyst. The cyst is mobile, easily selected from connections with surrounding organs.

Retention cysts arise at closing of lumen of pancreatic duct (concrement, sclerosis). The internal surface of cyst is covered with epithelium. Pain syndrome, violation of exocrine function of gland are characteristic.

Traumatic cysts belong to the pseudocysts with similar passing and clinic, as well as inflammatory pseudocysts.

Parasite cysts (to echinococcus, cysticercotic) are met as casuistry. In such patients Kaconi test and serological Weinberg's reaction are positive.

The variants of clinical passing of the real and unreal cysts depend on their complications.

Perforation in free abdominal cavity. Clinic of the poured peritonitis is characteristic. Tormina, positive symptoms of irritation of peritoneum, possible shock state as a result of irritation of peritoneum by pancreatic juice arise.

Perforation in stomach, duodenum, small, rarer in large intestine is accompanied by diminishment of cyst in sizes or complete disappearance, sometimes diarrhea appears.

Suppuration of maintenance of cyst is accompanied by pain which becomes more intensive, temperature rises, leucocytosis grows.

The erosive bleeding appears suddenly and is accompanied by the symptoms of internal bleeding (expressed general weakness, dizziness). The pallor of skin and mucus shells, sticky death-damp, tachycardia and anemia are observed.

Mechanical icterus arises as a result of compression of cyst on the terminal part of choledochus. The icterus of skin and mucus shells, acholic excrement, dark urine, hyperbilirubinemia, increase of the ALT and AsT level are exposed.

Portal hypertension develops as a result of compression of portal vein. Ascites, varicose expansion of veins of esophagus and stomach, moderate icterus are diagnosed.

Reactive exudation pleurisy more frequently arises in left pleura cavity, where roentgenologic exudation is diagnosed with high maintenance of amylase.

At malignization the walls of cyst specific symptoms are absent, a diagnosis is set during operation (surgical biopsy of cyst wall).

Diagnosis program

1. Anamnesis.
2. Biochemical blood test (amylase, sugar, bilirubin).
3. Analysis of urine on diastase.
4. Coprograma.
5. Sonography.
6. Contrasting sciagraphy of stomach and duodenum (relaxation duodenography).
7. Retrograde pancreatocholangiography.
8. Computer tomography.

Differential diagnostics

The cysts of pancreas are differentiated with the tumors of abdominal cavity and of retroperitoneal space.

Cancer of pancreas. For the cancer tumor of pancreas syndrome of “small signs” (discomfort in epigastric area, loss of appetite, general weakness), permanent dull pain, unrelated with the reception and composition of meal, icterus (cancer of head of gland), Courvoisier's symptom (increased, unpainfully gall-bladder) are characteristic. Inconstant pain at cysts of pancreas is more frequently related to faults in a diet; in anamnesis destructive pancreatitis, traumas of gland are carried. Sonography examination, retrograde pancreatocholangiography and computer tomography help in establishment of diagnosis.

Tumors of retroperitoneal space are passed asymptomatic, clinic shows up by a considerable compression on neighbouring organs. Nausea, vomit, chronic intestinal obstruction, dysuric disorders arise. Clinic of cysts of pancreas, on the opposite, are expressed on early stages. Pain, dyspepsia syndromes, syndrome of exocrine and endocrine insufficiency of pancreas are characteristic. Pain is related to the reception of meal and alcohol.

Aneurism of abdominal aorta. Dull, indefinite pain in abdomen which is unrelated with the reception of meal, pulsation and pulsating formation in abdomen are characteristic, auscultatory is systolic murmur. Aortography allows to confirm a diagnosis.

The cyst of mesentery of thin bowel has painless passing, at palpation it is mobile, easily changes position in abdomen. The cysts of pancreas are practically immobile, pain, anamnesis and laboratory information are characteristic.

The cyst of liver has protracted asymptomatic passing. Pain appears at infection of cyst. For this pathology symptoms which take place at the cysts of pancreas are not typical (pain related to the reception of rich food, alcohol, hyperamylasemia). Topic diagnostics is carried out at ultrasonic examination, scintigraphy, computer tomography.

Differential diagnostics and clinical variants

The basis of disease of pancreas is degenerative-inflammatory processes which are considered to be acute pancreatitis, the so called autolysis tissue by its own enzymes. In the structure of acute pathology of organs of abdominal cavity this disease takes the third place after acute appendicitis and cholecystitis. Women suffer from acute pancreatitis 3–3,5 times more frequently than men.

Acute pancreatitis is a polyetiology disease. Its secondary forms, which arise on the background of pathologies of bile-excreting system and duodenum are closely associated with anatomic and functionally with pancreas, and are met in clinical practice.

Among the “starting” factors of origin of cholelithiasis disease (biliary pancreatitis) abuse by an alcohol and food overloads (fat and irritating products), traumas of pancreas, operating-room in particular, and also separate infectious diseases (parotitis, mononucleosis) are most frequent, especially infection of bilious ways. However, in 10–20 % of patients the reason of acute pancreatitis remains unknown (cryptogenic form).

In the basis of such damages of pancreas and enzymic toxemia lies mainly activating of pancreatic, and then the tissue enzymes (trypsin, lipase, amylase). Often the combination of the broken outflow of pancreatic secret and promoted secretion takes place, which provokes intraductal hypertension.

Among explanations of primary mechanisms of activating of pancreatic enzymes the most value belongs to: a) theory of “general duct” with reflux of bile in the ducts of pancreas; b) blockade of outflow of pancreatic juice with development of intraductal hypertension and penetration of secret in interstitial tissue; in) violation of blood flow of pancreas (vasculitis, thrombophlebitis and embolisms, cardiac insufficiency and others like that); g) toxic and allergic damages of gland. The role of alcohol in such situations can be dual: stimulation of secretion of pancreas and direct damaging action on its tissue.

The process of acute inflammation of pancreas consistently passes the stages of edema, pancreatonecrosis and festering pancreatitis. In the stage of edema there is pancreas of hyperemic, increased in volume, with the shallow hearths of necrosis or, as it is in swingeing majority of cases, without them.

Pancreatonecrosis can pass with fatty or hemorrhagic character. In the first case, as a rule, pancreas is increased, dense, cut whity-yellow hearths are selected to necrosis. Increase of

crimson-black pancreas with darkly-brown infiltrate on a cut is characteristic for hemorrhagic pancreatonecrosis.

Dystrophy of parenchyma is exposed microscopically, up to necrosis, hemorrhages, thromboses of vessels and signs of inflammatory infiltration.

The disease begins suddenly, after the surplus reception of rich spicy food and use of alcohol. Pain, vomiting and phenomena of dynamic intestinal obstruction are considered the most characteristic signs of acute pancreatitis.

A stomach-ache is permanent and so strong, that can result in shock, localized in an epigastric area and left hypochondrium. Some patients feel pain in right hypochondrium with irradiation in the back, loin or breastbone.

In a short period of time after appearance of pain there is a repeated strong vomiting, that does not facilitate the state of patient.

In general vomiting is considered a frequent and characteristic symptom. It is repeated or continuous and never brings facilitation. Vomit masses contain bile, as admixture, and at the difficult form of acute pancreatitis remind "coffee-grounds".

Nausea, hiccup, belch and dryness in a mouth are attributed as less characteristic symptoms of this pathology.

During the examination the skin is pale, often subicterus. Some patients have cyanosis with a "marble picture" as a result of violation of microcirculation. Later the component of respiratory insufficiency can join it. At progressive general condition the patient quickly gets worse to passing of acute pancreatitis, intoxication grows. The skin takes shelter with sticky sweat.

The temperature of body of patients at the beginning of disease can be normal. It rises at resorption of products of autolysis tissue and development of inflammatory process in bilious ways.

The pulse in most cases is at first slow, then becomes frequent, notably passing ahead the increase of temperature of body.

Arterial pressure goes down.

The tongue in the first hour of disease is moist, assessed by white and grey raid. At vomiting by bile the raid has yellow or greenish tint.

The abdominal is blown away, peristaltic noises are loosened. The signs of paresis of stomach and intestine demonstrate early. They need to be included in the pathological process of mesentery root of bowel. At palpation painfulness in an epigastric area and in right, and sometimes and in left, hypochondrium is marked. However, in spite of great pain in stomach, it remains soft for a long time. A little later there is moderate tension or resistance of muscles of front abdominal wall.

Poor local symptoms during heavy intoxication are characteristic for the early period of acute pancreatitis. Later there are symptoms of irritation of peritoneum, and at percussion dulling is marked in lateral parts of abdominal as a result of accumulation of liquid, and also the sign of aseptic phlegmon of retroperitoneal cellulose as slurred or edema of lumbar area is seen. For diagnostics of acute pancreatitis there is the row of characteristic symptoms which have different clinical value.

The Mondor's symptom is violet spots on face and trunk.

The Lagermph's symptom is acute cyanosis of person.

The Halsted's Symptom is cyanosis of abdominal skin.

The Gray's symptom is cyanosis of lateral walls of abdomen.

The Kullen's symptom is the yellow colouring of skin near a belly-button.

The Korte's symptom is painful resistance as a lumbar bar in an epigastric area on 6–7 cm higher belly-button.

The Voskresynskyy's symptom is absence of pulsation of abdominal aorta in an epigastric area.

The Mayo-Robson's symptom is feeling of pain at pressure by fingers in the left costal-vertebral corner.

The Rozdolskyy's symptom — painfulness at percussion above pancreas.

The Blumberg's symptom — in patients with acute pancreatitis more frequently is low-grade. Such feature of this sign of irritation of peritoneum needs to be explained by character of localization of pathological process, mainly in retroperitoneal spaces.

In clinical passing of pancreatonecrosis it is possible to select three periods (V.S. Saveljev, 1978).

The I period (hemodynamic violations and pancreatogenic shock) lasts during 2–3 days. Violation of central hemodynamics, diminishment of volume of circulatory blood and disorders of microcirculation, which at first arise as a result of angiospasm, are considered the most characteristic signs, and later as a result of joining of the intravascular rolling up and laying of elements of blood.

The II period (insufficiency of parenchymatous organs) lasts from 3rd to the 7th day of disease. Violation of functions of basic organs and systems, sign of cardio-vascular, hepatic and kidney insufficiency and growth of violations of breathing are thus observed. In this period there is possible damaging of the central nervous system, which is erected mainly to disorders of psyche, appearances of delirium and comas which in the eventual result are the main reasons of patients' death.

The III period (postnecrosis dystrophic and festering complications) comes in 1–2 weeks after the beginning of disease. During it, on the background of progress of necrosis processes in pancreas, the regenerative changes develop, there are parapancreatic infiltrate and cysts, cystic fibrosis of pancreas. Aseptic retroperitoneal phlegmon which strengthens intoxication can also develop. There is festering pancreatitis at joining of infection. During this period such complications, as erosive bleeding, internal or external fistula, retroperitoneal phlegmon, can develop in patients.

From laboratory information leucocytosis which at the necrosis and hemorrhagic forms of pancreatitis sometimes arrives at $25-30 \times 10^9$, lymphopenia, change of leukocytic formula to the left and the increased ESR are characteristic. Growth of activity of amylase of blood and urine is very often marked, and is the important sign of pancreatitis. For estimation of the state of other organs maintenance of general albumen and its fractions, glucose of blood, bilirubin, urea, electrolytes, acid-base equilibrium (ABE), and also the state of blood coagulation are determined. It is necessary to mark that the exposure of hypocalcemia is considered a bad

predictive sign of heavy passing of acute pancreatitis.

Ultrasonic examination (Pic. 3.5.1) of gall-bladder and pancreas often specifies the increase of their sizes, bulge of walls and presence or absence of concrement of gall-bladder and general bilious duct.

Computer tomography enables to describe in details the changes in pancreas and surrounding organs.

At sciagraphy survey of organs of abdominal cavity gives a possibility to expose the unfolded "horseshoe" of duodenum, pneumatization, expansion of transverse colon (the Gobia's symptom). On the 1st stage of diagnostics in the plan of differential diagnosis of acute destructive pancreatitis with other diseases of abdominal cavity, diagnostics of distribution of destructive damaging of different parts of pancreas and estimation of distribution of parapancreatitis is possible only by the method of computer tomography which depending on clinico-laboratory signs and weight of passing is needed to apply in a different period, and sometimes a few times in dynamics with interval of 4–5 days.

Laparoscopy and laparocentesis are often used for a doubtful diagnosis or necessity of taking away the exudation of abdominal cavity for biochemical or bacteriological examination.

Retrograde endoscopic cholangiopancreatography is used in case of mechanical icterus and suspicion of choledocholithiasis. The last methods are invasive and can if it is necessary transform from diagnostic to manipulation treatments: laparoscopic draining of abdominal cavity at pancreatogenic peritonitis and endoscopic papillotomy at choledocholithiasis and biliary pancreatitis.

Clinical passing of disease can be abortive, slowly or quickly progressive. At abortive passing the process is limited to acute edema of pancreas with convalescence in 7–10 days.

Rapid progress is characteristic for pancreatonecrosis. In patients expressed toxemia, impregnation by exudation of retroperitoneal cellulose and development of fermentative hemorrhagic peritonitis can be seen. Strengthening of stomachache, continuous vomiting, proof paresis of intestine, positive symptoms of irritation of peritoneum and growth of hemodynamic violations are the clinical signs of necrosis of pancreas.

There is a formation of parapancreatic infiltrate at slow progress.

Among early complications of acute pancreatitis shock, peritonitis and acute cardiac, pulmonary, hepatic and kidney insufficiency can be distinguished.

Before later complications it is needed to deliver the abscesses of pancreas, subdiaphragmatic, interintestinal abscesses, pyogenic abscess omentum bag, phlegmons of retroperitoneal space and erosive bleeding.

In future formations of pseudocysts, fistula of pancreas, intestinal fistula and development of saccharine diabetes are possible.

Acute pancreatitis needs to be differentiated with the row of acute diseases of organs of abdominal cavity.

Acute mechanical intestinal obstruction. In patients with this pathology pain is of the alternated character and is accompanied by nausea, vomiting, delay of gases and emptying. It is possible to see the Kloyber bowls on the sciagram survey of organs of abdominal cavity.

Acute cholecystitis runs with characteristic localization of pain and muscular defense,

with presence of increased, painful gall-bladder or infiltrate in right hypochondrium. Often acute (especially lately) pancreatitis develops on the background of gallstone disease (biliary pancreatitis).

Thrombosis or embolism of mesenteric vessels. Both for pancreatitis and for the thrombosis of mesenteric vessels great pain at soft abdomen (absence of defense muscles of front abdominal wall), that precedes to development of peritonitis, is inherent. Yet from the beginning the disease gains heavy character of passing. In anamnesis in such patients a heart disease or heart attack of myocardium rheumatic is met. As a result of gangrene of intestine, the symptoms of peritonitis appear very quickly and intoxication grows. The fragments of mucus shell are found in flushing waters of intestine at the detailed examination, which have the appearance of "meat flushing".

A perforated gastric and duodenum ulcer is distinguished by the presence of dagger pain, defense of abdominal wall, ulcerous anamnesis.

The conservative method is considered the basic one for treatment of acute pancreatitis, but in connection with that unsuccessful conservative treatment of patients with acute pancreatitis can often put a question about the necessity of operation, therefore patients must be in permanent surgical establishment. Thus acute pancreatitis with heavy passing is necessary to be treated under the conditions of separation of intensive therapy.

Before conservative treatment hunger, bed rest, fight against pain and enzymic toxemia, conducting of acid-base state, prophylaxis of festering infection and acute ulcers of digestive duct are to be entered .

Patient's stomach is washed by cold soda solution and a cold on an epigastric area and left hypochondrium is used. Medicinal therapy is prescribed also: spasmolytics (papaverine, platyphyllin, no-shparum, baralgin, atropine); inhibitor of protease (contrical, trasilol, gordox, antagosan); cytostatic agent (5-fluorouracil, florafur). Positive action of inhibitor of protease is marked only in the first days of disease which are subject to conditioned application of large doses. Antibiotics of wide spectrum of action: a) tienam, which most effective in the prophylaxis of festering pancreatitis, as is selected by pancreatic juice; b) cephalosporins (kefzol, cefazoline); c) cefamizine (mefoxine).

Disintoxication therapy is conducted also (5 % but 10 % solutions of glucose, hemodes, reopolyhluquine, polyhluquine, plasma of blood, only from 3 to 5 liters on days, in accordance with a necessity).

For the improvement of rheological properties of blood heparine is prescribed (5 000 ODES every 4 hours).

If patients have the expressed pain syndrome and phenomena of general intoxication during all pain period plus 48 hours (by Bakulev), hunger is used. Such mode lasts on the average of 2–4 days. The parenteral feed of albuminous hydrolyzate is thus conducted, by the mixtures of amino acid and fatty emulsion. Alkaline water of to 1–2 l. and albuminous-carbohydrate diet are also appointed. Infusion therapy is complemented by plasma, by albumen, hemodes, reopolyhluquine. The improvements of microcirculation in pancreas are achieved due to introduction of reopolyhluquine, komplamine, trental and heparin 5000 ODES 6 times per days under the control the indexes of the coagulation system of blood. Anticholinergic drug

(sulfate of atropine, methacin, platyphyllin), H₂-histamin blocker (cimetidine, ranisan, ranitidine, famotidine, omeprazol) are also applied. For the removal of pain: 1) sulfate of the atropine 0,1 % — 1 ml + promedol 2 % — 1 ml + papaverine 2 % — 2 ml + analgin 50 % — 2 ml; 2) isotonic solution of chloride of sodium — 500 ml + baralgin — 5 ml + diphenhydramine hydrochloride 1 % — 1 ml + papaverine 2 % — 2 ml + magnesium the sulfate 25 % — 5 ml + ascorbic acid — 5 ml + lipoic acid 0,5 % — 2 ml + novocaine 0,5 % — 10 ml. are used. From the first days by a nasogastral probe the permanent aspiration of gastric maintenance is conducted also. The Motility function of gastro-intestinal highway gets better at application of cerucal or primperane. With the same purpose forced diuresis (maninil, furosemide, aminophylline) is used on the background of intravenous introduction of plenty of liquid.

At uneffective conservative treatment of patients with acute pancreatitis of middle weight and heavy form it is expedient to apply surgical treatment.

Surgical treatment is carried out for patients with biliary pancreatitis (for a day long from the beginning of disease) in combination with the destructive forms of cholecystitis, at complications of acute pancreatitis by peritonitis, abscess of omentum bag or phlegmon of retroperitoneal cellulose.

Overhead-middle laparotomy, which allows to estimate the state of pancreas, bilious ways and other organs of abdominal cavity, is the best access in this situation. In case of destructive pancreatitis the possible use of lumbar laparotomy from left to right hypochondrium through a mesogastric area is useful.

Cholecystectomy is executed at calculous cholecystitis, phlegmonous inflammation of walls of gall-bladder and biliary pancreatitis. If there are more than 0,9 cm at expansion of choledochus, presence of concrement, ointment-like bile in it, increase of concentration of bilirubin in the whey of blood over 21 mmol/L, choledocholithotomy is complemented by external draining of choledochus. Information of lithiasis of general bilious duct is absent, cholecystectomy in patients with acute pancreatitis is complemented by external draining of choledochus, better by Pikovskyy method (through stump of cystic duct).

Transduodenal sphincteroplasty is shown at fixed concrement of large duodenal papilla (Pic. 3.5.2), if they are diagnosed intraoperative, and also in the cases of papillotomy with extraction of concrement when there is no possibility to execute endoscopic operation .

Omentopancreatopexy. After laparotomy and cutting of gastro-colon and gastro-pancreatic ligament mobile part of large omentum through opening in gastro-colon ligament is conducted and fixed by separate stitches to the peritoneum along the overhead and lower edges of pancreas. Such operation needs to be considered rational at the expressed edema of pancreas and presence of necrosis in it.

Abdominisation of pancreas. A cellulose round pancreas (along the lower and overhead edges of body and tail) is infiltrated by solution of novocaine, after it parietal peritoneum is cut. Under the body and tail glands free end of omentum is conducted and is bundled by a gland. This operation is able to warn the hit of enzymes and products of disintegration in retroperitoneal space.

Sequestrectomy is deleting of necrosis part of gland within the limits of nonviable tissue.

Operation is executed in a dull way.

Necrectomy (deleting of necrosis part of gland within the limits of healthy tissue) is executed by an acute way: tissue of gland is cut on verge of necrosis and bleeding vessels are carefully bandaged.

The resection of pancreas is deleting the part of organ with its transversal cutting within the limits of the unchanged (ad oculus) tissue of gland. The resections of tail and body of pancreas are distinguished (Pic. 3.5.3).

Pancreatectomy is a complete deleting of pancreas. Operative treatment is applied infrequently. After the resection of pancreas adequate draining of its bed is very responsible.

The prognosis of disease depends on character of morphological changes of parapancreatic to the cellulose in pancreas. The more difficult destructive changes, the worst the prognosis.

Chronic pancreatitis is a progressive inflammation of pancreas with the periodic acutening and remission, related to the process of autolysis, that shows up by pain, by violation of exocrine and endocrine functions of gland with the eventual result of fibrosis of organ and high risk of malignization.

A gallstone disease is considered the most frequent reason of chronic pancreatitis. Pathogenesis of cholangiogenic pancreatitis acted in pancreatic ducts (theory of general duct) is in part of difficulty of outflow of pancreatic secret and reflux of infected bile or maintenance of duodenum. Dyskinesia, spasms and stenosis of the Vater's papilla of duodenum are instrumental in reflux. Bile or duodenal maintenance, that gets Wirsung's duct, activates the enzymes of pancreas and is instrumental in the origin of its inflammation. Development of pancreatitis potentiates infection. The last can penetrate pancreas not only due to reflux but also in a hematogenic or lymphogenic way.

Thus, chronic pancreatitis develops as a result of functional violations of pancreas, which with the flow of time pass to organic. The reasons of such violations are the attack of acute pancreatitis suffered the in past, alcoholism, traumas of gland, pathology of its vessels, gastroduodenal ulcers, gastritis or duodenostasis.

The morphological changes in pancreas at chronic pancreatitis are mainly taken to development of passionately-degenerative processes and atrophy of parenchyma. Connecting tissue in such cases develops both in the particles of gland and between them. In one case the process has diffuse character, in the other it is limited. Thus pancreas becomes dense as a result of excrescence of connecting tissue. It can be multiplied, taking shape of chronic hypertrophy pancreatitis. Atrophy of gland comes in other cases, besides, not evenly in different parts.

The inflammatory edema of parenchyma is exposed in case of acutening of process. Hemorrhages, fatty necrosis and pseudocysts are exposed on the surface of cut.

As passing of disease has cyclic character with the periodic changes of remission and acutening, the clinic of chronic pancreatitis depends on the phase of development of inflammatory process. Violation of excretory and incretory functions of pancreas influences polymorphic of symptoms which remission is especially determining in the phase.

Pain, dyspepsia phenomena and progressive loss of weight of body are the basic signs of chronic pancreatitis. Besides, pain, is permanent, changes only its intensity, mainly in epigastric region, sometimes on the left, burning, squeezing or prickly, comes forward the

unique symptom of disease, complaints about it precede other symptoms. In some patients the pain feelings increase in lying position. Therefore patients occupy forced sitting position. Intensity of pain can change throughout a day. Patients explain it by acceptance of rich, fried food, boiled eggs, coffee. The last is the principal reason of acutening of process with acute pain syndrome.

It is needed to mark, that occasionally passing of chronic pancreatitis can take hidden, smooth shapes, with the moderately expressed pain syndrome or pain, that has atypical character, for example, stenocardia. In such patients the symptoms related to violations of exogenous function of pancreas come forward. They complain about absence of appetite, nausea, belch, sometimes vomiting and diarrhea with putrid smell. Thirst, general weakness and progressive loss of weight is observed also.

At palpation of abdomen pain does not arise, or it is quite insignificant. It is sometimes succeeded to palpate horizontally placed pancreas as dense, moderately painful tension bar. The transmission of pulsation of aorta at palpation in a epigastric area count characteristic for pathology.

During intervals between the attacks the feeling of patients remains satisfactory.

Development of saccharine diabetes is the basic sign of endocrine insufficiency, hypoglycemia is rarer. The feature of this form of saccharine diabetes consists in the fact that it shows up in a few years after the beginning of disease, runs easier and often carries latent character. There can be hypoglycemia at the insufficient products of glucagon.

The syndrome of biliary hypertension with development of mechanical icterus and cholangitis determining it can develop in some patients. The reasons for such cholestasis more frequently are tubular stenosis of choledochus, choledocholithiasis or stenotic papillitis. There is duodenal obstruction in some cases.

Important information about it can be given by the laboratory and instrumental methods of examination.

Examination of excretory function of pancreas is based on establishment of level of amylase in the whey of blood and urine. In acutening period of chronic pancreatitis this level of amylase rises, the numbers of tripsin and lipase grow.

Coprologic examination. Macroscopic picture of excrement gets greyish color, in large masses — with unpleasant smell. Steatorrhea (increase of amount of neutral fat) and creatorrhea are characteristic for it (a plenty of muscular fibres).

Examination of incretory function of pancreas includes: 1) determination of sugar in blood and urine (characteristic is hyperglycemia and glycosuria); 2) radioimmunoassay of hormones (insulin, C-peptide and glucagon).

Sciagraphy survey of organs of abdominal cavity in two projections enables to expose existent concrement in ducts and calcificat in parenchyma of pancreas.

Relaxation duodenography. Thus the development of “horseshoe” of duodenum and change of relief of its mucus can be seen (Pic. 3.5.4).

Cholecystocholangiography with the purpose of diagnostics of gallstone disease and second damaging of bilious ways is conducted.

Ultrasonic examination (sonography) is one of the basic methods of diagnostics. With the

help of symptoms of chronic pancreatitis it is possible to expose inequality of contours of gland, increase of closeness of its parenchyma, increase or diminishment of sizes of organ, expansion of pancreatic duct and wirsungolithiasis or presence of concrement of parenchyma. Thus it is necessary to inspect gall-bladder, liver and bile-excreting ways for diagnostics of gallstone disease and choledocholithiasis (Pic. 3.5.5).

Scintigraphy of pancreas. On early stages strengthening of scintigraphic picture is observed, on later ones — defects of accumulation to radionuclide (symptom of “sieve” or “bee honeycomb”).

Computer tomography allows to expose the increase or diminishment of sizes of gland, presence of calcificats, concrement, inequality of contours of organ, focuses or diffuse changes of its structure (Pic. 3.5.6, Pic. 3.5.7).

Endoscopic retrograde cholangiopancreatography (ERCPG). Expansion of pancreatic duct its deformation, wirsungolithiasis is marked, (Pic. 3.5.8).

It is expedient to apply laparoscopy in the phase of acutening of chronic pancreatitis at development of fatty and hemorrhagic pancreatonecrosis (“stearin name-plates”, exudation).

The puncture biopsy of pancreas under sonography control can have an important value for differential diagnostics of pancreatitis and cancer.

Percutaneous transhepatic cholangioduodenography and -stomy. This method is used both for differential diagnostics of pseudo tumor-like form of chronic pancreatitis and cancer of pancreas and with the purpose of preoperative preparation at presence of icterus. During it there is a possibility to expose expansion of intra- and out-of-hepatic ducts, localization and slowness of their stricture.

Chronic recurrent pancreatitis. The changes of periods of acutening and remission are characteristic for it. The first period shows up by the attacks of pain of different frequency and duration, and during remission patients feel satisfactory.

Chronic pain pancreatitis. Intensive pain in the overhead half of abdomen with an irradiation in loin and region of heart is inherent for this form. Also belting pain often appears.

Chronic painless (latent) pancreatitis. In patients with this form of pathology for a long time the pain is either absent in general or arises after the reception of spicy food rich and can be insignificantly expressed. Violation of excretory or incretory function of pancreas come forward on the first plan.

Chronic pseudo tumor-like pancreatitis. Dull pain in the projection of head of pancreas, dyspepsia disorders and syndrome of biliary hypertension are clinical its signs.

Chronic cholangiogenic pancreatitis. Both clinic of chronic cholecystitis and cholelithiasis and clinic of pancreatitis are characteristic for this form.

Chronic indurative pancreatitis. In patients with this diseases symptoms of excretory and incretory insufficiency of pancreas are present. The low indexes of amylase in blood and urine are characteristic. At the expressed sclerosis of head of pancreas the with including process of general bilious duct, development of mechanical icterus is possible.

Among complications of chronic pancreatitis, fatty dystrophy and cirrhosis of liver, stricture of terminal part of general bilious duct, ulcers of duodenum, thrombosis of splenic vein, saccharine diabetes, pseudocysts of pancreas, exudation pleurisy and pericarditis and

heart attack of myocardium are observed.

Disease of gall-bladder and bilious ways (gallstone disease, dyskinesia of bilious ways). For these diseases pain in right hypochondrium is inherent, that irradiates in right shoulder-blade and shoulder. At chronic pancreatitis pain is localized in epigastric area, left hypochondrium, often is of belting character. One of the basic additional methods of inspection for confirmation of diseases of gall-bladder and ducts is sonography.

Ulcerous disease of stomach and duodenum. Pain at ulcerous disease is seasonal (relapses more frequent in spring and autumn), unites with heartburn and has tendency to diminishment after vomiting. In patients with chronic pancreatitis pain arises after faults in a diet, often is of belting character. Frequent vomiting is determining, that does not bring facilitation to the patient. Also violations of excretory and incretory functions of pancreas can take place.

Abdominal ischemic syndrome. Patients with this pathology complain about pain, that arises at once after the reception of meal, somewhat diminishes after application of spasmolytics. For the disease considerable weight loss and waiver of meal in connection with dread of pain attack can be characteristic. The basic method of examination, with a necessity for differential diagnostics, celiacography is useful, which enables to expose occlusion of abdominal trunk or its compression. During conducting of differential diagnostics with two last nosologies it is necessary to state a possibility of origin of secondary pancreatitis.

Cancer of pancreas. Mechanical icterus and presence of Courvoisier's symptom are considered the clearest and most important displays of cancer of head of pancreas, and carcinoma of body and tail is a proof pain syndrome. For the cancer the damage of pancreas, rapid progress of symptomatology are characteristic, and for chronic pancreatitis the protracted passing with proper clinical symptomatology and changes which can be exposed by the laboratory, roentgenologic and instrumental methods of examination are characteristic. The most informative among methods of diagnostics of cancer of pancreas are sonography (echo-producing formations in parenchyma of pancreas), computer tomography (tumor knots) and puncture biopsy of gland with the histological examination (reliable diagnostics of cancer).

Heart attack of myocardium. In anamnesis of patients with the heart attack of myocardium it is possible to expose pain behind breastbone, that arises at the physical activity and emotional stress, it is irradiated in left shoulder-blade and left shoulder, unrelated with the reception of meal and disappears as a result of action of coronarolytics. The typical changes of ECG confirm the diagnosis of heart attack of myocardium. In addition, no violations of external and incretions of pancreas are characteristic. The roentgenologic and instrumental methods of examination can help in differential diagnostics.

Treatment is conducted in the phase of acutening of chronic pancreatitis, as well as at its acute form. In the first days the bed rest and medical starvation is prescribed without limitation of alkaline drink (mineral water). The fight against pain syndrome includes application of anaesthetic preparations and spasmolytics (promedol, analgin, baralgin, papaverine, no-shparum, platyphyllin). Preparation action is directed on the decline of pancreatic secretion (atropine, methacin, sandostatine, dalargin, stilamine, somatostatine) or on oppression of gastric secretion: H2-blockers (hystodil, cimetidine, hastrocepin, ranisan, tagamet and others like that), antiacides (almagel, gastropan). Appoint, next to it, and antihistaminic preparations

(diphenhydramine hydrochloride, suprastine, fenkarol, tavegil). Antienzymic therapy is also important: a) inhibitor of protease (contrical, trasilol, hordox, antagosan), the dose of which must depend on the level of hyperenzymeemia; b) cytostatic agent (ftorafur, 5-fluorouracil); c) chemical inhibitor of tripsin (aminocapronic acid, pentoxil). For the improvement of microcirculation at this pathology heparin, reopolyhlucline and reohluman are applied. The ponderable value is achieved by disintoxication therapy (hemodes, hluconeodes, enterodes). With the purpose of parenteral feed 5–10–40 % glucose with insulin, plasma, albumen, alvesyn, polyamin and lipofundine are used. Normalization of agile function of organs of digestion is achieved by settings of cerucal and reglan. In complex treatment it is necessary to include vitamins (C, B1, B6, B12) and anabolic hormones (retabolil, nerobol).

At calming down of the inflammatory phenomena a diet № 5 is prescribed in pancreas and conduct correction of excretory insufficiency of pancreas (festal, pansinorm, pancceosymin, digestal and others like that). With the purpose of stimulation of function of pancreas it is possible to apply secretin.

Correction of endocrine insufficiency of pancreas. At development of the secondary saccharine diabetes of easy degree a diet is recommended with limitation of carbohydrates, bukarban, maninil and other peroral preparations, at middle and heavy degrees — insulinotherapy.

Physical therapy procedures. Except medical treatment it is possible to apply inductothermy, microwave therapy (high frequency) and electro-stimulation of duodenum. For spa treatment visiting of Morshyn, Husjatyn, Shidnytsja is recommend.

Indication to operation and its volume depend on the form of pancreatitis. Acutening of chronic cholangiogenic pancreatitis at presence of gallstone disease must be examined as indication to operation in first 24 hours since disease's beginning. Operative treatment is done in case of:

- 1) calcinosis pancreas with the expressed pain syndrome;
- 2) violation of patency of duct of pancreas;
- 3) presence of cyst or fistula of resistance to conservative therapy during 2–4 months;
- 4) mechanical icterus on soil of tubular stenosis of distal part of general bilious duct;
- 5) compression and thrombosis of portal vein;
- 6) gallstone disease complicated by chronic pancreatitis;
- 7) ulcerous disease of stomach and duodenum complicated by secondary pancreatitis;
- 8) duodenostasis, complicated by chronic pancreatitis;
- 9) impossibility of exception to operation tumors or violations of arterial circulation of blood of pancreas.

Cholecystectomy at presence of calculous cholecystitis and secondary pancreatitis, acute destructive cholecystitis or hydropsy of gall-bladder.

Choledocholithotomy is executed for patients with cholangiolithiasis: a) with the deaf stitch of general bilious duct (use rarely); b) with its external draining for taking of infected bile (cholangitis), decline of biliary hypertension (at the edema of head of pancreas); c) with internal draining (at tubular stenosis of distal part of general bilious duct, acute expansion of choledochus with the complete loss of elasticity of its wall (execute one of variants of

cholecholedochoduodenostomy).

Papillosphincterotomy: a) execute transduodenal with papillosphincteroplasty; b) endoscopic is recommended at the isolated or connected with choledocholithiasis stenosis of large duodenal papilla, fixed concrement of large papilla of duodenum.

Wirsungoplasty is scission of plastic arts of narrow part or distal part of main pancreatic duct (apply at patients with stricture of proximal part of duct by a slowness no more than 2 cm). Lately at the isolated stenosis of bee-entrance of main pancreatic duct endoscopic wirsungotomy is executed.

Pancreatojejunostomy: a) longitudinal (it is executed at considerable expansion of pancreatic duct);) caudal (by Duval) with the resection of distal part of pancreas (Pic. 3.5.9).

Resection of pancreas: a) distal or caudal; b) distal subtotal; c) pancreatoduodenal (PDR); e) total duodenopancreatectomy heads or bodies of gland (execute in case of fibrous-degenerative pancreatitis).

Oklusion of ducts of pancreas by polymeric connections (cianocrylat, prolamine, neopren and others like that) results in atrophy of exocrine parenchyma, but keeps to the islet of tissue.

Operations on the nervous system are used in case of the pain forms of chronic indurative pancreatitis, resistant to conservative therapy, in default of rough morphological changes of parenchyma, stroma of gland and deformation of main pancreatic duct: a) left-side splanchnicectomy; b) bilateral pectoral splanchnicectomy and sympathectomy; c) postganglionic neurotomy of pancreas.

Cyst of pancreas is a cavity, filled by liquid (pancreatic juice, exudation, pus), intimately soldered with head, body or tail of organ, is limited by capsule, which has epithelium on internal surface.

Pseudocyst (unreal cyst) is a cavity in pancreas which appears as a result of its destruction, limited by capsule, that does not have epithelium on internal surface.

The reasons of pseudocysts are destructive pancreatitis, traumas of pancreas, oklusion of Wirsung's duct by parasite, concrement, tumors, innate anomalies of development.

To the real cysts belong: innate (dysontogenetic) cysts which are anomalic in development; acquired retention cysts which develop as a result of difficult outflow of pancreatic juice, cystadenoma and cystadenocarcinoma (by mechanism the origins belong more frequently to proliferative, sometimes — degenerative cysts).

The mechanism of development of pseudocysts consists in the focus necrosis of gland, difficult normal outflow of its secret, there is a destruction of walls of pancreatic ducts with overrun of pancreatic juice gland that causes reactive inflammation of peritoneum of surrounding organs which form the walls of pseudocyst.

Morphologically the cysts of pancreas are divided into: pseudocysts retention to the duct are innate, single and multiple.

Pseudocysts are fresh and old. The internal surface of fresh pseudocyst is rough, granulating, grey-red. The table of contents is alkaline, grey or with a brown tint. In an old pseudocyst the wall is smooth and shiny, pale-grey. The table of contents is lighter. Epithelium pseudocysts is absent. More frequently they are met in body and tail of gland and are not connected with ducts.

Retention cysts connected with an obturated duct. The cavity has smooth, grey-white surface, maintenance is transparent, watery or mucous-like. Innate cysts are mainly multiple and shallow. A simple retention cyst differ from those that are always connected with the anomalies of development of ducts and are unite with polycystosis buds and liver.

Rarely there are echinococcus cysts, which have a clear chitinous shell, liquid in cavity and daughter's blisters. They are localized in the area of head of pancreas.

According to clinical passing pseudocysts are divided into acute, subacute and chronic.

According to weight of passing — into simple (uncomplicated) and complicated.

In patients with the cystic damaging of pancreas there can be pain of different character and intensity (dull, permanent, cramp-like and belting). It is localized more frequently in right hypochondrium, epigastric area (cyst of head and body of gland), left hypochondrium (cyst of tail of pancreas). Pain is irradiated in the back, left shoulder-blade, shoulder and spine.

Dyspepsia violations are characteristic. Nausea, vomiting and belch are observed.

The syndrome of functional insufficiency of pancreas shows up by disorders of exocrine and endocrine insufficiency and depends on the degree of damage of organ. The unsteady emptying, replacement of diarrhea of constipation, steatorrhea and creatorrhea, development of the second diabetes are marked.

Compression syndrome. Arises as a result of compression of neighbouring organs. Clinically the compression of organs of gastro-intestinal highway shows up by complete or partial obstruction of general bilious duct (mechanical icterus), vein (portal hypertension) gate, splenic vein (splenomegaly).

During the examination patients with large cysts are marked by asymmetry of abdomen in epigastric and mesogastric areas. At palpation of abdomen tumular formation of elastic consistency with an even, immobile surface is found.

Sonography examination shows echo-free formation with a clear capsule, determines localization and sizes of cyst (Pic. 3.5.10).

Contrasting roentgenologic examination of stomach and duodenum with the sulfate of barium at the cyst of head of pancreas exposes moving of pyloric part of stomach upwards and breeding of „horseshoe” duodenum (at relaxation duodenography in the conditions of low artificial blood pressure). If a cyst is localized in the area of body of gland, displacement of stomach is marked forward and upwards or downward, rapprochement of its walls, moving of duodenal transition and loops of thin bowel downward and to the right; at lateral projection the distance between stomach and spine is increased. The cyst localized in the area of tail of gland, displaces the stomach forward and upwards, to the left or to the right (Pic. 3.5.11).

Cholecystocholangiography exposes calculous cholecystitis and cholelithiasis.

Retrograde pancreatocholangiography exposes the changed and deformed, infrequently extended pancreatic duct, occasionally there can be filling of cavity of cyst by the contrasting matter.

Computer tomography shows accumulation of liquid limited by the capsule of different closeness and thickness (Pic. 3.5.12).

Laboratory examinations exposes hyperamylasemia, steatorrhea and creatorrhea, sometimes — hyperglycemia and glycosuria.

Clinical passing of cysts of pancreas depends on their kind, localization, size, stage of forming and complications.

Four stages of forming of pseudocyst are distinguished (P.G. Karaguljan, 1972).

I stage (1–1,5 months last) — in the center of inflammatory process the cavity of disintegration, which takes surrounding tissue, appears in an omentum bag.

The II stage (2–3 months) is characterized by the beginning of forming of capsule of pseudocyst. Cyst is magnificent, unformed, acute inflammatory phenomena calms down.

The III stage (3–12 months) is completion of forming of capsule of pseudocyst. Last accretes with surrounding organs.

The IV stage (begins an in year from the origin of cyst) is a separated cyst. The cyst is mobile, easily selected from connections with surrounding organs.

Retention cysts arise at closing of lumen of pancreatic duct (concrement, sclerosis). The internal surface of cyst is covered with epithelium. Pain syndrome, violation of exocrine function of gland are characteristic.

Traumatic cysts belong to the pseudocysts with similar passing and clinic, as well as inflammatory pseudocysts.

Parasite cysts (to echinococcus, cysticercotic) are met as casuistry. In such patients Kaconi test and serological Weinberg's reaction are positive.

The variants of clinical passing of the real and unreal cysts depend on their complications.

Perforation in free abdominal cavity. Clinic of the poured peritonitis is characteristic. Tormina, positive symptoms of irritation of peritoneum, possible shock state as a result of irritation of peritoneum by pancreatic juice arise.

Perforation in stomach, duodenum, small, rarer in large intestine is accompanied by diminishment of cyst in sizes or complete disappearance, sometimes diarrhea appears.

Suppuration of maintenance of cyst is accompanied by pain which becomes more intensive, temperature rises, leucocytosis grows.

The erosive bleeding appears suddenly and is accompanied by the symptoms of internal bleeding (expressed general weakness, dizziness). The pallor of skin and mucus shells, sticky death-damp, tachycardia and anemia are observed.

Mechanical icterus arises as a result of compression of cyst on the terminal part of choledochus. The icterus of skin and mucus shells, acholic excrement, dark urine, hyperbilirubinemia, increase of the ALT and AsT level are exposed.

Portal hypertension develops as a result of compression of portal vein. Ascites, varicose expansion of veins of esophagus and stomach, moderate icterus are diagnosed.

Reactive exudation pleurisy more frequently arises in left pleura cavity, where roentgenologic exudation is diagnosed with high maintenance of amylase.

At malignization the walls of cyst specific symptoms are absent, a diagnosis is set during operation (surgical biopsy of cyst wall).

The cysts of pancreas are differentiated with the tumors of abdominal cavity and of retroperitoneal space.

Cancer of pancreas. For the cancer tumor of pancreas syndrome of “small signs” (discomfort in epigastric area, loss of appetite, general weakness), permanent dull pain,

unrelated with the reception and composition of meal, icterus (cancer of head of gland), Courvoisier's symptom (increased, unpainfully gall-bladder) are characteristic. Inconstant pain at cysts of pancreas is more frequently related to faults in a diet; in anamnesis destructive pancreatitis, traumas of gland are carried. Sonography examination, retrograde pancreatocholangiography and computer tomography help in establishment of diagnosis.

Tumors of retroperitoneal space are passed asymptomatic, clinic shows up by a considerable compression on neighbouring organs. Nausea, vomit, chronic intestinal obstruction, dysuric disorders arise. Clinic of cysts of pancreas, on the opposite, are expressed on early stages. Pain, dyspepsia syndromes, syndrome of exocrine and endocrine insufficiency of pancreas are characteristic. Pain is related to the reception of meal and alcohol.

Aneurism of abdominal aorta. Dull, indefinite pain in abdomen which is unrelated with the reception of meal, pulsation and pulsating formation in abdomen are characteristic, auscultatory is systolic murmur. Aortography allows to confirm a diagnosis.

The cyst of mesentery of thin bowel has painless passing, at palpation it is mobile, easily changes position in abdomen. The cysts of pancreas are practically immobile, pain, anamnesis and laboratory information are characteristic.

The cyst of liver has protracted asymptomatic passing. Pain appears at infection of cyst. For this pathology symptoms which take place at the cysts of pancreas are not typical (pain related to the reception of rich food, alcohol, hyperamylasemia). Topic diagnostics is carried out at ultrasonic examination, scintigraphy, computer tomography.

Conservative treatment. Treatment of acute or chronic pancreatitis is conducted in accordance with principles. At the unfavorable dynamics of passing the diseases hunger with the permanent sucking of gastric maintenance, parenteral feed and intravenous introduction of liquids are appointed. Puncture of cysts is used through abdominal wall under sonography control with aspiration of maintenance.

Surgical treatment is the method of choice of treatment of cysts of pancreas. The choice of treatment method depends on the stage of forming of pancreas cysts.

On the I stage operation is not used, conservative treatment of pancreatitis is conducted. On the II stage it is used at suppuration of pseudocyst (external draining of cyst). On the III — internal draining of cyst is used. More frequently cystojejunostomy on the eliminated loop of thin bowel by Roux (Pic. 3.5.13), cystojejunostomy with entero-entero anastomosis by Brawn and closing of afferent loop by Shalimov. Cystogastrostomy (Pic. 3.5.14) are executed and cystoduodenostomy is now not applied because of possible complications (infection of cyst, erosive bleeding). Marsupialization (opening and sewing down of cyst to the parietal peritoneum and skin) is used infrequently (at suppuration of cyst is seriously patientsing with the septic state). On the IV stage external and internal draining of cyst and radical operations are applied: a) enucleation of cysts (executed very rarely); b) distal resection of pancreas with a cyst.

The cancer of pancreas is a malignant tumor of epithelium tissue. Its specific gravity among all malignant tumors makes 10 %. Greater part of patients with cancer of pancreas (to 80 %) is made by the persons of capable working age.

The origin of cancer of pancreas is related to character of nutrition: with the promoted

maintenance of albumens and fats in meal.

Shortage of vitamins, especially B and C, harmful habits (abuse of alcohol, smoking), presence of carcinogenic matters in food (nitrite, nitrates and others like that), tonsillectomy suffered in the past also belong to etiologic factors. The cancer tumor of pancreas can arise on the background of protracted period of chronic pancreatitis.

A cancer tumor is localized in the head. Rarer — in the area of body or tail, rarer there is a diffuse damage of pancreas.

A tumor has the appearance of a dense knot or conglomerate of knots of different sizes. It resembles epithelium of pancreatic ducts or epithelium of acinous tissue, sometimes — the Langerhans' islet.

Adenocarcinoma (50–55 %) is exposed microscopically, carcinoid (32–35 %), epidermoid cancer or skir is seldom met.

The cancer of pancreas gives metastases quickly enough which spread in lymphogenic way in parapancreatic lymphatic knots, and afterwards — in the gate of liver. The hematogenic metastases are often exposed in lungs, bones, buds and brain. Possible also remote metastases to the type of Virhov's, Shnitsler's, Krukenberg's.

The clinical signs and passing of cancer of pancreas are various. They depend both on localization of tumor in pancreas and the mutual relations of pathological process with surrounding organs or tissue.

Pain is a permanent symptom on which 60–90 % patients specify. It is conditioned by involvement in the process of nervous elements of pancreas and retroperitoneum space. The pain feelings at cancer of pancreas are unrelated with acceptance of meal, can be periodic with irradiation in the back. The insignificant loss of weight makes progress and for a short time becomes considerable enough. Such is clinic of cancer of body and tail of pancreas.

Icterus is characteristic of the cancer of head of pancreas, that arises as a result of obturation of general bilious duct and develops slowly but with steady growth. At palpation of abdomen Courvoisier's symptom is observed. Protracted, to 3–4 weeks, icterus results in piling up of products of disintegration of bile in blood and tissue, causing heavy intoxication of organism, violation of liver unction, buds and coagulation system of blood. Obturation of duct of pancreas causes dyspepsia disorders: belch, nausea, vomiting, diarrhea (“fat” emptying). Distributions of tumor on duodenum and narrowing of its lumen show up by the signs of stenosis of exit from the stomach of a different degree (feeling of plenitude in a epigastric area, periodic pain, belch and vomiting).

Bilirubinemia grows gradually, mainly due to direct bilirubin. The increase of activity of alkaline phosphatase and level of cholesterol are observed in blood. As at mechanical icterus a bile does not get the intestine, stercobilin in excrement is absent (acholic excrement). There is also no urobiliny in urine, although bilious pigments are present there (bilirubin). It is possible to expose steatorrhea and kreatorrhea in excrement as a result of obturation of pancreatic duct and exception of enzymes of pancreas from digestion.

With the help of radioimmunoassay it is sometimes succeeded to mark the increase of level of tumor markers in the whey of blood: cancer-embryo to the antigen, ferritin.

Sciagraphy of gastro-intestinal highway can expose the cancer heads of pancreas, the

unfolded “horseshoe” of duodenum, and in case of localization of tumor in the body of gland — displacement of back wall of stomach forward. At duodenoscopy rigidity of mucus shell of descending part of duodenum, narrowing of its lumen are determined, and sometimes there is germination of bowel by tumor.

Scanning is an informing method of examination with the use of ^{75}Se -methionine. Such examinations can expose the hearths of reduced accumulation of isotope or its absence in tissue of gland at the damage by tumor.

During laparoscopy the cancer of pancreas is visualized infrequently, however, dissemination of peritoneum and its metastatic hearths in liver are diagnosed without difficulties.

By ultrasonic (sonography) examination it is succeeded to expose the places of promoted closeness of tissue of gland, sign of mechanical icterus at localization of tumor in the head.

Most informing among all is computer tomography (Pic. 3.5.15). It is possible to define both the tumor of gland and its size and metastatic knots. The changes of main duct of pancreas as segmental stenosis or breaking are fixed on retrograde endoscopic pancreatography.

Clinical passing of cancer of pancreas in 70 % patients is marked by the background diseases and complications. This circumstance allows to select a few clinical forms of the cancer of pancreas before appearance of icterus: pancreatitic, diabetogenic, cholangitic and gastritis-like. The names specify the feature of clinical signs of different forms of disease.

Mechanical icterus is the heaviest complication of cancer of pancreas. With the increase of duration and growth of its intensity development of such dangerous complications, as hepatic or hepatic-kidney insufficiency, cholemic bleeding is possible.

Anamnesis has an important value for differential diagnostics. The presence of attacks of pain or intermittent icterus testifies its calculous origin. A pain syndrome at the cancer of pancreas does not have such acuteness and intensity, as at gallstone disease. Icterus in cancer patients, unlike cholelithiasis, develops gradually, incessantly grows and is of proof character.

Often substantial difficulties arise during conducting the differential diagnostics of obturative and infectious icterus. It is necessary to remember, that at viral hepatitis the level of transaminase and aldolase in the whey of blood rises by 2–3 times. At obturation icterus their level does not change substantially, and the increase of activity of alkaline phosphatase and instead of that the level of cholesterol is marked.

However, most operation difficulties are met during conducting the differential diagnosis of the cancer of pancreas and chronic indurative pancreatitis. In fact both processes during examination and palpation produce similar pictures. In such cases puncture of the densest area of pancreas is executed and cytologic examination is quickly conducted.

Treatment of cancer of pancreas is mainly surgical. The choice of method and volume of operation depends on localization of tumor, stage of process, age of patient and his general condition.

Taking it into account, as practice shows, radical operations in the moment of establishment of final diagnosis are successfully executed only in 15–20 % of patients. Pancreatoduodenal resection is the method of choice of operation in patients with the damage of head of pancreas. Operation foresees deleting one block of head of pancreas, distal part of

stomach, duodenum and distal part of general bilious duct. Four anastomosis are thus imposed: gastroenteroanastomosis, cholecysto-enteroanastomosis or choledochoenteroanastomosis, pancreatoentero-anastomosis and enteroenteroanastomosis. Sometimes this operation is executed in two stages. On the first one biliary-enteric anastomosis is formed for taking bile and improvement of function of liver, and the second stage is carried out in 3–4 weeks. However, more frequently symptomatic operations are to be executed: cholecysto-enteroanastomosis or choledochoduodenoanastomosis. They are able to liquidate icterus and prolong the life of patients for 5–9 months. In case of damage of body and tail of pancreas the distal subtotal resection of gland with spleen is radical.

Chemotherapy can give partial remission. With this purpose 5-fluorouracil, adriablastine, methotrexate are mainly used.

Some palliative effect also comes after gamma-ray teletherapy.

Tactics and choice of treatment method

Conservative treatment. Treatment of acute or chronic pancreatitis is conducted in accordance with principles. At the unfavorable dynamics of passing the diseases hunger with the permanent sucking of gastric maintenance, parenteral feed and intravenous introduction of liquids are appointed. Puncture of cysts is used through abdominal wall under sonography control with aspiration of maintenance.

Surgical treatment is the method of choice of treatment of cysts of pancreas. The choice of treatment method depends on the stage of forming of pancreas cysts.

On the I stage operation is not used, conservative treatment of pancreatitis is conducted.

On the II stage it is used at suppuration of pseudocyst (external draining of cyst). On the III — internal draining of cyst is used. More frequently cystojejunostomy on the eliminated loop of thin bowel by Roux (Fig.5), cystojejunostomy with entero-entero anastomosis by Brawn and closing of afferent loop by Shalimov.

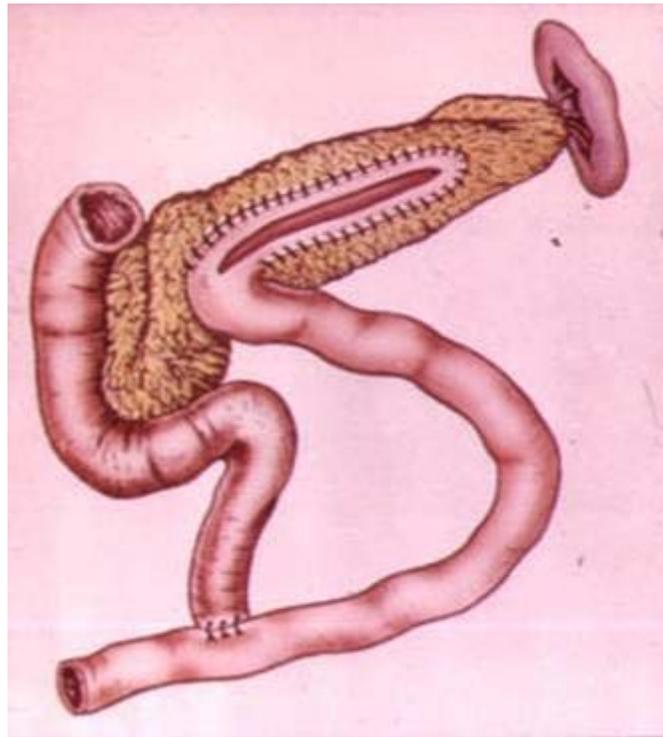

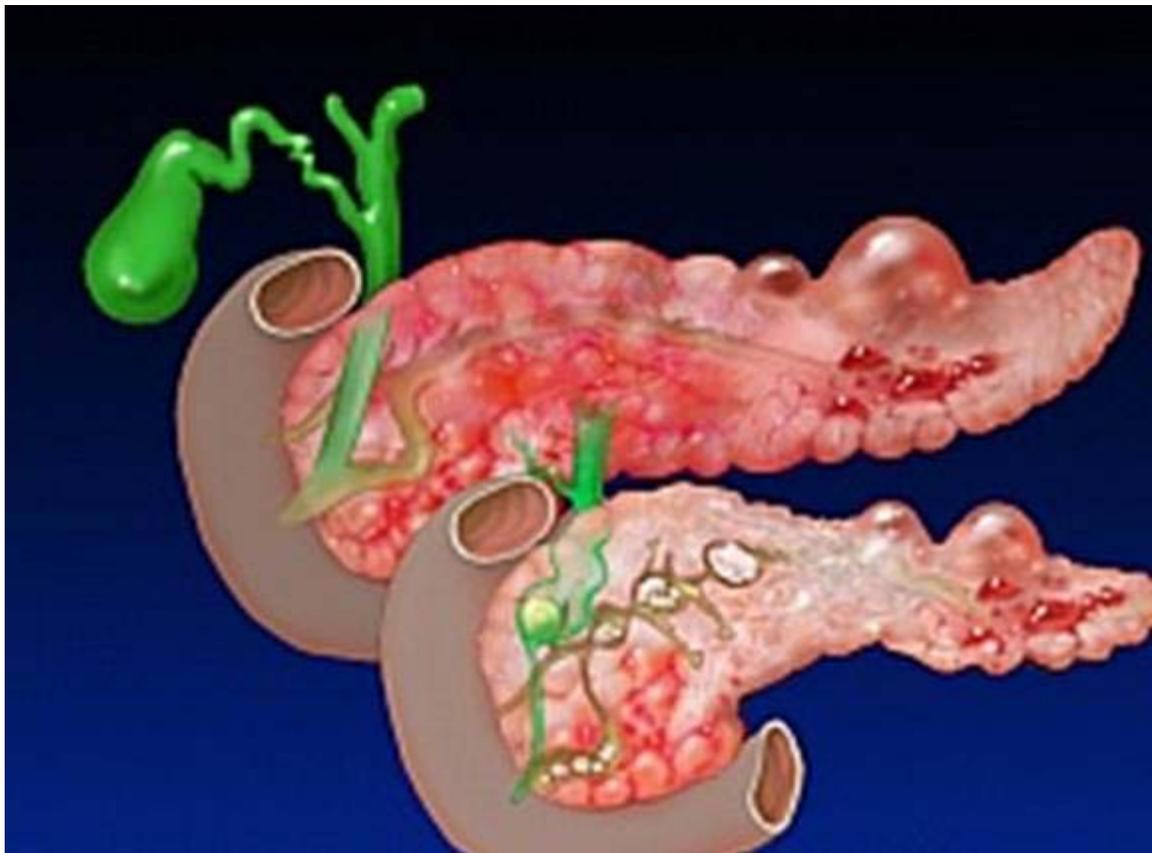

Fig.5

Cystogastrostomy are executed and cystoduodenostomy is now not applied because of possible complications (infection of cyst, erosive bleeding). Marsupialization (opening and sewing down of cyst to the parietal peritoneum and skin) is used infrequently (at suppuration of cyst is seriously patientsing with the septic state).

On the IV stage external and internal draining of cyst and radical operations are applied: a) enucleation of cysts (executed very rarely);
b) distal resection of pancreas with a cyst.

(PANCREATITUOS PERITONITIS, PANCREONECROSIS, FALSE CYSTS
OF THE PANCREAS). TACTICS OF TREATMENT.**

ACUTE PANCREATITIS

Anatomy and function

The **pancreas** is an organ located in the abdomen. It plays an essential role in converting the food we eat into fuel for the body's cells. The pancreas has two main functions: an **exocrine** function that helps in digestion and an **endocrine** function that regulates blood sugar.

Basic Anatomy: The pancreas is located behind the stomach and is surrounded by other organs including the small intestine, liver, and spleen. It is about six inches long and is shaped like a flat pear. The wide part, called the head of the pancreas, is positioned

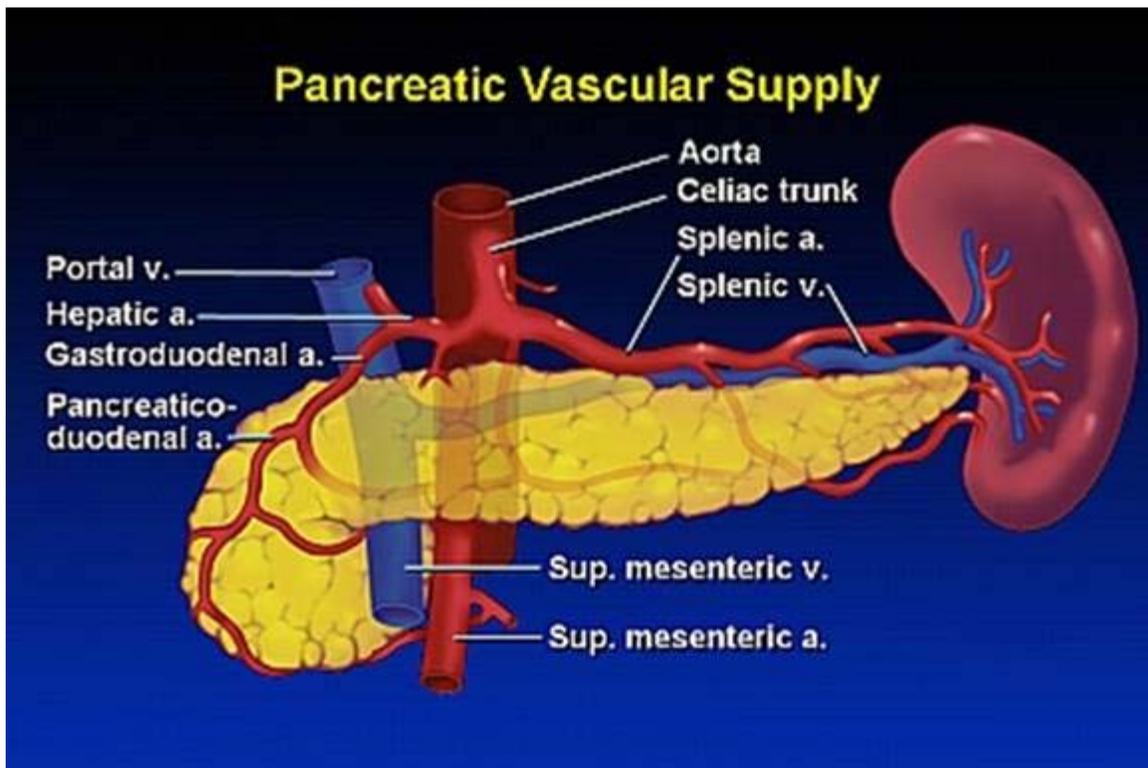

toward the center of the abdomen; the middle section is called the neck and the body of the pancreas; the thin end is called the tail and extends to the left side. Several major blood vessels surround the pancreas, the superior mesenteric artery, the superior mesenteric vein, the portal vein and the celiac axis, supplying blood to the pancreas and other abdominal organs.

Exocrine Function: The pancreas contains exocrine glands that produce **enzymes** important to digestion. When food enters the stomach, these pancreatic juices are released into a system of ducts that culminate in the main **pancreatic duct**. The pancreatic duct joins the **common bile duct** to form the **ampulla of Vater** which is located at the first portion of the small intestine, called the **duodenum**. The common bile duct originates in the liver and the **gallbladder** and produces another important digestive juice called **bile**. The pancreatic juices and bile that are released into the duodenum, help the body to digest fats, carbohydrates, and proteins.

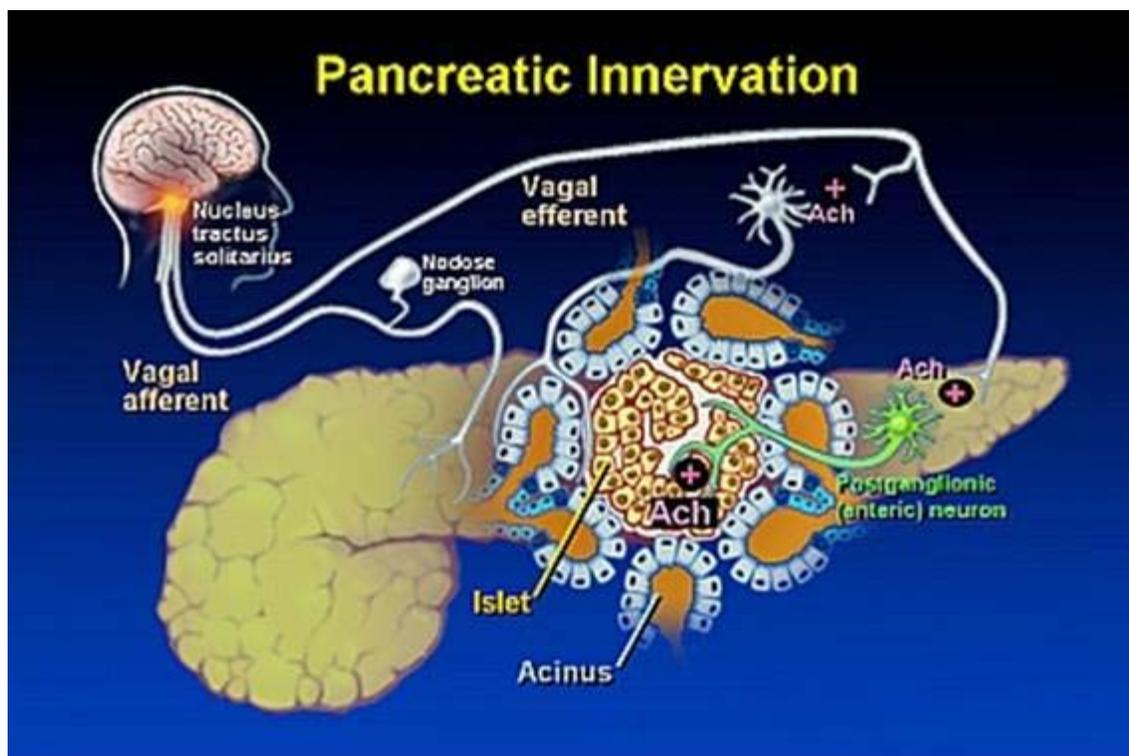

Endocrine Function: The endocrine component of the pancreas consists of islet cells that create and release important **hormones** directly into the bloodstream. Two of the main pancreatic hormones are **insulin**, which acts to lower blood sugar, and **glucagon**, which acts to raise blood sugar. Maintaining proper blood sugar levels is crucial to the functioning of key organs including the brain, liver, and kidneys.

Acute pancreatitis

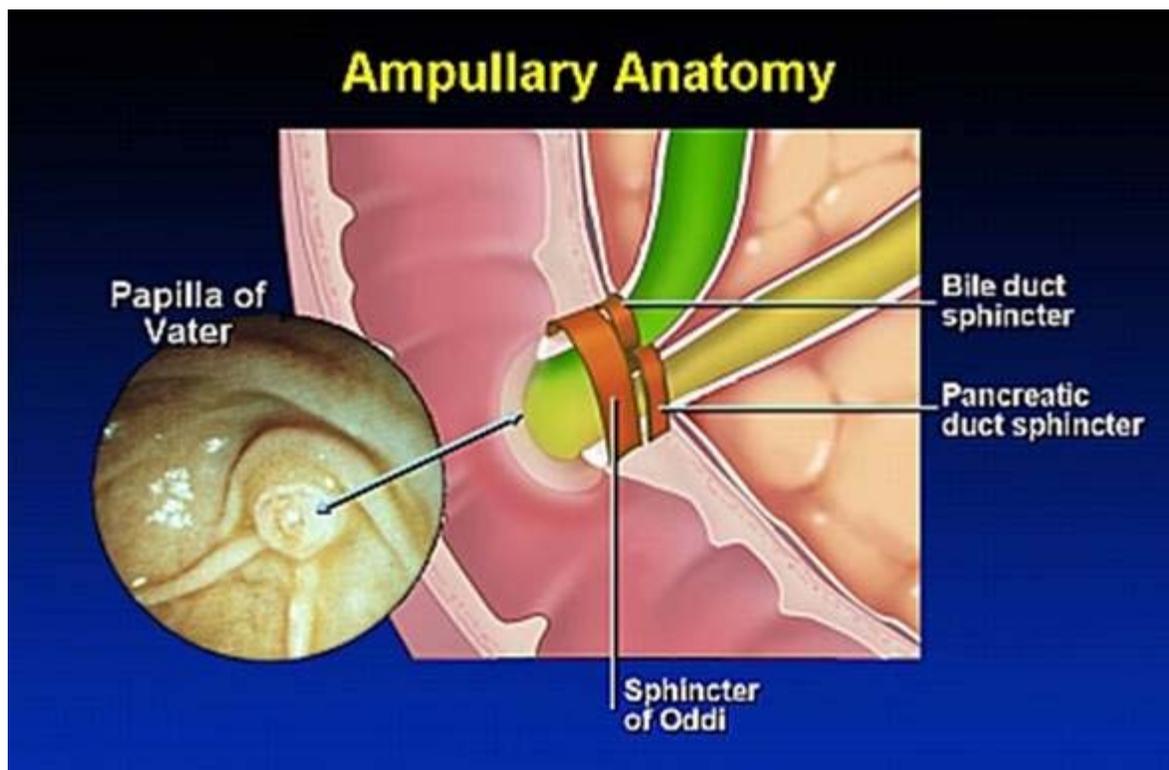

The basis of disease of pancreas is degenerative-inflammatory processes which are considered to be acute pancreatitis, the so called autolysis tissue by its own enzymes. In the structure of acute pathology of organs of abdominal cavity this disease takes the third place after acute appendicitis and cholecystitis. Women suffer from acute pancreatitis 3–3,5 times more frequently than men.

Pic. Pancreatic vascular supply.

Pic. Pancreatic Innervation

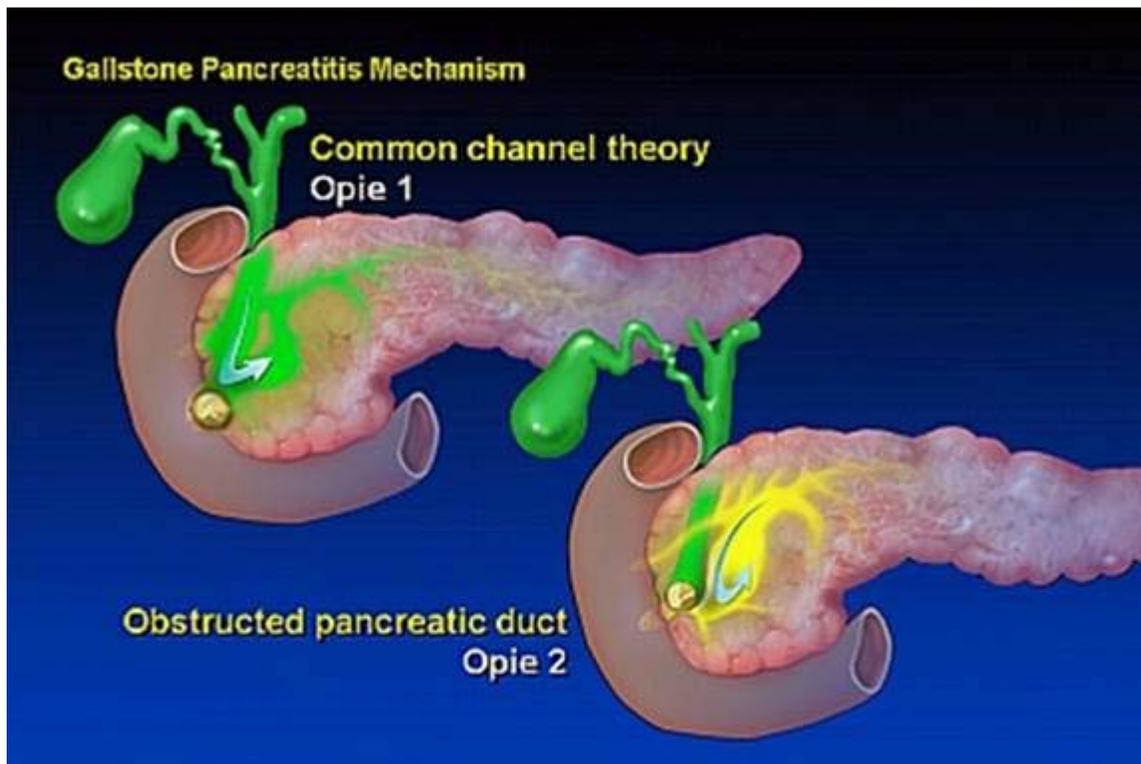

Pic. Ampullary Anatomy

Etiology and pathogenesis

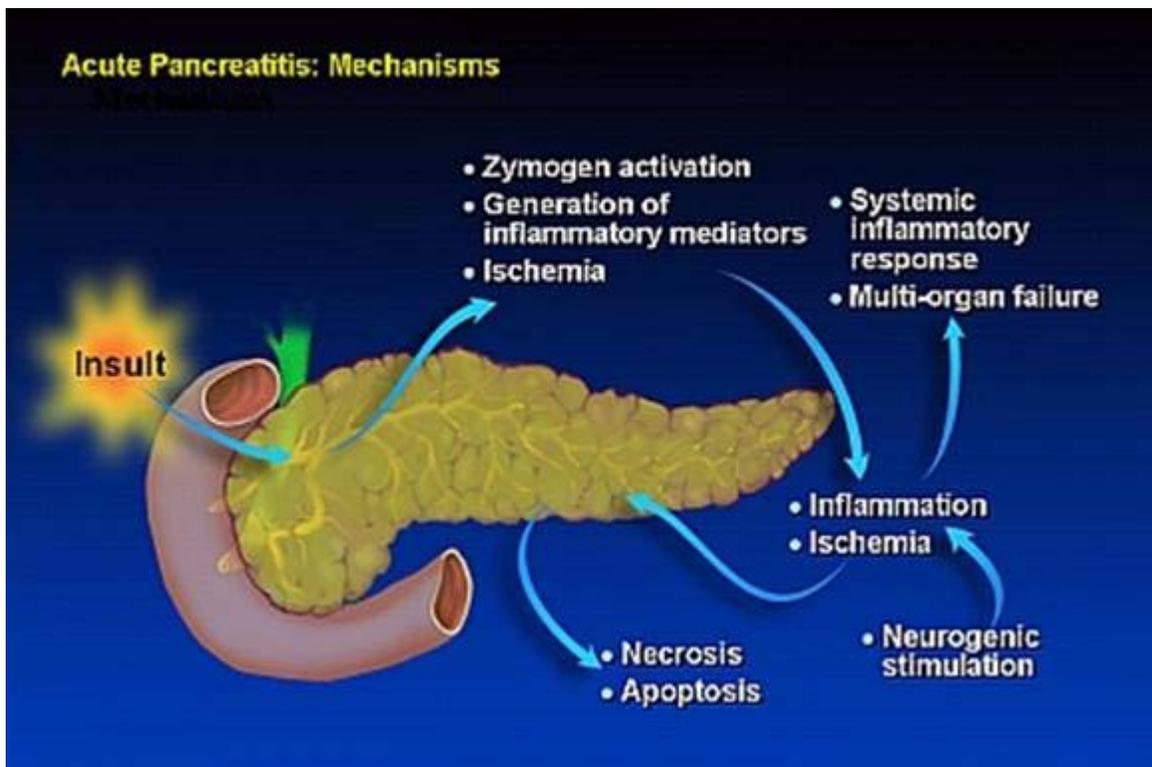

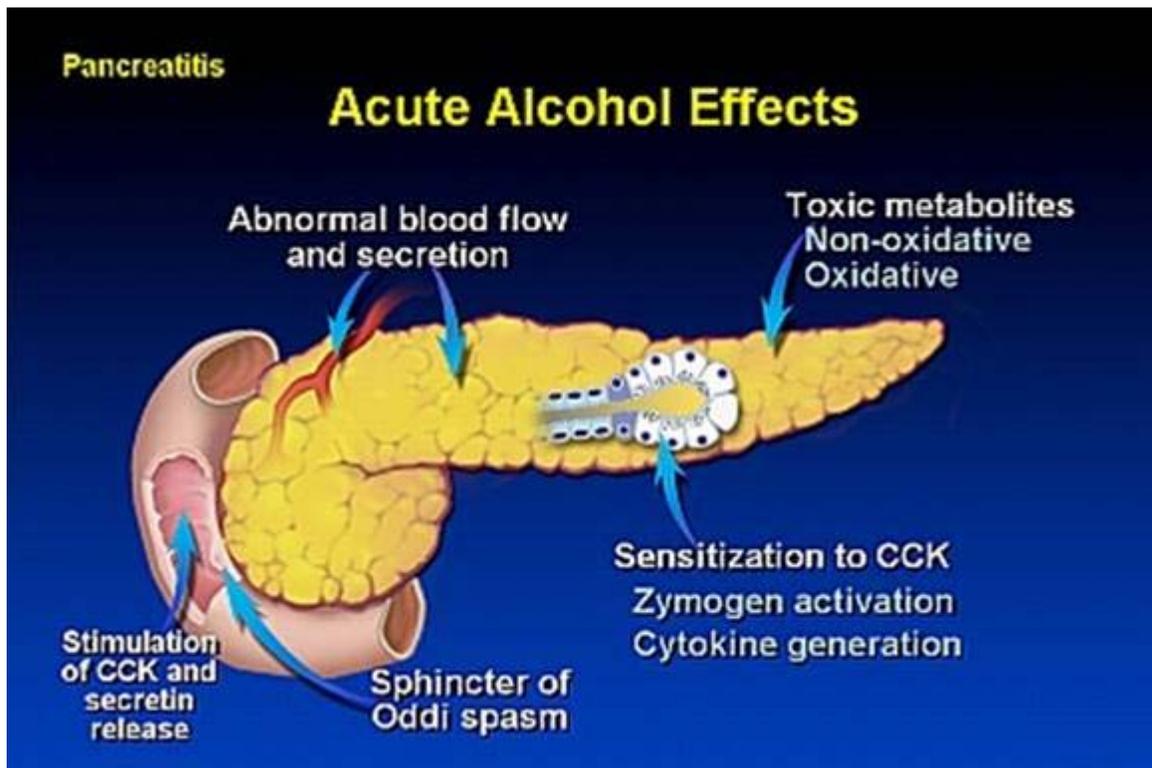

Acute pancreatitis is a polyetiology disease. Its secondary forms, which arise on the background of pathologies of bile-excreting system and duodenum are closely associated with anatomic and functionally with pancreas, and are met in clinical practice.

Among the “starting” factors of origin of cholelithiasis disease (biliary pancreatitis) abuse by an alcohol and food overloads (fat and irritating products), traumas of pancreas, operating-room in particular, and also separate infectious diseases (parotitis, mononucleosis) are most frequent, especially infection of bilious ways. However, in 10–20 % of patients the reason of acute pancreatitis remains unknown (cryptogenic form).

In the basis of such damages of pancreas and enzymic toxemia lies mainly activating of pancreatic, and then the tissue enzymes (trypsin, lipase, amylase). Often the combination of the broken outflow of pancreatic secret and promoted secretion takes place, which provokes intraductal hypertension.

Among explanations of primary mechanisms of activating of pancreatic enzymes the most value belongs to: a) theory of “general duct” with reflux of bile in the ducts of pancreas; b) blockade of outflow of pancreatic juice with development of intraductal hypertension and penetration of secret in interstitial tissue; in) violation of blood flow of pancreas (vasculitis, thrombophlebitis and embolisms, cardiac insufficiency and others like that); g) toxic and allergic damages of gland. The role of alcohol in such situations can be dual: stimulation of secretion of pancreas and direct damaging action on its tissue.

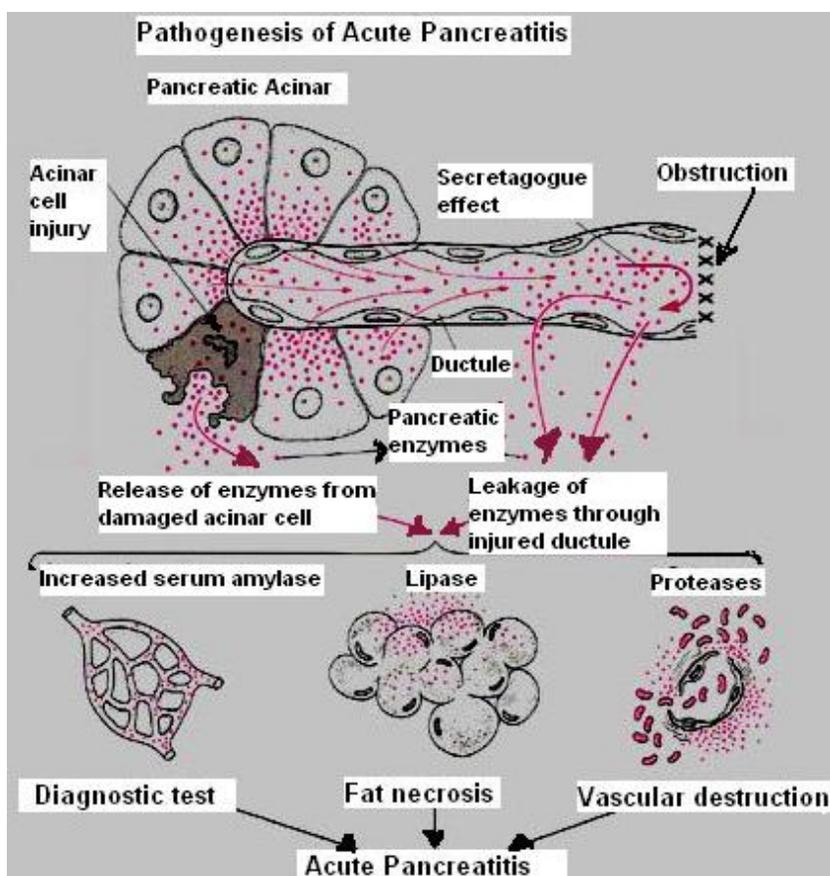

Acute pancreatitis: Mechanisms

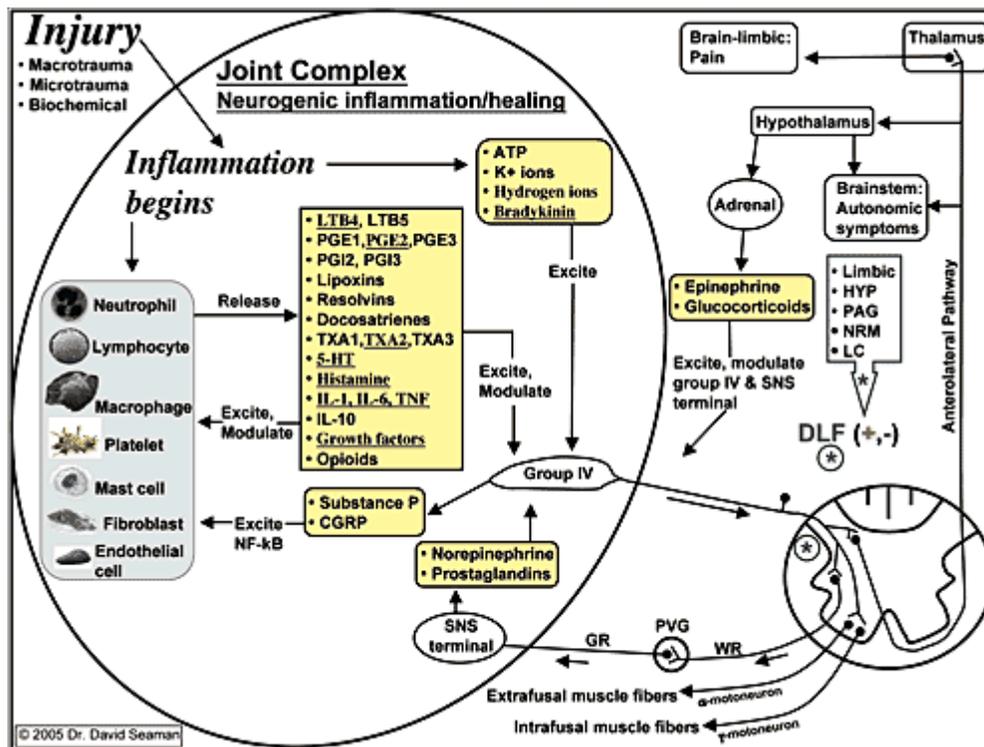

Pathomorphology

The process of acute inflammation of pancreas consistently passes the stages of edema, pancreatonecrosis and festering pancreatitis. In the stage of edema there is pancreas of hyperemic, increased in volume, with the shallow hearths of necrosis or, as it is in swingeing majority of cases, without them.

Pancreatonecrosis can pass with fatty or hemorrhagic character. In the first case, as a rule, pancreas is increased, dense, cut whity-yellow hearths are selected to necrosis. Increase of crimson-black pancreas with darkly-brown infiltrate on a cut is characteristic for hemorrhagic pancreatonecrosis.

Dystrophy of parenchyma is exposed microscopically, up to necrosis, hemorrhages, thromboses of vessels and signs of inflammatory infiltration.

Classification

(V All-russian convention of surgeons, 1978)

I. Clinico-anatomy forms:

1. Arching form.
2. Fatty pancreatonecrosis.
3. Hemorrhagic pancreatonecrosis.

II. Prevalence of necrosis:

1. Local (focus) damage of gland.
2. Subtotal damage of gland.
3. Total damage of gland.

III. Ran across: abortive, progressive.

IV. Periods of disease:

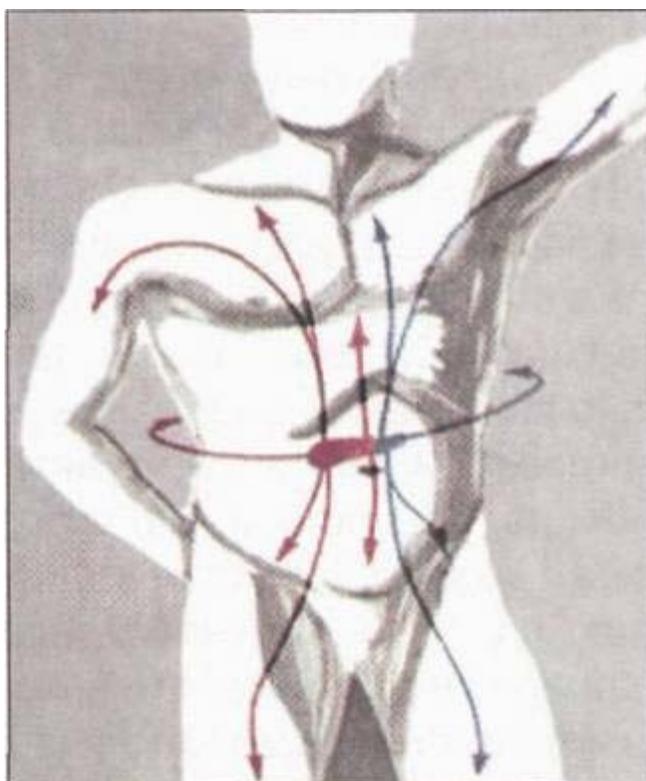

1. Period of hemodynamic violations and pancreatogenic shock.

2. Period of functional insufficiency of parenchymatous organs.
3. Period of degenerative and festering complications.

Symptoms and clinical passing

The disease begins suddenly, after the surplus reception of rich spicy food and use of alcohol. Pain, vomiting and phenomena of dynamic intestinal obstruction are considered the most characteristic signs of acute pancreatitis.

A stomach-ache is permanent and so strong, that can result in shock, localized in an epigastric area and left hypochondrium. Some patients feel pain in right hypochondrium with irradiation in the back, loin or breastbone.

Pain irradiation on acute pancreatitis

In a short period of time after appearance of pain there is a repeated strong vomiting, that does not facilitate the state of patient.

In general vomiting is considered a frequent and characteristic symptom. It is

repeated or continuous and never brings facilitation. Vomit masses contain bile, as admixture, and at the difficult form of acute pancreatitis remind “coffee-grounds”.

Nausea, hiccup, belch and dryness in a mouth are attributed as less characteristic symptoms of this pathology.

During the examination the skin is pale, often subicterus. Some patients have cyanosys with a “marble picture” as a result of violation of microcirculation. Later the component of respiratory insufficiency can join it. At progressive general condition the patient quickly gets worse to passing of acute pancreatitis, intoxication grows. The skin takes shelter with sticky sweat.

The temperature of body of patients at the beginning of disease can be normal. It rises at resorption of products of autolysis tissue and development of inflammatory process in bilious ways.

The pulse in most cases is at first slow, then becomes frequent, notably passing ahead the increase of temperature of body.

Arterial pressure goes down.

The tongue in the first hour of disease is moist, assessed by white and grey raid. At vomiting by bile the raid has yellow or greenish tint.

The abdominal is blown away, peristaltic noises are loosened. The signs of paresis of stomach and intestine demonstrate early. They need to be included in the pathological process of mesentery root of bowel. At palpation painfulness in an epigastric area and in right, and sometimes and in left, hypochondrium is marked. However, in spite of great pain in stomach, it remains soft for a long time. A little later there is moderate tension or resistance of muscles of front abdominal wall.

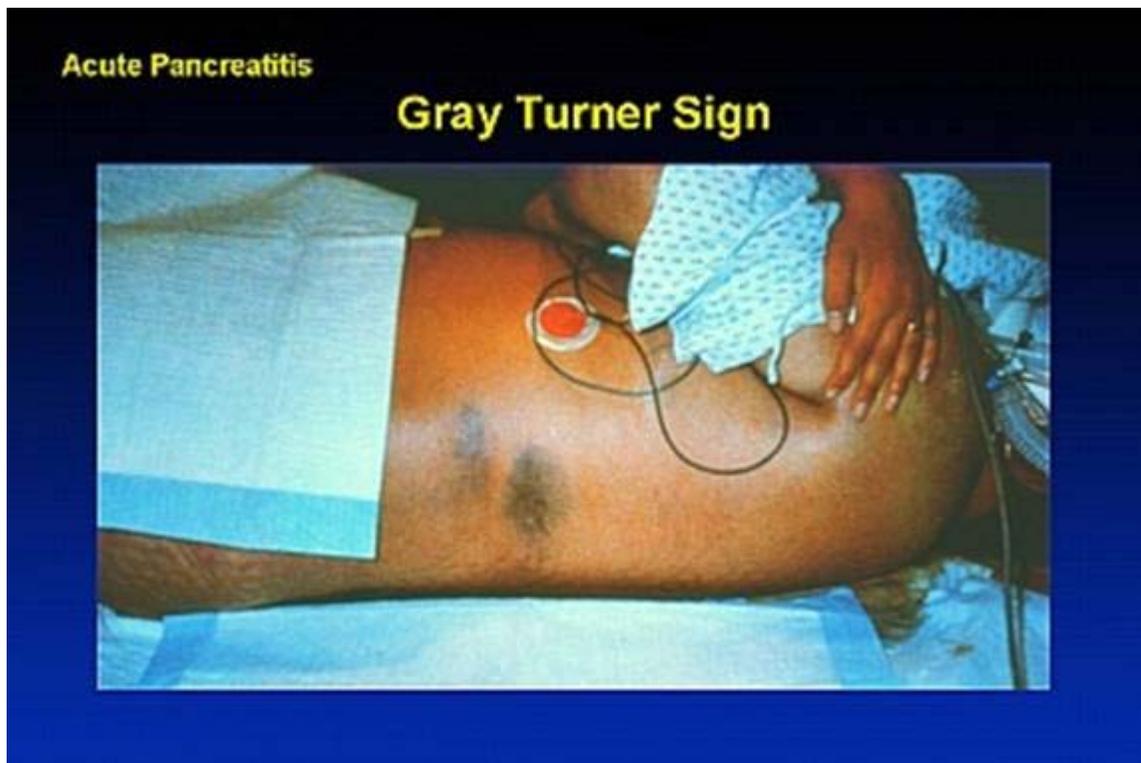

Poor local symptoms during heavy intoxication are characteristic for the early period of acute pancreatitis. Later there are symptoms of irritation of peritoneum, and at percussion dulling is marked in lateral parts of abdominal as a result of accumulation of liquid, and also the sign of aseptic phlegmon of retroperitoneal cellulose as slurred or edema of lumbar area is seen. For diagnostics of acute pancreatitis there is the row of characteristic symptoms which have different clinical value.

The Mondor's symptom is violet spots on face and trunk.

The Lagermph's symptom is acute cyanosis of person.

The Halsted's Symptom is cyanosis of abdominal skin.

The Gray's symptom is cyanosis of lateral walls of abdomen.

The Kullen's symptom is the yellow colouring of skin near a belly-button.

The Korte's symptom is painful resistance as a lumbar bar in a epigastric area on 6–7 cm higher belly-button.

The Voskresynskyy's symptom is absence of pulsation of abdominal aorta in an epigastric area.

The Mayo-Robson's symptom is feeling of pain at pressure by fingers in the left costal-vertebral corner.

The Rozdolskyy's symptom — painfulness at percussion above pancreas.

The Blumberg's symptom — in patients with acute pancreatitis more frequently is low-grade. Such feature of this sign of irritation of peritoneum needs to be explained by character of localization of pathological process, mainly in retroperitoneal spacious.

In clinical passing of pancreatonecrosis it is possible to select three periods (V.S.

Saveljev, 1978).

The I period (hemodynamic violations and pancreatogenic shock) lasts during 2–3 days. Violation of central hemodynamics, diminishment of volume of circulatory blood and disorders of microcirculation, which at first arise as a result of angiospasm, are considered the most characteristic signs, and later as a result of joining of the intravascular rolling up and laying of elements of blood.

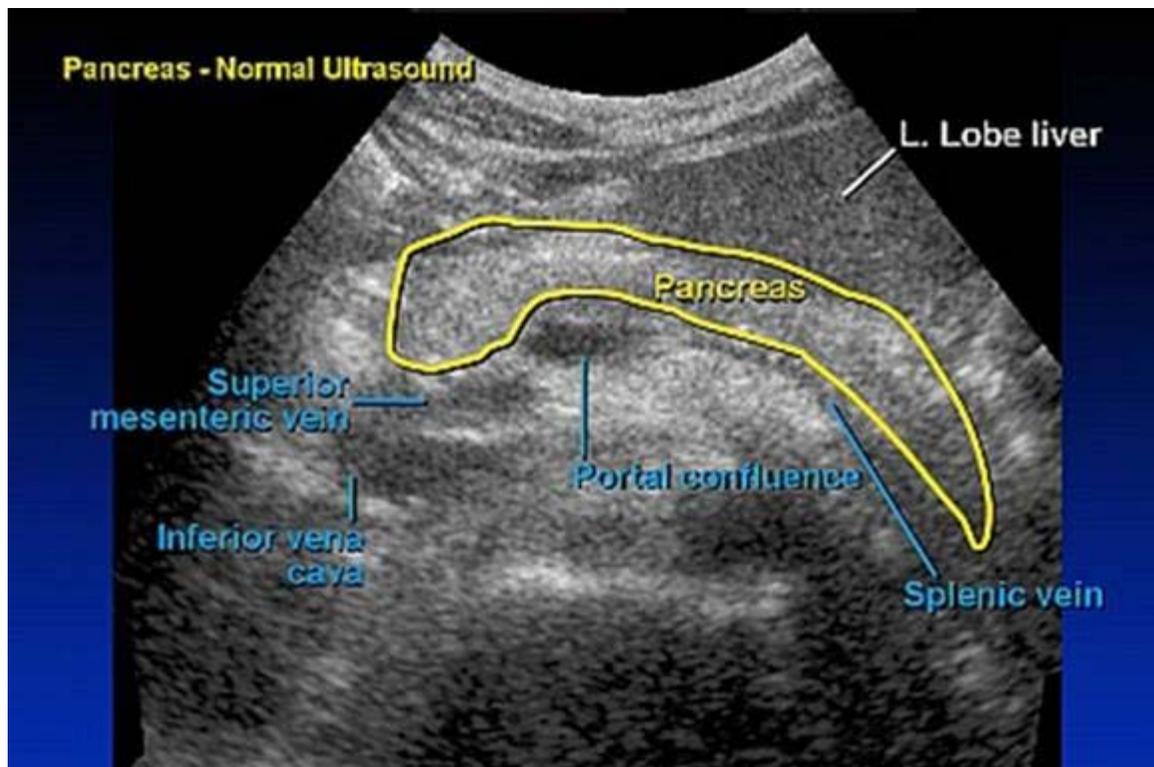

The II period (insufficiency of parenchymatous organs) lasts from 3rd to the 7th day of disease. Violation of functions of basic organs and systems, sign of cardio-vascular, hepatic and kidney insufficiency and growth of violations of breathing are thus observed. In this period there is possible damaging of the central nervous system, which is erected mainly to disorders of psyche, appearances of delirium and commas which in the eventual result are the main reasons of patients' death.

The III period (postnecrosis dystrophic and festering complications) comes in 1–2 weeks after the beginning of disease. During it, on the background of progress of necrosis processes in pancreas, the regenerative changes develop, there are parapancreatic infiltrate and cysts, cystic fibrosis of pancreas. Aseptic retroperitoneal phlegmon which strengthens intoxication can also develop. There is festering pancreatitis at joining of infection. During this period such complications, as erosive bleeding, internal or external fistula, retroperitoneal phlegmon, can develop in patients.

From laboratory information leucocytosis which at the necrosis and hemorrhagic forms of pancreatitis sometimes arrives at $25-30 \times 10^9$, lymphopenia, change of leukocytic formula to the left and the increased ESR are characteristic. Growth of activity of amylase of blood and urine is very often marked, and is the important sign of pancreatitis. For estimation of the state of other organs maintenance of general albumen and its factions, glucose of blood, bilirubin, urea, electrolytes, acid-base equilibrium (ABE), and also the state of blood coagulation are determined. It is necessary to mark that the exposure of hypocalcemia is considered a bad predictive sign of heavy passing of acute pancreatitis.

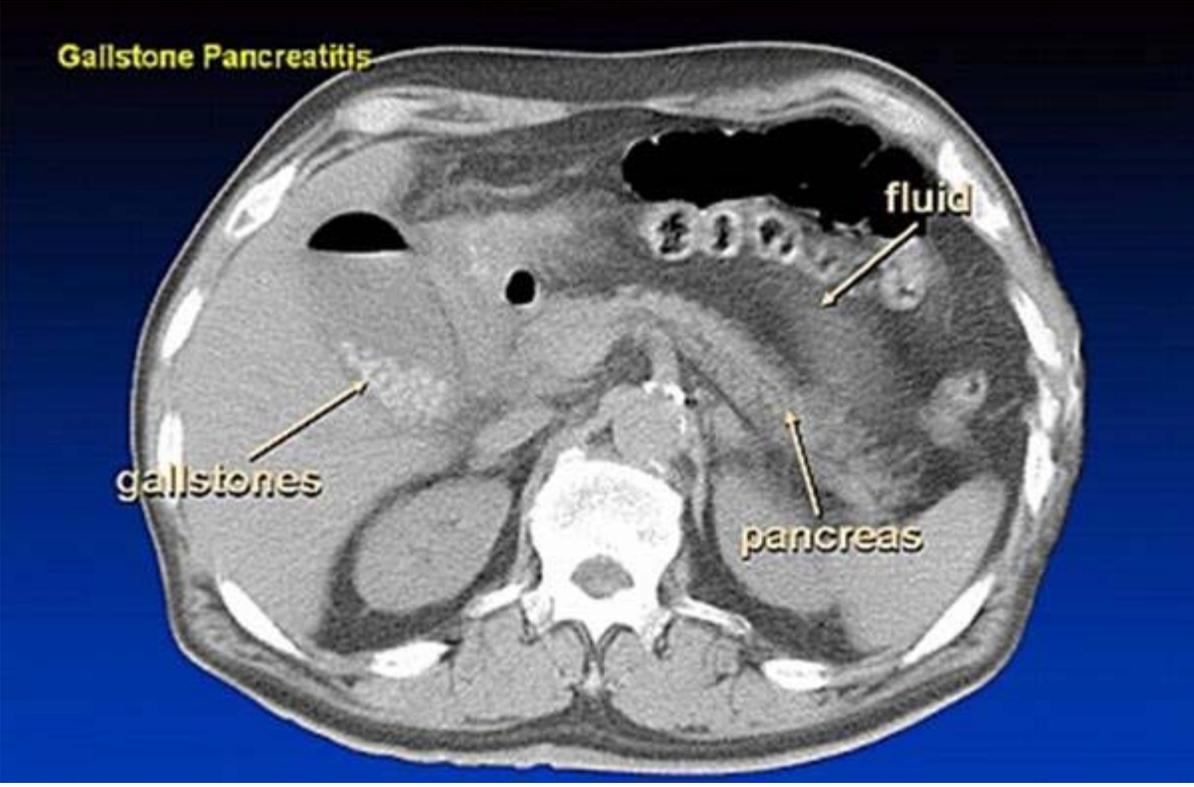

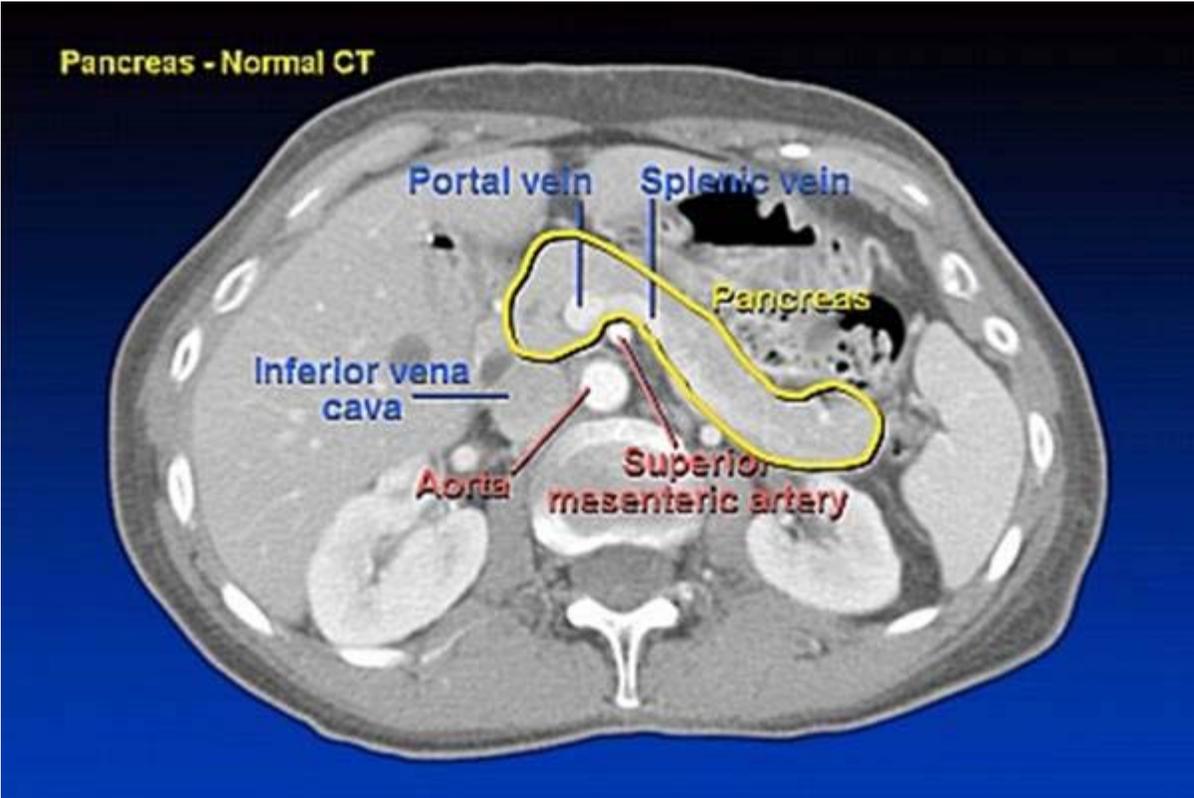

Ultrasonic examination of gall-bladder and pancreas often specifies the increase of their sizes, bulge of walls and presence or absence of concrement of gall-bladder and

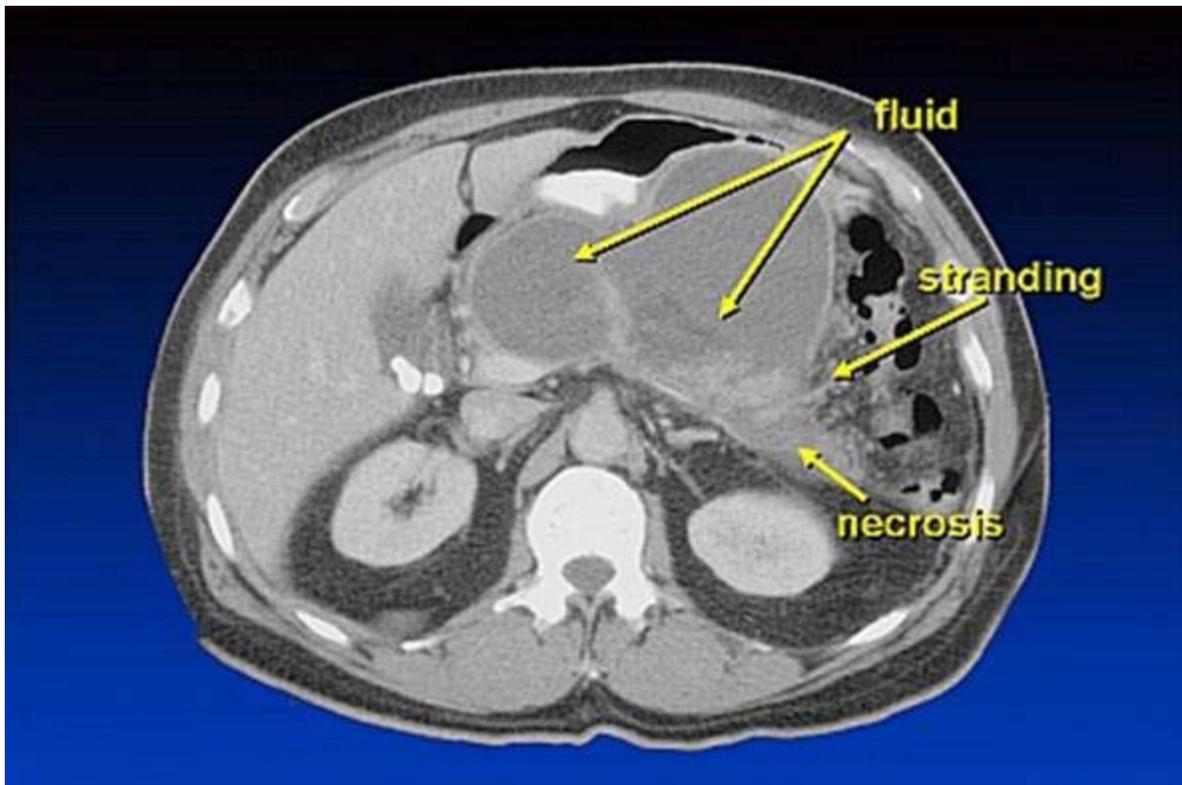

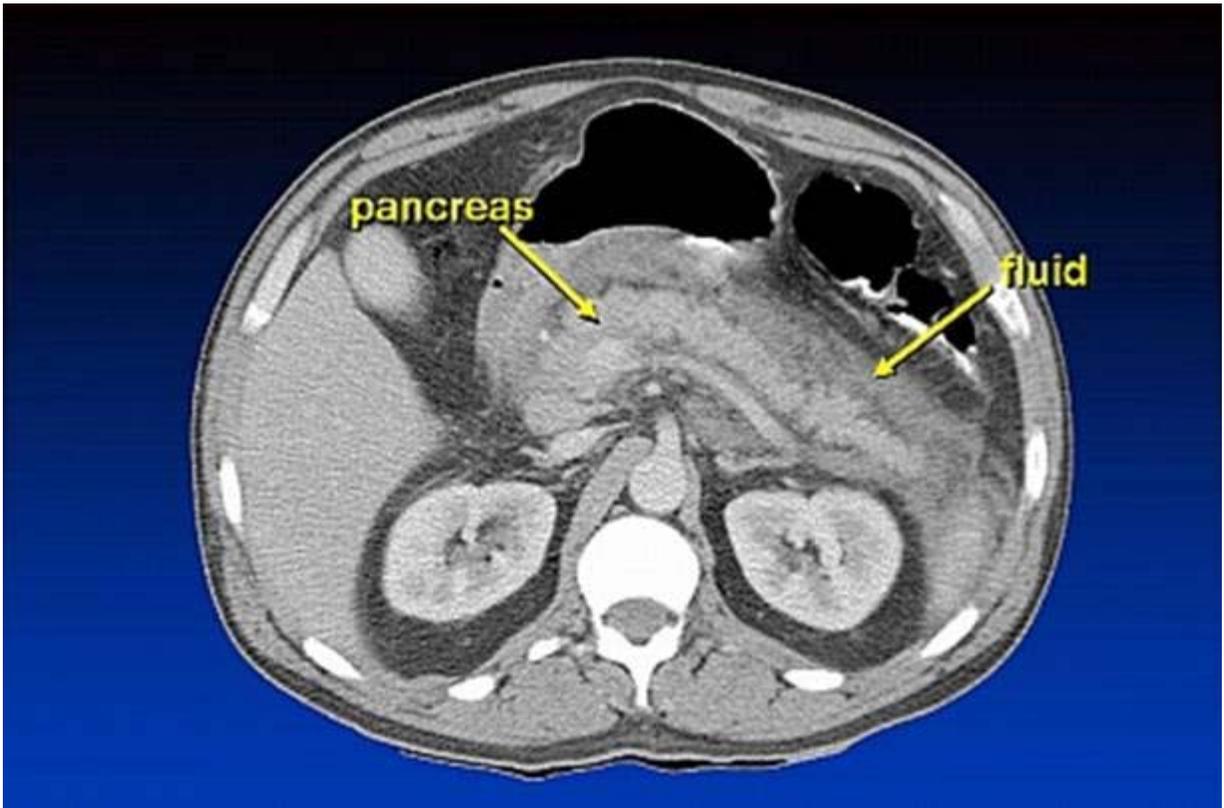

general bilious duct.

Pic. Sonography.

Computer tomography enables to describe in details the changes in pancreas and surrounding organs.

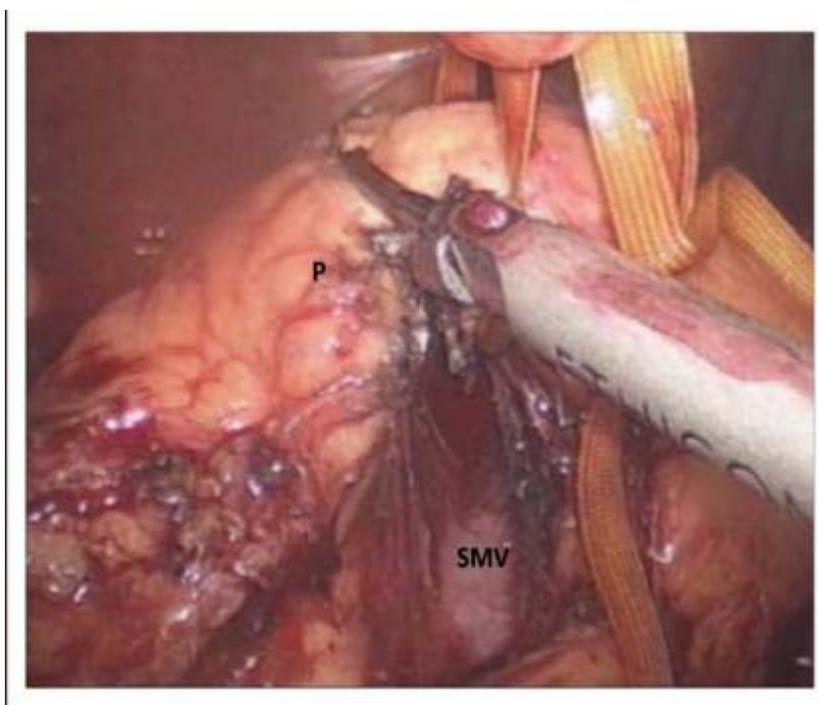

Pic. Computer tomography

At sciagraphy survey of organs of abdominal cavity gives a possibility to expose the

unfolded “horseshoe” of duodenum, pneumatization, expansion of transverse colon (*the Gobia's symptom*). On the 1st stage of diagnostics in the plan of differential diagnosis of acute destructive pancreatitis with other diseases of abdominal cavity, diagnostics of distribution of destructive damaging of different parts of pancreas and estimation of distribution of parapancreatitis is possible only by the method of computer tomography which depending on clinico-laboratory signs and weight of passing is needed to apply in a different period, and sometimes a few times in dynamics with interval of 4–5 days.

Laparoscopy and laparocentesis are often used for a doubtful diagnosis or necessity of taking away the exudation of abdominal cavity for biochemical or bacteriological examination.

Retrograde endoscopic cholangiopancreatography is used in case of mechanical icterus and suspicion of choledocholithiasis. The last methods are invasive and can if it is necessary transform from diagnostic to manipulation treatments: laparoscopic draining of abdominal cavity at pancreatogenic peritonitis and endoscopic papillotomy at choledocholithiasis and biliary pancreatitis.

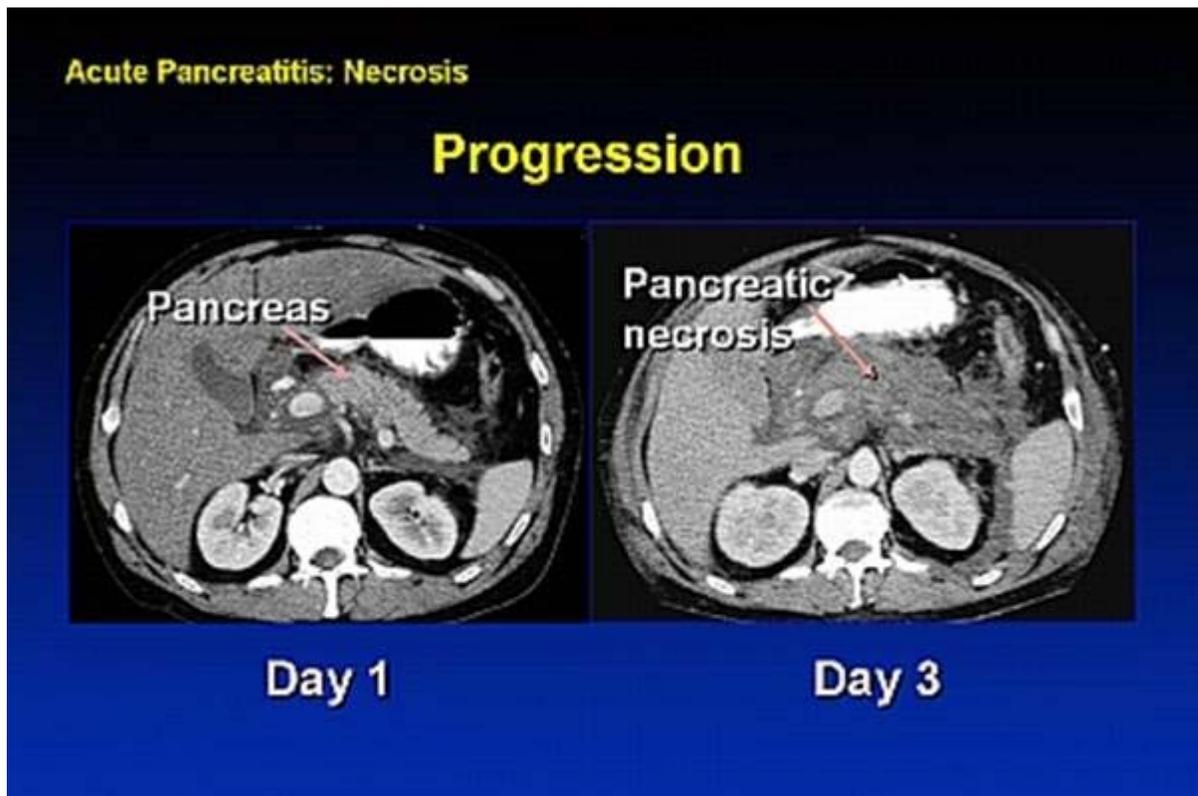

Variants of clinical passing and complications

Clinical passing of disease can be abortive, slowly or quickly progressive. At *abortive passing* the process is limited to acute edema of pancreas with convalescence in 7–10 days.

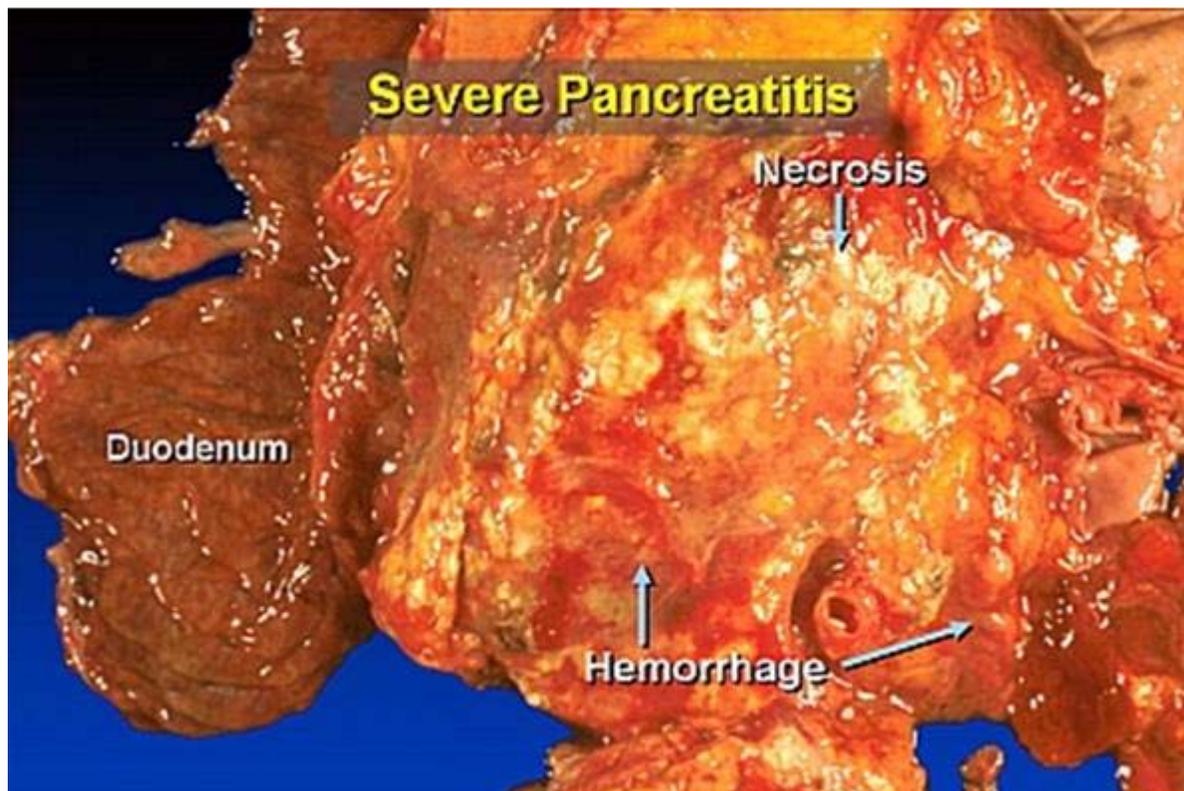

Rapid progress is characteristic for pancreatonecrosis. In patients expressed toxemia, impregnation by exudation of retroperitoneal cellulose and development of fermentative hemorrhagic peritonitis can be seen. Strengthening of stomachache, continuous vomiting, proof paresis of intestine, positive symptoms of irritation of peritoneum and growth of hemodynamic violations are the clinical signs of necrosis of pancreas.

There is a formation of parapancreatic infiltrate at *slow progress*.

Among early complications of acute pancreatitis shock, peritonitis and acute cardiac, pulmonary, hepatic and kidney insufficiency can be distinguished.

Before later complications it is needed to deliver the abscesses of pancreas, subdiaphragmatic, interintestinal abscesses, pyogenic abscess omentum bag, phlegmons of retroperitoneal space and erosive bleeding.

In future formations of pseudocysts, fistula of pancreas, intestinal fistula and development of saccharine diabetes are possible.

Diagnosis program

1. Anamnesis and physical methods of inspection.
2. General analysis of blood and urine.
3. Biochemical blood test (amylase, bilirubin, sugar).
4. Analysis of urine on diastase.
5. Sonography.
6. Computer tomography.
7. Cholecystocholangiography.
8. Endoscopic retrograde cholangiopancreatography.
9. Laparoscopy.
10. Laparocentesis.

Physical Examination:

The following physical examination findings may be noted, varying with the severity of the disease:

- Fever (76%) and tachycardia (65%) are common abnormal vital signs; hypotension may be noted
- Abdominal tenderness, muscular guarding (68%), and distention (65%) are observed in most patients; bowel sounds are often diminished or absent because of gastric and transverse colonic ileus; guarding tends to be more pronounced in the upper abdomen
- A minority of patients exhibit jaundice (28%)
- Some patients experience dyspnea (10%), which may be caused by irritation of the diaphragm (resulting from inflammation), pleural effusion, or a more serious condition, such as acute respiratory distress syndrome (ARDS); tachypnea may occur; lung auscultation may reveal basilar rales, especially in the left lung
- In severe cases, hemodynamic instability is evident (10%) and hematemesis or melena sometimes develops (5%); in addition, patients with severe acute pancreatitis are often pale, diaphoretic, and listless
- Occasionally, in the extremities, muscular spasm may be noted secondary to hypocalcemia

A few uncommon physical findings are associated with severe necrotizing pancreatitis:

- The Cullen sign is a bluish discoloration around the umbilicus resulting from hemoperitoneum
- The Grey-Turner sign is a reddish-brown discoloration along the flanks resulting from retroperitoneal blood dissecting along tissue planes; more commonly, patients may have a ruddy erythema in the flanks secondary to extravasated pancreatic exudate
- Erythematous skin nodules may result from focal subcutaneous fat necrosis; these are usually not more than 1 cm in size and are typically located on extensor skin surfaces; in addition, polyarthrititis is occasionally seen

Rarely, abnormalities on fundoscopic examination may be seen in severe

pancreatitis. Termed Purtscher retinopathy, this ischemic injury to the retina appears to be caused by activation of complement and agglutination of blood cells within retinal vessels. It may cause temporary or permanent blindness.

Differential diagnostics

- Acute Mesenteric Ischemia
- Acute Respiratory Distress Syndrome
- Bacterial Pneumonia
- Cholangitis
- Cholecystitis
- Choledocholithiasis
- Cholelithiasis
- Chronic Pancreatitis
- Colon Adenocarcinoma
- Colonic Obstruction
- Community-Acquired Pneumonia
- Duodenal Ulcers
- Gastric Cancer
- Gastroenteritis in Emergency Medicine
- Irritable Bowel Syndrome
- Myocardial Infarction
- Pancreatic Cancer
- Pancreatic Pseudocysts
- Viral Hepatitis in Emergency Medicine

Acute pancreatitis needs to be differentiated with the row of acute diseases of organs of abdominal cavity.

Differential Diagnosis of Acute Pancreatitis		
Disease	Characteristics	Findings
Perforated viscus, especially peptic ulcer	Sudden onset of pain that increases over 30-60 min	Intraperitoneal air present
Acute cholecystitis and biliary colic	Epigastric or right upper quadrant pain that radiates to right shoulder or shoulder blade	Liver enzymes often elevated; ultrasonography may show thickened gallbladder, pericholecystic fluid
Intestinal obstruction	Constant colicky pain	Obstructive pattern can be seen on CT scan or abdominal series
Mesenteric vascular occlusion	Classic triad is postprandial abdominal pain, weight loss, and abdominal bruit	Discrepancy between symptoms (severe pain) and examination (benign abdominal examination)
Dissecting aortic aneurysm	Sudden onset; pain may radiate to the lower extremities	
Renal colic	Flank pain radiates to the genitals; dysuria may be present	Urinalysis with active sediment
Myocardial infarction	Upper abdominal or chest pain	Electrocardiography usually abnormal
Connective tissue disorders with vasculitis	Acute pancreatitis can be due to vasculitis	Other signs of vasculitis usually present (skin, joint, eye, and kidney involvement)
Appendicitis	Pain may start in epigastrium or periumbilical then migrate to right lower quadrant	Ultrasonography and and CT aid in diagnosis
Ectopic pregnancy	Sudden onset of pain; menstrual abnormalities often precede pain	Rapid drop in hematocrit and intraperitoneal pelvic fluid on imaging should raise suspicion
Pneumonia	Fever, malaise, and other respiratory symptoms (dyspnea, cough, sputum production, chest pain) usually present	Changes on physical examination of the chest and abnormalities on chest X-ray possibly due to ARDS or pleural effusion

AP = acute pancreatitis; ARDS = acute respiratory distress syndrome; CT = computed tomography; HCT = hematocrit.

Acute mechanical intestinal obstruction. In patients with this pathology pain is of the alternated character and is accompanied by nausea, vomiting, delay of gases and emptying. It is possible to see the Kloyber bowls on the sciagram survey of organs of abdominal cavity.

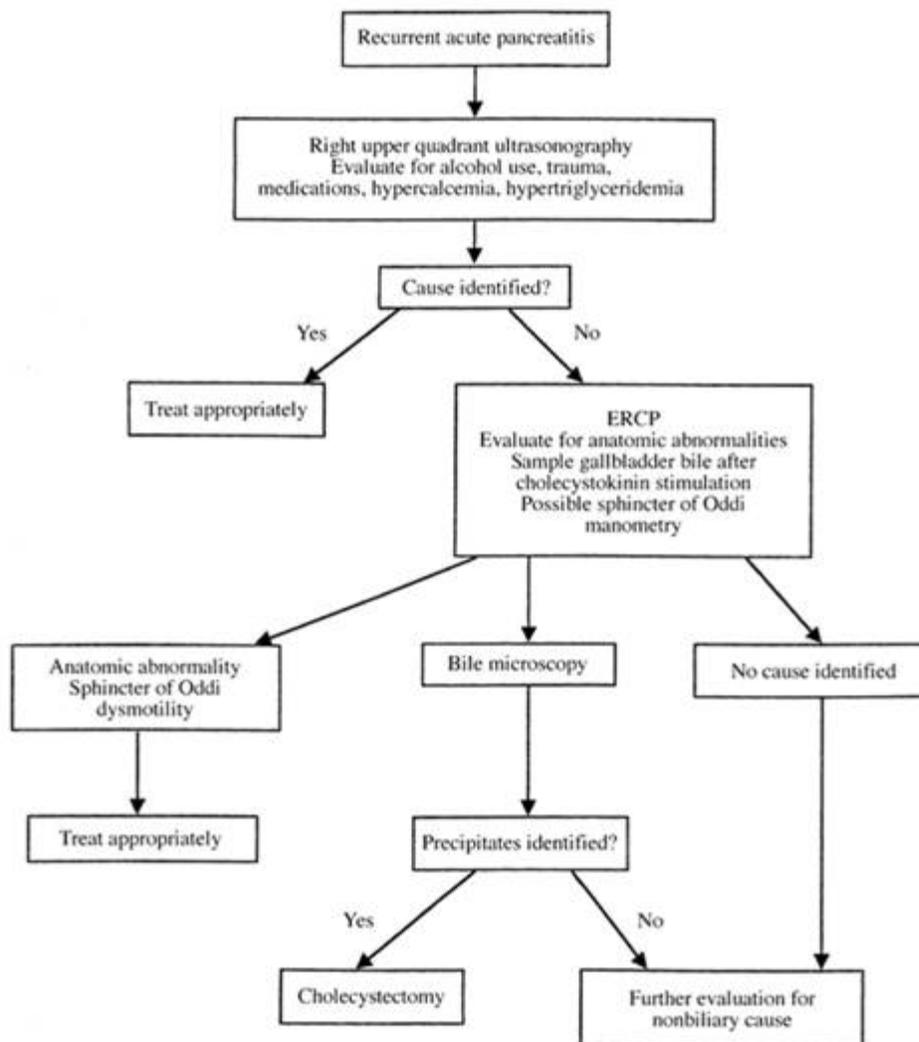

Acute cholecystitis runs with characteristic localization of pain and muscular defense, with presence of increased, painful gall-bladder or infiltrate in right hypochondrium. Often acute (especially lately) pancreatitis develops on the background of gallstone disease (biliary pancreatitis).

Thrombosis or embolism of mesenteric vessels. Both for pancreatitis and for the thrombosis of mesenteric vessels great pain at soft abdomen (absence of defense muscles of front abdominal wall), that precedes to development of peritonitis, is inherent. Yet from the beginning the disease gains heavy character of passing. In anamnesis in such patients a heart disease or heart attack of myocardium rheumatic is met. As a result of gangrene of intestine, the symptoms of peritonitis appear very quickly and intoxication grows. The fragments of mucus shell are found in flushing waters of intestine at the detailed examination, which have the appearance of "meat flushing".

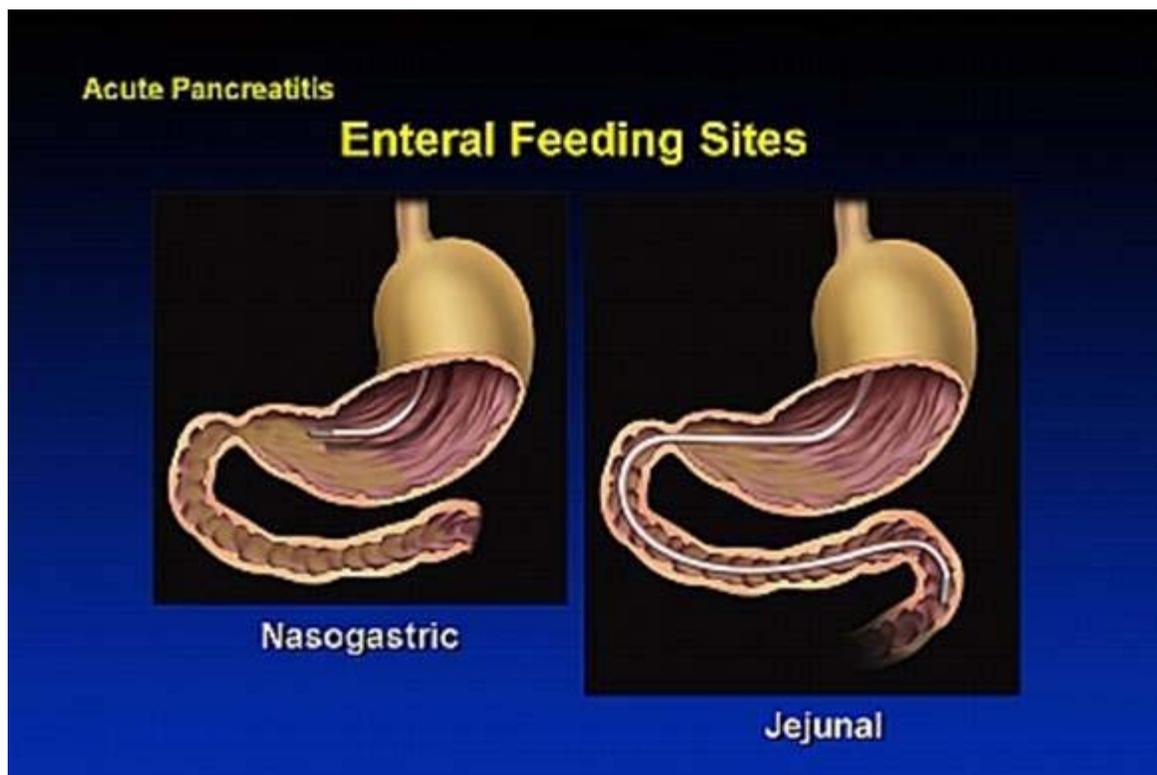

A perforated gastric and duodenum ulcer is distinguished by the presence of dagger pain, defense of abdominal wall, ulcerous anamnesis.

Tactics and choice of treatment method

The conservative method is considered the basic one for treatment of acute pancreatitis, but in connection with that unsuccessful conservative treatment of patients with acute pancreatitis can often put a question about the necessity of operation, therefore patients must be in permanent surgical establishment. Thus acute pancreatitis with heavy passing is necessary to be treated under the conditions of separation of intensive therapy.

Before conservative treatment hunger, bed rest, fight against pain and enzymic toxemia, conducting of acid-base state, prophylaxis of festering infection and acute ulcers of digestive duct are to be entered .

Patient's stomach is washed by cold soda solution and a cold on an epigastric area and left hypochondrium is used. Medicinal therapy is prescribed also: spasmolytics (papaverine, platyphyllin, no-shparum, baralgine, atropine); inhibitor of protease (contrical, trasilol, gordox, antagosan); cytostatic agent (5-fluorouracil, ftorafur). Positive action of inhibitor of protease is marked only in the first days of disease which are subject to conditioned application of large doses. Antibiotics of wide spectrum of action: a) tienam, which most effective in the prophylaxis of festering pancreatitis, as is selected by pancreatic juice; b) cephalosporins (kefzol, cefazoline); c) cefamizine (mefoxine).

Disintoxication therapy is conducted also (5 % but 10 % solutions of glucose, hemodes, reopolyhluquine, polyhluquine, plasma of blood, only from 3 to 5 liters on days, in accordance with a necessity).

For the improvement of rheological properties of blood heparine is prescribed (5 000 ODES every 4 hours).

If patients have the expressed pain syndrome and phenomena of general intoxication during all pain period plus 48 hours (by Bakulev), hunger is used. Such mode lasts on the average of 2–4 days. The parenteral feed of albuminous hydrolyzate is thus

conducted, by the mixtures of amino acid and fatty emulsion. Alkaline water of to 1–2 l. and albuminous-carbohydrate diet are also appointed. Infusion therapy is complemented by plasma, by albumen, hemodes, reopolyhluquine. The improvements of microcirculation in pancreas are achieved due to introduction of reopolyhluquine, komplamine, trental and heparin 5000 ODES 6 times per days under the control the indexes of the coagulation system of blood. Anticholinergic drug (sulfate of atropine, methacin, platyphyllin), H₂-histamin blocker (cimetidine, ranisan, ranitidine, famotidine, omeprazol) are also applied. For the removal of pain: 1) sulfate of the atropine 0,1 % — 1 ml + promedol 2 % — 1 ml + papaverine 2 % — 2 ml + analgin 50 % — 2 ml; 2) isotonic solution of chloride of sodium — 500 ml + baralgin — 5 ml + diphenhydramine hydrochloride 1 % — 1 ml + papaverine 2 % — 2 ml + magnesium the sulfate 25 % — 5 ml + ascorbic acid — 5 ml + lipoic acid 0,5 % — 2 ml + novocaine 0,5 % — 10 ml. are used. From the first days by a nasogastral probe the permanent aspiration of gastric maintenance is conducted also. The Motility function of gastro-intestinal highway gets better at application of cerucal or primperane. With the same purpose forced diuresis (maninil, furosemide, aminophylline) is used on the background of intravenous introduction of plenty of liquid.

At uneffective conservative treatment of patients with acute pancreatitis of middle weight and heavy form it is expedient to apply surgical treatment.

Surgical treatment is carried out for patients with biliary pancreatitis (for a day long from the beginning of disease) in combination with the destructive forms of cholecystitis, at complications of acute pancreatitis by peritonitis, abscess of omentum bag or phlegmon of retroperitoneal cellulose.

Overhead-middle laparotomy, which allows to estimate the state of pancreas, bilious ways and other organs of abdominal cavity, is the best access in this situation. In case of destructive pancreatitis the possible use of lumbar laparotomy from left to right hypochondrium through a mesogastric area is useful.

Cholecystectomy is executed at calculous cholecystitis, phlegmonous inflammation of walls of gall-bladder and biliary pancreatitis. If there are more than 0,9 cm at expansion of choledochus, presence of concrement, ointment-like bile in it, increase of

concentration of bilirubin in the whey of blood over 21 mmol/L, choledocholithotomy is complemented by external draining of choledochus. Information of lithiasis of general bilious duct is absent, cholecystectomy in patients with acute pancreatitis is complemented by external draining of choledochus, better by Pikovskyy method (through stump of cystic duct).

Transduodenal sphincteroplasty is shown at fixed concrement of large duodenal papilla, if they are diagnosed intraoperative, and also in the cases of papillotomy with extraction of concrement when there is no possibility to execute endoscopic operation .

Omentopancreatopexy. After laparotomy and cutting of gastro-colon and gastro-pancreatic ligament mobile part of large omentum through opening in gastro-colon ligament is conducted and fixed by separate stitches to the peritoneum along the overhead and lower edges of pancreas. Such operation needs to be considered rational at the expressed edema of pancreas and presence of necrosis in it.

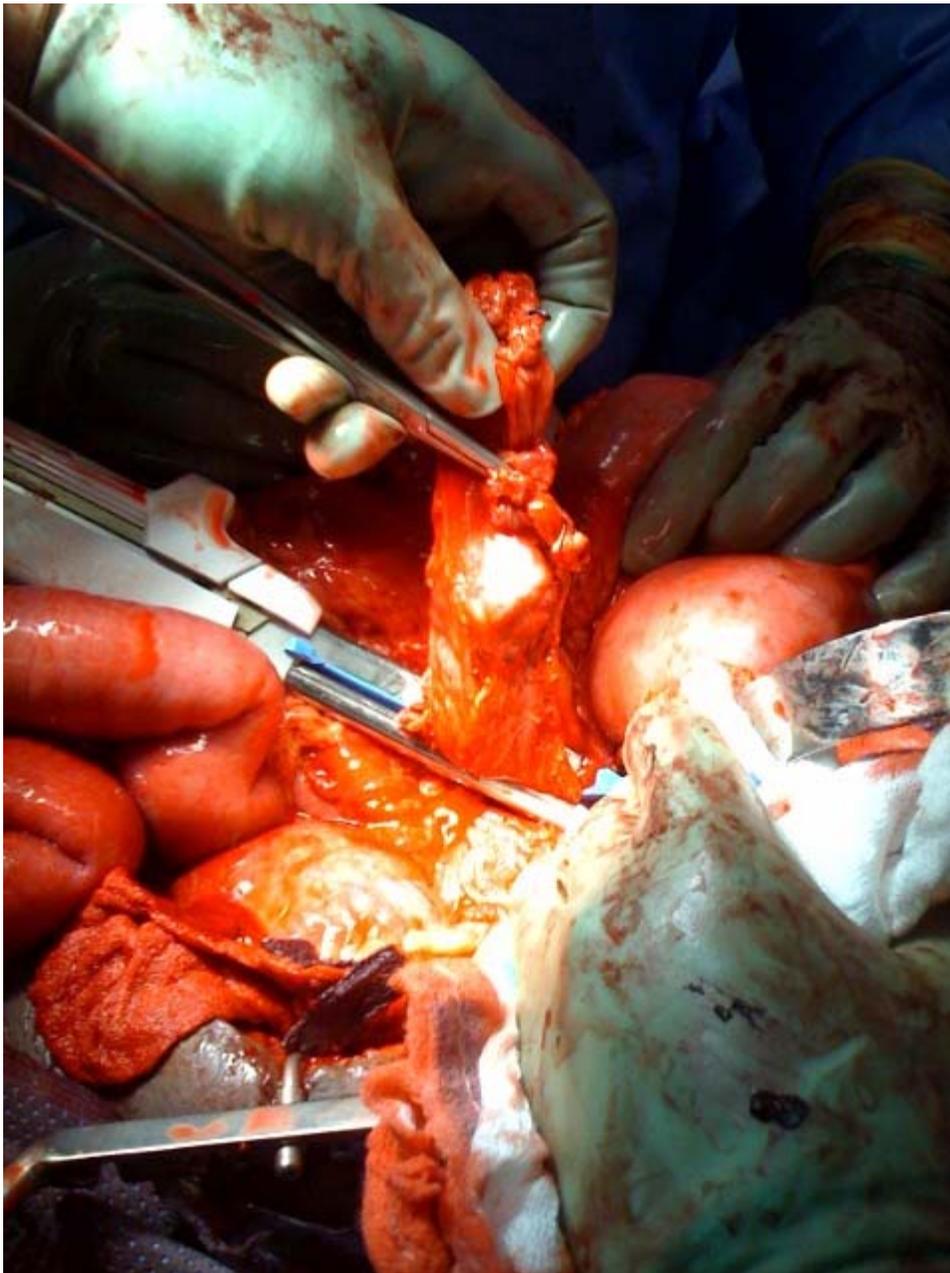

Abdominisation of pancreas. A cellulose round pancreas (along the lower and overhead edges of body and tail) is infiltrated by solution of novocaine, after it parietal peritoneum is cut. Under the body and tail glands free end of omentum is conducted and is bundled by a gland. This operation is able to warn the hit of enzymes and products of disintegration in retroperitoneal space.

Sequestrectomy is deleting of necrosis part of gland within the limits of nonviable tissue. Operation is executed in a dull way.

Necrectomy (deleting of necrosis part of gland within the limits of healthy tissue) is executed by an acute way: tissue of gland is cut on verge of necrosis and bleeding vessels are carefully bandaged.

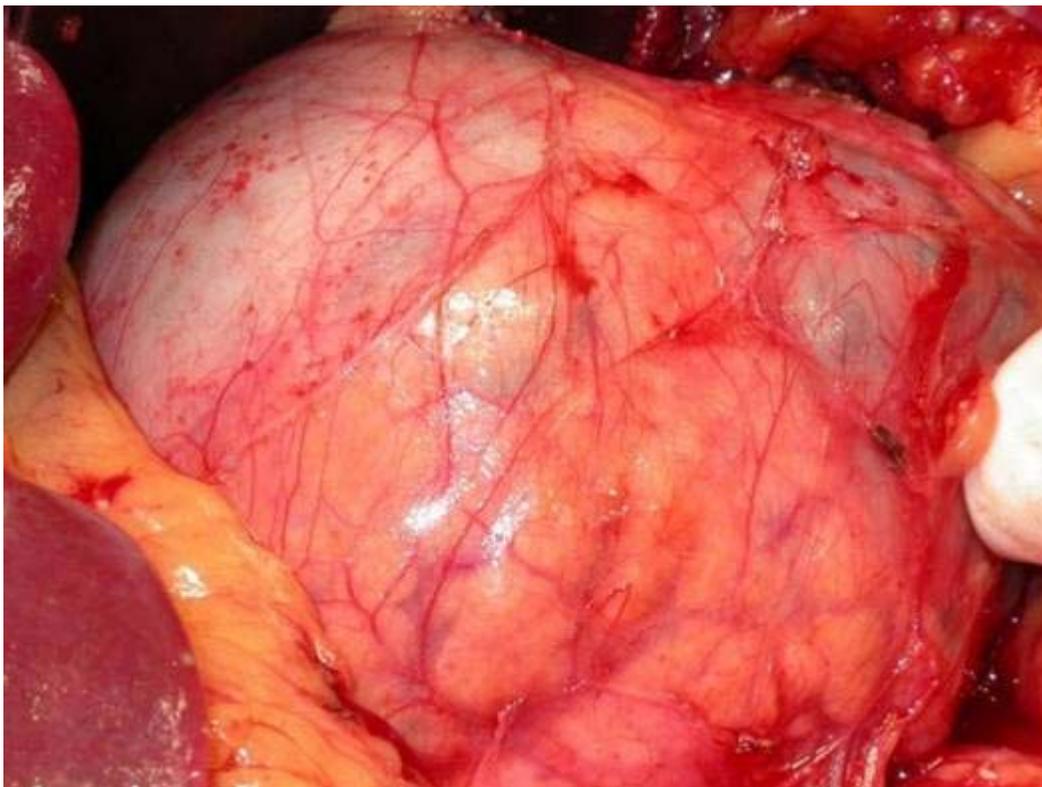

The resection of pancreas is deleting the part of organ with its transversal cutting within the limits of the unchanged (ad oculus) tissue of gland. The resections of tail and body of pancreas are distinguished.

Pancreatectomy is a complete deleting of pancreas. Operative treatment is applied infrequently. After the resection of pancreas adequate draining of its bed is very responsible.

The prognosis of disease depends on character of morphological changes of parapancreatic to the cellulose in pancreas. The more difficult destructive changes, the worst the prognosis.

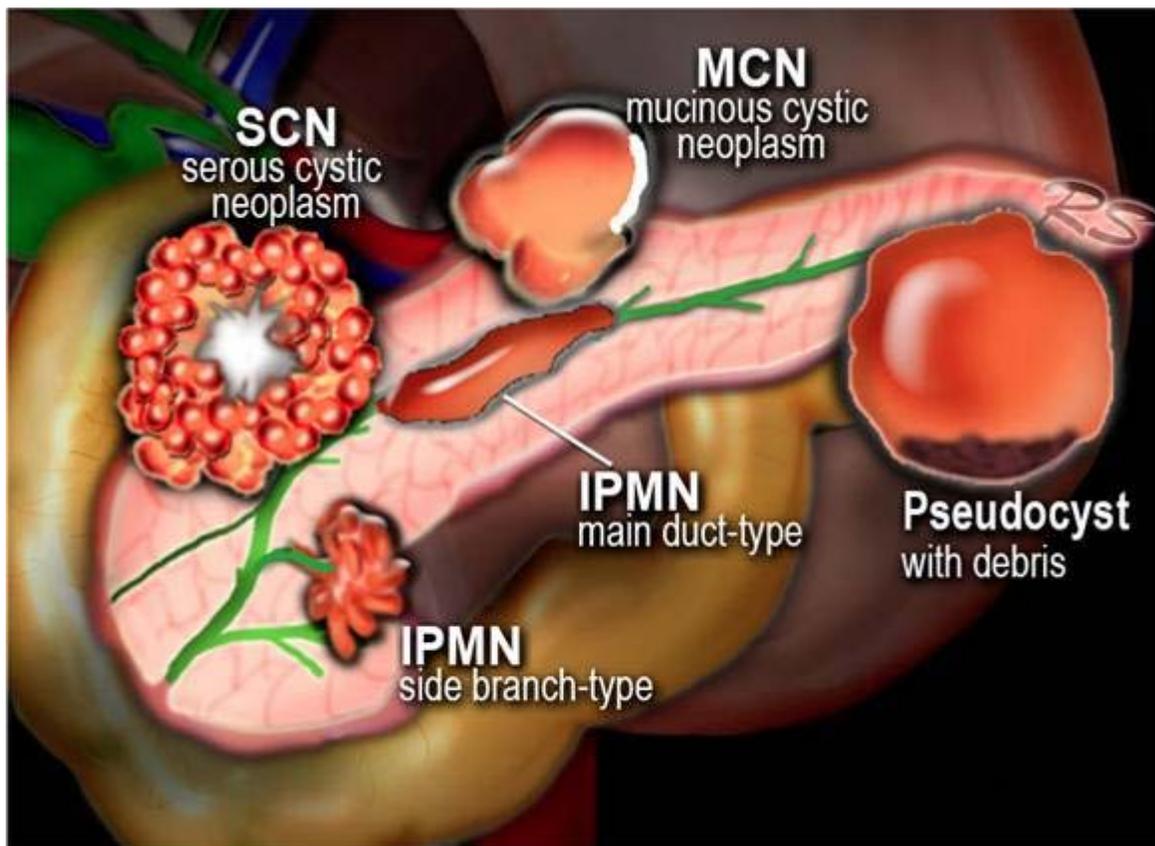

CYSTS OF PANCREAS

Cyst of pancreas is a cavity, filled by liquid (pancreatic juice, exudation, pus), intimately soldered with head, body or tail of organ, is limited by capsule, which has epithelium on internal surface.

Pseudocyst (unreal cyst) is a cavity in pancreas which appears as a result of its destruction, limited by capsule, that does not have epithelium on internal surface.

Etiology and pathogenesis

Acute or chronic pancreatitis or abdominal trauma causes pseudocysts. If no history of pancreatitis or trauma exists, the diagnosis must be carefully confirmed. The reasons of pseudocysts are destructive pancreatitis, traumas of pancreas, oklusion of Wirsung's duct by parasite, concrement, tumors, innate anomalies of development.

To the real cysts belong: innate (dysontogenetic) cysts which are anomalic in development; acquired retention cysts which develop as a result of difficult outflow of pancreatic juice, cystadenoma and cystadenocarcinoma (by mechanism the origins belong more frequently to proliferative, sometimes — degenerative cysts).

The mechanism of development of pseudocysts consists in the focus necrosis of gland, difficult normal outflow of its secret, there is a destruction of walls of pancreatic ducts with overrun of pancreatic juice gland that causes reactive inflammation of peritoneum of surrounding organs which form the walls of pseudocyst.

Pancreatic pseudocysts can be single or multiple. Multiple cysts are more frequently observed in patients with alcoholism, and they can be multiple in about 15% of cases. Size varies from 2-30 cm. About one third of pseudocysts manifest in the head of the gland, and two thirds appear in the tail. The fluid in pseudocysts has been well

characterized as clear or watery, or it can be xanthochromic. The fluid in pseudocysts usually contains very high amounts of amylase, lipase, and trypsin, though the amylase level may decrease over time.

The pathogenesis of pseudocysts seems to stem from disruptions of the pancreatic duct due to pancreatitis and extravasation of enzymatic material. Two thirds of patients with pseudocysts have demonstrable connections to the pancreatic duct. In the other third, an inflammatory reaction is supposed to have sealed the connection so that it is not demonstrable. The cause of pseudocysts parallels the cause of acute pancreatitis; 75-85% of cases are caused by alcohol or gallstone disease-related pancreatitis. In children, pseudocysts and trauma are frequently associated.

Pathomorphology

Morphologically the cysts of pancreas are divided into: pseudocysts retention to the duct are innate, single and multiple.

Pseudocysts are fresh and old. The internal surface of fresh pseudocyst is rough, granulating, grey-red. The table of contents is alkaline, grey or with a brown tint. In an old pseudocyst the wall is smooth and shiny, pale-grey. The table of contents is lighter. Epithelium pseudocysts is absent. More frequently they are met in body and tail of gland and are not connected with ducts.

Retention cysts connected with an obturated duct. The cavity has smooth, grey-white surface, maintenance is transparent, watery or mucous-like. Innate cysts are mainly multiple and shallow. A simple retention cyst differ from those that are always connected with the anomalies of development of ducts and are unite with polycystosis buds and liver.

Rarely there are echinococcus cysts, which have a clear chitinous shell, liquid in cavity and daughter's blisters. They are localized in the area of head of pancreas.

Classification

(by A.N. Bakulev and V.V. Vinogradov, 1952)

I. Innate cysts of pancreas:

1. Dermoid cysts.
2. Teratoid cysts.
3. Innate adenomas.
4. Fibrocystic degeneration.
5. Polycystic degeneration.

II. Inflammatory cysts:

1. Pseudocysts.
2. Retention cysts.

III. Traumatic cysts:

1. As a result of direct damage of gland.
2. As a result of indirect damage of gland.

IV. Parasite cysts:

1. Echinococcosis glands.
2. Cysticercosis glands.

V. Neoplasty cysts:

1. Cyst-adenoma.
2. Cyst-adenocarcinoma.
3. Cavernous hemangioma.
4. Cystic epithelioma.

Pathomorphologyo cysts are divided on:

1. The true cyst.
2. Pseudocysts.

According to clinical passing pseudocysts are divided into acute, subacute and chronic.

According to weight of passing — into simple (uncomplicated) and complicated.

Symptoms and clinical passing

In patients with the cystic damaging of pancreas there can be pain of different character and intensity (dull, permanent, cramp-like and belting). It is localized more frequently in right hypochondrium, epigastric area (cyst of head and body of gland), left hypochondrium (cyst of tail of pancreas). Pain is irradiated in the back, left shoulder-blade, shoulder and spine.

Dyspepsia violations are characteristic. Nausea, vomiting and belch are observed.

The syndrome of functional insufficiency of pancreas shows up by disorders of exocrine and endocrine insufficiency and depends on the degree of damage of organ. The unsteady emptying, replacement of diarrhea of constipation, steatorrhea and creatorrhea, development of the second diabetes are marked.

Compression syndrome. Arises as a result of compression of neighbouring organs. Clinically the compression of organs of gastro-intestinal highway shows up by complete or partial obstruction of general bilious duct (mechanical icterus), vein (portal

hypertension) gate, splenic vein (splenomegaly).

Physical:

- The sensitivity of physical examination findings is limited.
 - Patients very frequently have a tender abdomen.
 - Patients occasionally have a palpable mass in the abdomen.
- Peritoneal signs suggest rupture of the cyst or infection.
- Other possible findings include the following:
 - Fever
 - Scleral icterus
 - Pleural effusion

Diagnosis program

1. Anamnesis.
2. Biochemical blood test (amylase, sugar, bilirubin).
3. Analysis of urine on diastase.
4. Coprograma.
5. Sonography.
6. Contrasting sciagraphy of stomach and duodenum (relaxation duodenography).
7. Retrograde pancreatocholangiography.
8. Computer tomography.

X-ray examination. Shift the stomach to the left

During the examination patients with large cysts are marked by asymmetry of abdomen in epigastric and mesogastric areas. At palpation of abdomen tumular formation of elastic consistency with an even, immobile surface is found.

Abdominal ultrasound: Sonography examination shows echo-free formation with a clear capsule, determines localization and sizes of cyst. While cystic fluid collections in and around the pancreas may be visualized via ultrasound, the technique is limited by the operator's skill, the patient's habitus, and any overlying bowel gas. As such, ultrasound is not the study of choice to establish a diagnosis.

Sonography

Contrasting roentgenologic examination of stomach and duodenum with the sulfate of barium at the cyst of head of pancreas exposes moving of pyloric part of stomach upwards and breeding of „horseshoe” duodenum (at relaxation duodenography in the conditions of low artificial blood pressure). If a cyst is localized in the area of body of gland, displacement of stomach is marked forward and upwards or downward, rapprochement of its walls, moving of duodenal transition and loops of thin bowel downward and to the right; at lateral projection the distance between stomach and spine is increased. The cyst localized in the area of tail of gland, displaces the stomach forward and upwards, to the left or to the right.

Cholecystocholangiography exposes calculous cholecystitis and cholelithiasis.

Retrograde pancreatocholangiography exposes the changed and deformed, infrequently extended pancreatic duct, occasionally there can be filling of cavity of cyst

by the contrasting matter.

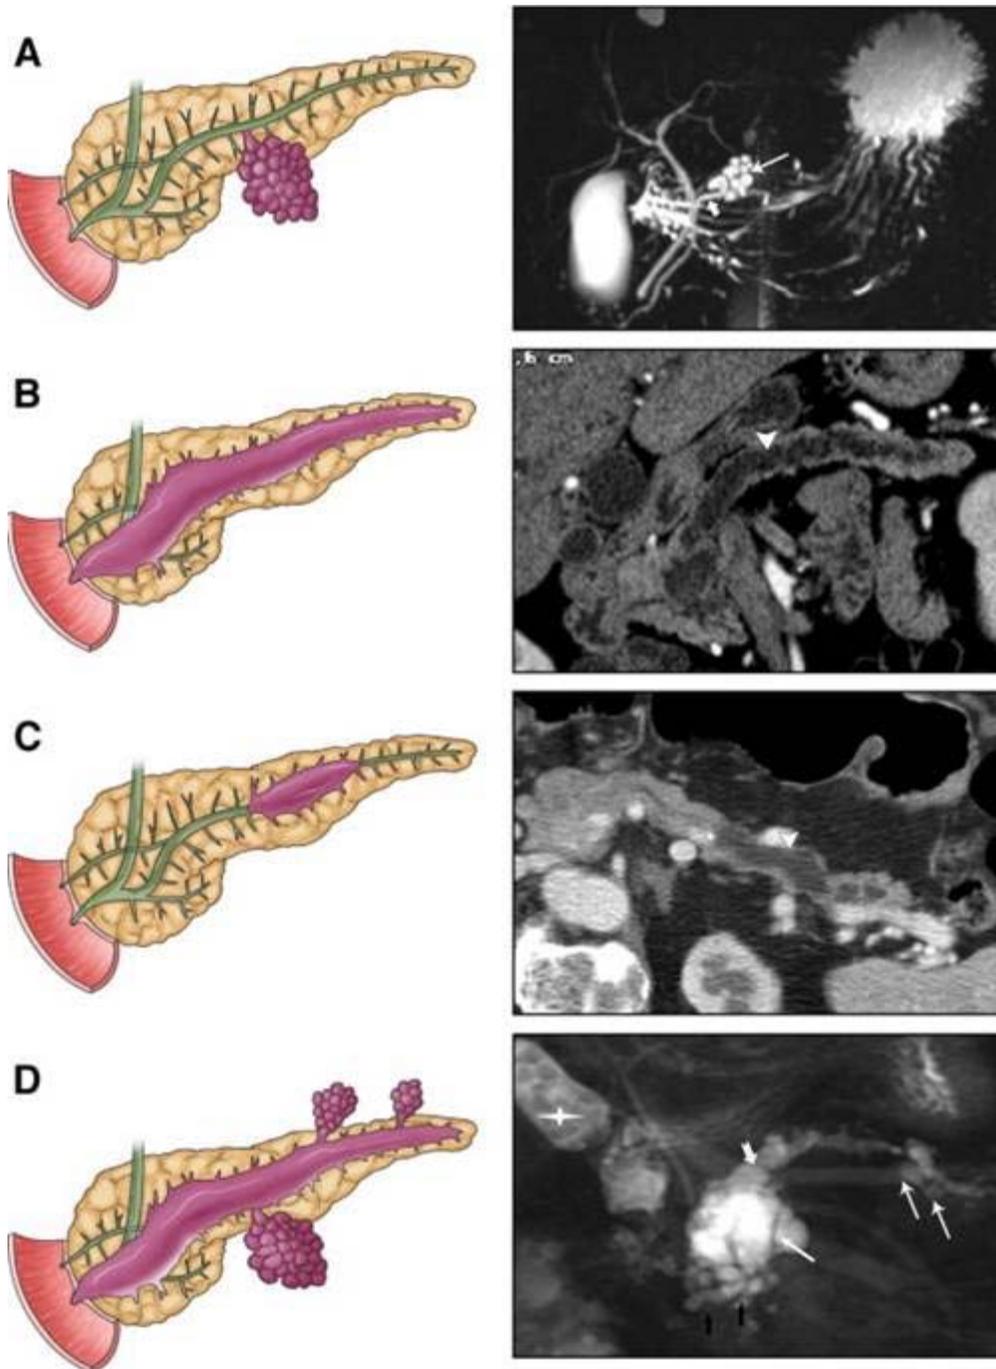

Abdominal CT scan: Computer tomography shows accumulation of liquid limited by the capsule of different closeness and thickness.

CT Scan. Cyst of the pancreas

- CT scan is the imaging criterion standard for pancreatic pseudocysts. It has a sensitivity of 90-100% and is not operator dependent.
- The usual finding on CT scan is a large cyst cavity in and around the pancreas.
- Multiple cysts may be present.
- The pancreas may appear irregular or have calcifications.
- Pseudoaneurysms of the splenic artery, bleeding into a pseudocyst, biliary and enteric obstruction, and other complications may be noted on CT scan.

- The CT scan provides a very good appreciation of the wall thickness of the pseudocyst, which is useful in planning therapy.

Endoscopic retrograde cholangiopancreatography:

- Endoscopic retrograde cholangiopancreatography (ERCP) is not necessary in diagnosing pseudocysts; however, it is useful in planning drainage strategy.
- A study by Neil et al investigated the use of ERCP and the treatment of pseudocysts and acute pancreatitis and reported that a change in management occurred 35% of the time after the ERCP findings in pseudocysts were evaluated. Therefore,

many authors recommend performing an ERCP before contemplated drainage procedures.

MRI:

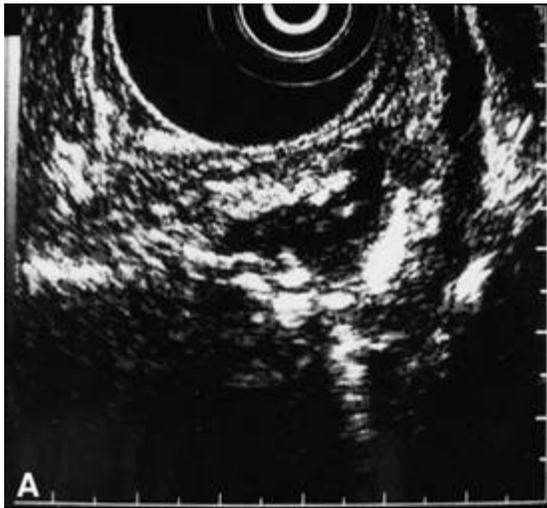

- MRI is not necessary to establish a diagnosis of pseudocysts; however, it is useful in detecting a solid component to the cyst and in differentiating between organized necrosis and a pseudocyst.

- A solid component makes catheter drainage difficult; therefore, in the setting of acute necrotizing pancreatitis with resultant pseudocyst, an MRI may be very important before a planned catheter drainage procedure.

Endoscopic ultrasound:

- Endoscopic ultrasound (EUS) is not necessary to establish a diagnosis but is very important in planning therapy, particularly if endoscopic drainage is contemplated.
- A gastric wall with a thickness greater than 1 cm next to the cyst tends to predict a poor outcome with endoscopic drainage.
- EUS may also be helpful in detecting small portal collaterals from otherwise undetected portal hypertension that may increase bleeding risks with transmural drainage.
- Transmural drainage may be performed only when the symptomatic pseudocyst is positioned next to the gut wall.

Laboratory examinations exposes hyperamylasemia, steatorrhea and creatorrhea, sometimes — hyperglycemia and glycosuria.

Laboratory Studies:

- Serum tests have limited use.
 - Amylase and lipase levels are often elevated but may be within reference ranges.
 - Bilirubin and liver function test (LFT) findings may be elevated if the biliary tree is involved.
- Analysis of the cyst fluid may help differentiate pseudocysts from tumors. Attempt to exclude tumors in any patient who does not have a clear history of pancreatitis.
 - Carcinoembryonic antigen (CEA) and carcinoembryonic antigen-125 (CEA-125) tumor marker levels are low in pseudocysts and elevated in tumors.
 - Fluid viscosity is low in pseudocysts and elevated in tumors.
 - Amylase levels are usually high in pseudocysts and low in tumors.
 - Cytology is occasionally helpful in diagnosing tumors, but a negative result does not exclude tumors.
 - A CEA level of greater than 400 ng/mL within the cyst fluid strongly suggests malignancy.

Clinical passing of cysts of pancreas depends on their kind, localization, size, stage of forming and complications.

Four stages of forming of pseudocyst are distinguished (P.G. Karaguljan, 1972).

I stage (1–1,5 months last) — in the center of inflammatory process the cavity of disintegration, which takes surrounding tissue, appears in an omentum bag.

The II stage (2–3 months) is characterized by the beginning of forming of capsule of pseudocyst. Cyst is magnificent, unformed, acute inflammatory phenomena calms down.

The III stage (3–12 months) is completion of forming of capsule of pseudocyst. Last accretes with surrounding organs.

The IV stage (begins an in year from the origin of cyst) is a separated cyst. The cyst is mobile, easily selected from connections with surrounding organs.

Retention cysts arise at closing of lumen of pancreatic duct (concrement, sclerosis). The internal surface of cyst is covered with epithelium. Pain syndrome, violation of exocrine function of gland are characteristic.

Traumatic cysts belong to the pseudocysts with similar passing and clinic, as well as inflammatory pseudocysts.

Parasite cysts (to echinococcus, cysticercotic) are met as casuistry. In such patients Kaconi test and serological Weinberg's reaction are positive.

The variants of clinical passing of the real and unreal cysts depend on their complications.

Perforation in free abdominal cavity. Clinic of the poured peritonitis is characteristic. Tormina, positive symptoms of irritation of peritoneum, possible shock state as a result of irritation of peritoneum by pancreatic juice arise.

Perforation in stomach, duodenum, small, rarer in large intestine is accompanied by diminishment of cyst in sizes or complete disappearance, sometimes diarrhea appears.

Suppuration of maintenance of cyst is accompanied by pain which becomes more intensive, temperature rises, leucocytosis grows.

The erosive bleeding appears suddenly and is accompanied by the symptoms of internal bleeding (expressed general weakness, dizziness). The pallor of skin and mucus shells, sticky death-damp, tachycardia and anemia are observed.

Mechanical icterus arises as a result of compression of cyst on the terminal part of choledochus. The icterus of skin and mucus shells, acholic excrement, dark urine, hyperbilirubinemia, increase of the ALT and AsT level are exposed.

Portal hypertension develops as a result of compression of portal vein. Ascites, varicose expansion of veins of esophagus and stomach, moderate icterus are diagnosed.

Reactive exudation pleurisy more frequently arises in left pleura cavity, where roentgenologic exudation is diagnosed with high maintenance of amylase.

At malignization the walls of cyst specific symptoms are absent, a diagnosis is set during operation (surgical biopsy of cyst wall).

Differential diagnostics

- Pancreatic Cancer
- Pancreatic Necrosis and Pancreatic Abscess
- Pancreatic Pseudoaneurysm
- Pancreatitis, Acute
- Pancreatitis, Chronic
- von Hippel-Lindau Disease

The cysts of pancreas are differentiated with the tumors of abdominal cavity and of retroperitoneal space.

Cancer of pancreas. For the cancer tumor of pancreas syndrome of “small signs” (discomfort in epigastric area, loss of appetite, general weakness), permanent dull pain, unrelated with the reception and composition of meal, icterus (cancer of head of gland), Courvoisier's symptom (increased, unpainfully gall-bladder) are characteristic. Inconstant pain at cysts of pancreas is more frequently related to faults in a diet; in anamnesis destructive pancreatitis, traumas of gland are carried. Sonography examination, retrograde pancreatocholangiography and computer tomography help in establishment of diagnosis.

Tumors of retroperitoneal space are passed asymptomatic, clinic shows up by a

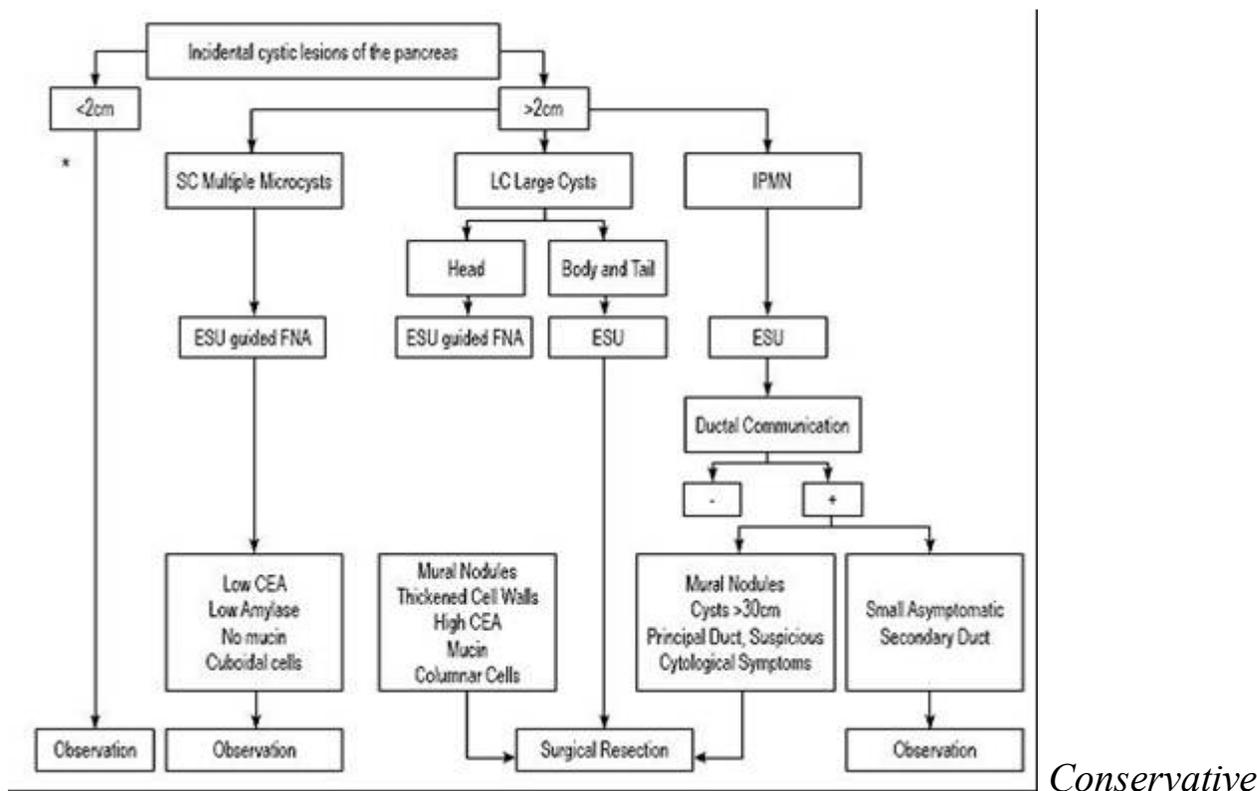

considerable compression on neighbouring organs. Nausea, vomit, chronic intestinal obstruction, dysuric disorders arise. Clinic of cysts of pancreas, on the opposite, are expressed on early stages. Pain, dyspepsia syndromes, syndrome of exocrine and endocrine insufficiency of pancreas are characteristic. Pain is related to the reception of meal and alcohol.

Aneurism of abdominal aorta. Dull, indefinite pain in abdomen which is unrelated with the reception of meal, pulsation and pulsating formation in abdomen are characteristic, auscultatory is systolic murmur. Aortography allows to confirm a diagnosis.

The cyst of mesentery of thin bowel has painless passing, at palpation it is mobile, easily changes position in abdomen. The cysts of pancreas are practically immobile, pain, anamnesis and laboratory information are characteristic.

The cyst of liver has protracted asymptomatic passing. Pain appears at infection of cyst. For this pathology symptoms which take place at the cysts of pancreas are not typical (pain related to the reception of rich food, alcohol, hyperamylasemia). Topic diagnostics is carried out at ultrasonic examination, scintigraphy, computer tomography.

Tactics and choice of treatment method

treatment. Treatment of acute or chronic pancreatitis is conducted in accordance with principles. At the unfavorable dynamics of passing the diseases hunger with the permanent sucking of gastric maintenance, parenteral feed and intravenous introduction of liquids are appointed. Puncture of cysts is used through abdominal wall under sonography control with aspiration of maintenance.

Peripancreatic fluid collections persisting for more than 4 weeks are referred to as acute pseudocysts. Pseudocysts lack an epithelial layer and thus are not considered true cysts. They also differ from true cysts in that they are usually filled with necrotic debris rather than fluid. Accordingly, pseudocysts may be better described by the term organized necrosis.

Surgical treatment is the method of choice of treatment of cysts of pancreas. The choice of treatment method depends on the stage of forming of pancreas cysts.

In selected patients with very large fluid collections, percutaneous aspiration of pancreatic pseudocysts is a reasonable approach. Even though treatment failures are common when the pseudocyst communicates with the pancreatic ductal system, percutaneous drainage serves as a temporizing measure that may later lead to successful endoscopic or surgical intervention. Often, an infected pseudocyst (which by definition is

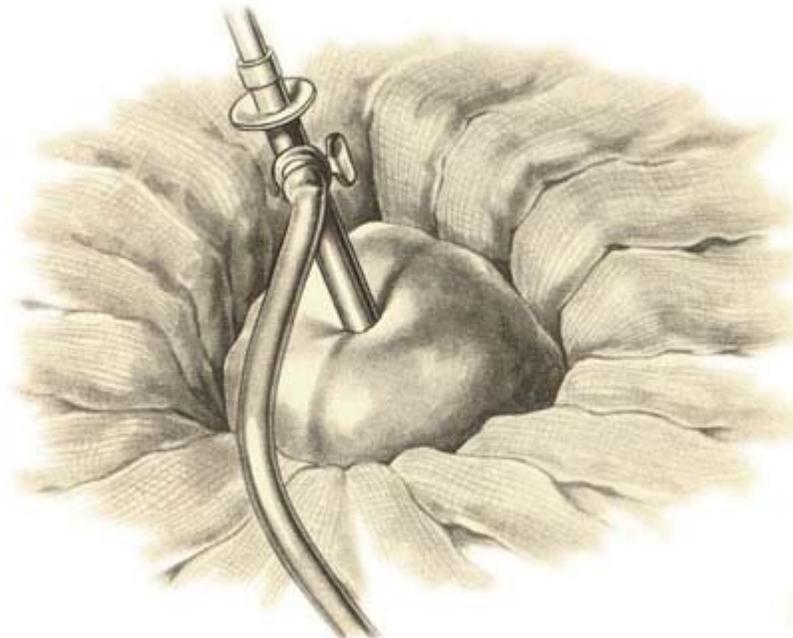

regarded as a pancreatic abscess) can be successfully managed by means of percutaneous drainage.

Pseudocysts may also be managed endoscopically with transpapillary or transmural techniques. Transpapillary drainage requires the main pancreatic duct to communicate with the pseudocyst cavity, ideally in the head or body of the gland. The proximal end of the stent (which should be smaller than the diameter of the pancreatic duct) is placed into the cavity. The technical success rate is 83%, the complication rate 12%. Generally, however, pancreatic stents are difficult to monitor and prone to obstruction and carry an increased risk of infection and ductal injury.

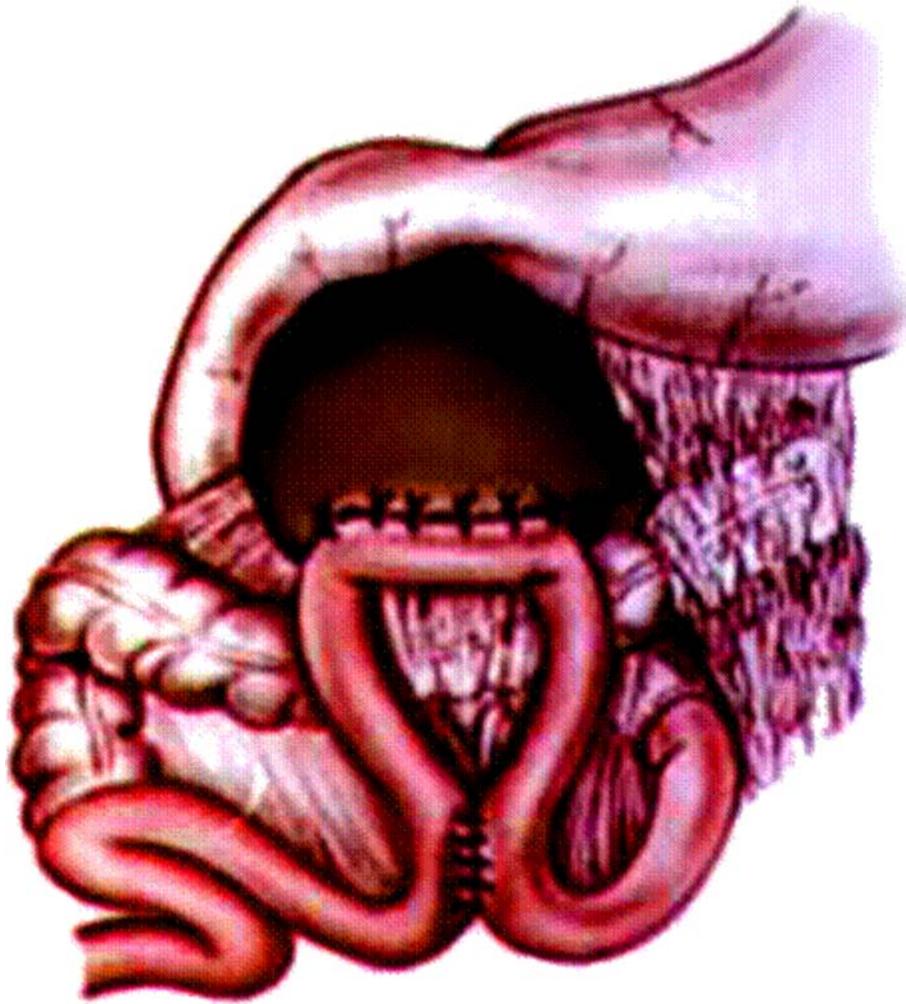

Some noncommunicating pseudocysts may be amenable to transmural enterocystostomy. Technical success requires a mature cyst that bulges into the foregut, and the distance from the lumen to the cyst cavity should be less than 1 cm. The success rate is 85%, the complication rate 17%. The transduodenal approach is associated with fewer complications and recurrences than the transgastric approach.

On the basis of prospective data from the 1970s, surgery was recommended for persistent large (> 7 cm) pancreatic pseudocysts because complications developed in 41% of patients, 13% of whom died. Internal pseudocyst-enteric anastomosis became the standard of care, with an operative mortality of 3-5%. This dogma was subsequently challenged by 2 retrospective studies in which patients with smaller (ie, < 5 cm) asymptomatic pseudocysts rarely ($< 10\%$) developed complications.

On the I stage operation is not used, conservative treatment of pancreatitis is conducted. On the II stage it is used at suppuration of pseudocyst (external draining of cyst). On the III — internal draining of cyst is used.

More frequently cystojejunostomy on the eliminated loop of thin bowel by Roux, cystojejunostomy with entero-entero anastomosis by Brawn and closing of afferent loop by Shalimov. Cystogastrostomy are executed and cystoduodenostomy is now not applied because of possible complications (infection of cyst, erosive bleeding). Marsupialization (opening and sewing down of cyst to the parietal peritoneum and skin) is used infrequently (at suppuration of cyst is seriously patientsing with the septic state). On the IV stage external and internal draining of cyst and radical operations are applied: a) enucleation of cysts (executed very rarely); b) distal resection of pancreas with a cyst.

Cystojejunostomy

Complications:

- Bleeding is the most feared complication and is caused by the erosion of the pseudocyst into a vessel.
 - Consider the possibility of bleeding in any patient who has a sudden increase in abdominal pain coupled with a drop in hematocrit level or a change in vital signs.
 - Therapy is emergent surgery or angiography with embolization of the bleeding vessel.
 - Do not perform a percutaneous or endoscopic drainage procedure under any circumstances in patients with suspected bleeding into a pseudocyst.
- Consider the possibility of infection of the pseudocyst in patients who develop

fever or an elevated WBC count. Treat infection with antibiotics and urgent drainage.

- GI obstruction, manifesting as nausea and vomiting, is an indication for drainage.
- The pseudocyst can also rupture.
 - A controlled rupture into an enteric organ occasionally causes GI bleeding.
 - On rare occasions, a profound rupture into the peritoneal cavity causes peritonitis and death.

METHODICAL INSTRUCTIONS FOR 5th YEAR STUDENTS METHODOLOGICAL INSTRUCTION TO LESSON №9

PORTAL HYPERTENSION, CHRONIC PANCREATITIS

I. AIM. To be able to diagnose, to know symptoms of cirrhosis and portal hypertension, their complications depending on clinical type of the disease. Principles of conservative and surgical treatment. To be able to diagnose, to know symptoms of chronic pancreatitis, cysts and cancer of the pancreas, depending on clinical type of the disease. Principles of conservative and surgical treatment. To be able to diagnose, to know symptoms of euthyroid and toxic goiter, depending on clinical type of the disease, principles of conservative and surgical treatment.

II. Professional orientation of the student.

Hepatic cirrhosis progressing causes dangerous complications. Conservative treatment of these complications is not always effective. The knowledge of surgical treatment principles gives a possibility to correct patient's management, saving his life.

The consequences of chronic pancreatitis, pancreatic cancer are rather resistant to treatment. In-time diagnosing of these diseases and adequate surgical intervention leads to healing or significant improving of patient's state.

Diseases of thyroid gland set the first place in surgical endocrinology. Untimely and not proper choice of the method of treatment frequently causes irreversible consequences appearing, that cause patient's disablement or even are threatening to his life.

Methodology of Practical Class 9.00-12.00.

Algorithm of communicative skills:

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints. Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened.

Student's independent work program:

Theme №1. HEPATIC CIRRHOSIS AND PORTAL HYPERTENSION

1. Anatomical, morphological and functional peculiarities of liver (anatomy, topographical anatomy, anatomical pathology, histology, propaedeutical therapy).
2. Etiology, pathogenesis of hepatic cirrhosis and types of portal hypertension (pathological physiology,

propaedeutical therapy).

3. Estimation of laboratory and x-ray (transumbilical portography, splenoportography, celiacography) data, and also of radionuclide scanning, reography, echography, percutaneous transhepatic cholangioduodenography, laparoscopy, puncture biopsy.
4. Mechanism of hepatoprotectors, blood specimens, protamine sulfate solution action.

Theme №2. CHRONIC PANCREATITIS, CYSTS AND CANCER OF PANCREAS

1. Anatomical, morphological and functional peculiarities of pancreas (anatomy, anatomical pathology, histology).
2. Etiology, pathogenesis and classification of chronic pancreatitis, cysts and cancer of pancreas (pathological physiology, propaedeutical therapy).
3. Estimation of functional, x-ray, endoscopic findings (rhoetgenology).
4. Mechanism of pancreatic proteases inhibitors action.

Break 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.

Basic level of knowledge and skills:

The student must know:

1. Surgical peculiarities of liver blood supply.
2. Etiological factors of hepatic cirrhosis development.
3. Syndromes of hepatic cirrhosis
4. Clinical classification of hepatic cirrhosis (Hawaiian, 1958).
5. Clinical stages of cirrhoses.
6. Classification of portal hypertension.
7. Methods of examination of patients with portal hypertension.
8. Natural portocaval anastomoses (by Tonkov).
9. Complications of portocaval anastomoses.
10. Indications to surgical treatment of portal hypertension.
11. Palliative methods of portal hypertension management.
12. Radical methods of portal hypertension management.
13. Methods of surgical treatment of ascitis at hepatic cirrhosis.
14. Methods of portal system unloading.
15. Methods of treatment of bleeding from esophageal varicose veins.
16. Etiological factors of chronic pancreatitis.
17. Classification of chronic pancreatitis.
18. Clinical manifestations of chronic pancreatitis.
19. Non-invasive x-ray and instrumental methods of examination at chronic pancreatitis.
20. Invasive methods of examination at chronic pancreatitis.
21. Conservative treatment of chronic pancreatitis.
22. Operations on the pancreas and its ducts at chronic pancreatitis.

23. Operations at cholangiogenic pancreatitis.
24. Operations on vegetative nervous system at chronic pancreatitis.
25. Treatment of chronic pancreatitis, caused by the diseases of gastro-intestinal tract.
26. Classification of pancreatic cysts.
27. Clinical symptoms of pancreatic cysts.
28. X-ray signs of pancreatic cysts.
29. Surgical tactics, depending on the stage of pancreatic cysts formation.
30. Palliative operations at pancreatic cysts.
31. Radical operations at pancreatic cysts.
32. Groups of symptoms at pancreatic cancer.
33. Instrumental methods of pancreatic cancer diagnosing.
34. Classification of pancreas cancer (clinical and morphological ones).
35. Palliative and radical operations at cancer of pancreas.

The student has to be able to:

1. Reveal basic clinical signs of hepatic cirrhosis and portal hypertension.
2. Substantiate and formulate the clinical diagnosis.
3. Make differential diagnosis.
4. Substantiate pharmacotherapy, indications and contraindications to surgical treatment.
5. Reveal basic clinical signs of chronic pancreatitis, cysts and cancer of pancreas.
6. Substantiate and formulate the clinical diagnosis.
7. Make differential diagnosis.
8. Substantiate conservative treatment, indications for surgical treatment.
9. Reveal basic clinical signs of euthyreoid and toxic goiter.
10. Substantiate and formulate the clinical diagnosis.
11. Make differential diagnosis.
12. Substantiate conservative treatment, indications for surgical treatment.

Technical means and material provision of lectures (names and numbers of tables, compact discs, instruments quantity, subjectpatients, etc.) –
Multimedia projection of demonstration material (pictures, tables, videofilms) from compact disc “Clinical Surgery”, videofilms with operations.

Test evaluation and situational tasks 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions.

(the instructor has tests & situational tasks)

1. 51-year old patient, has alcohol abuse for a long time, suffers on hepatic cirrhosis. During recent months periodically noticed black stool. Once there was a bloody vomiting. The patient passed treatment courses in gastroenterological department, took syrepar, essentielle, albumin, aminocapronic acid infusions, vicasol, multivitamins. After course of treatment bleeding stopped. After repeated alcohol abuse bleeding has appeared again. Blood analysis data reveal insignificant anemia. Serum bilirubin is on normal level. Liver is insignificantly atrophied in size. Ascites is absent.

Management tactics?

2. 38-year old patient, had severe form of viral hepatitis in young age. During course of treatment hormonal therapy

was used. The patient keeps diet, has no alcohol abuse. During last year periodically notices dull pain in right hypochondrium. Liver is 2-3 sm under costal arch. Serum bilirubin periodically rises up to 28-32 mkmol/l.

Presumptive diagnosis?

Following tactics?

3. 54-years old patient, suffers on frequent attacks of chronic pancreatitis. On intravenous cholangiocholangiography 3 concrements in the distant part of choledochus were found. Whole blood bilirubin is 260 mkmol/l, the level of urine diastase is not increased. During an operation pancreas is dense. By means of supraduodenal choledochotomy only 1 stone was removed; the probe doesn't pass into duodenum.

Surgeon's tactics?

4. During an operation upon stomach cancer, no malignant process was found. The cyst of pancreas body, 15x15 cm in size, that is intimately adhered with back wall of the stomach, mesocolon and mesentery was found.

Surgeon's tactics?

5. 40-years old female patient, is ill with diffuse toxic goiter for 3 years. During all this time she has been undergoing the conservative treatment, in spite of what gradual increasing of thyroid gland up to the IV degree is observed. She mentions body weight loss and progressing of nerve-psycho disorders.

Tactics of treatment?

6. 50-years old patient with diagnosis "Diffuse toxic goiter of IV degree; thyreotoxicosis of severe degree". At the same time, he has chronic pneumonia with signs of lung insufficiency of II degree.

Surgeon's tactics?

ENDEMIC AND SPORADIC GOITER .

DIFFUSE GOITER WITH HYPERTHYROIDISM.

INFLAMMATORY DISEASES OF THYROID GLAND

DISEASES OF MAMMARY GLAND

Endemic goiter is the pathology of thyroid gland, which occurs in biogeochemical regions with iodine deficiency in environment (regional pathology).

Sporadic goiter is the disease of thyroid gland, which occurs in unendemic for goiter regions.

Anatomy(Fig.1;Fig.2;Fig.3.)

Etiology and pathogenesis

Except iodine deficiency, the goitrous endemia is contributed by excessive contents of calcium in environment, deficiency of bromine, poor sanitary and hygienic conditions. Decreased contents of cobalt, manganese, and zinc in environment also influence on expression of goitrous endemia. The lack of iodine in the organism blocks the synthesis of thyroid hormones. It results in hypersecretion of thyroidstimulating hormone of hypophysis, which in turn leads to hypertrophy and hyperplasia of thyroid epithelium that on initial stages can be compensated, but further transformed into the goiter.

The gravity of endemia is assessed by such indexes:

- 1) relationship between men and women with goiter (if it approaches to 1, the endemia is more severe);
- 2) predominance of the nodular form of goiter above its other forms;
- 3) presence of cretinism;
- 4) goiter in animals;
- 5) a number of persons with thyroid hyperplasia.

Sporadic goiter arises from relative iodine deficiency, which results from disturbance of iodine ingestion, liver dysfunction.

Pathology

Macroscopically the goiter is divided onto diffuse, nodular and mixed. According to histological structure distinguished parenchymatous and colloid ones. Sometimes occur cystic transformation of the gland and calcification. The enlarged nodes may result in atrophy of adjacent tissues and organs. So, the advanced forms of goiter can cause compression of trachea and its softening (tracheomalacia). The sings of hyperthyroid transformation of euthyroid goiter include: the transformation of thyroid epithelium from squamous cell into cubic and cylindrical, presence of papillomatous overgrowth, agglomeration of lymphocytes, liquid vacuolated colloid.

Classification

According to the form of enlargement of thyroid gland distinguished:

- 1) diffuse goiter;
- 2) nodular goiter;

3) mixed goiter.

For determining of the degree of goiter used such scale:

0 - the thyroid gland is not palpated;

I - the isthmus of the gland is noticeable during swallowing and could be palpated;

II - entire gland is noticeable during swallowing and could be palpated;

III - the enlargement of gland results in evident thickening of neck ("a thick neck");

IV – the gland considerably enlarged, and sharply deforms neck;

V - the enlargement reaches excessive size (goiter of major sizes).

According to the functional state of thyroid distinguished:

1) euthyroid goiter (normal function);

2) hyperthyroid goiter (excessive function);

3) hypothyroid (reduced function).

Diffuse enlargement of thyroid of I-II degrees without disturbances of function and nodular transformation referred to compensatory hyperplasia of the gland.

According to localization distinguished:

1) typical localization (anterior surface of neck);

2) retrosternal goiter;

3) ectopic goiter (goiter of the base of the tongue, intrathoracic goiter);

4) goiter of additional glands (aberrant goiter);

5) presternal goiter.

Symptomatology and clinical course

In the patients with **endemic euthyroid goiter** the clinical signs are basically caused by mechanical and reflex influence of enlarged thyroid gland on adjacent organs. Patients mainly complain of the presence of "tumour" and neck deformity. Sense of tightness in the neck, difficult breathing, swallowing, and also sudden attacks of cough (owing to compression of laryngeal nerves by goiter) trouble them. In case of great goiter (particularly retrosternal,) periodical dyspnea may develop (especially in the night), up to asphyxia, which is result of compression and inflection of trachea. Retrosternal goiter frequently accompanied with hoarseness, distended veins of face and neck.

The goiter with low thyroid function, as a rule, clinically manifests by general weakness, malaise, sleepiness, hypomnesia, chilliness, dry skin and edemas, particularly around eyes. Sometimes in such patients observed constipation.

The patients with **hyperthyroid goiter** complain of irritability, heartbeat, excessive sweating, and tremor of arms, sleeplessness, feeling of fever. Sometimes observed loss of weight, diarrhea. The thyroid hyperfunction in endemic goiter mainly slightly expressed, and not associated with exophthalmus.

Enlargement of thyroid gland in patients with endemic goiter mostly often has nodular or mixed character, and only in small number of the patients (mainly of younger age) observed diffuse enlargement of thyroid gland.

Nodular goiter is palpated as painless tumour with regular contours, smooth surface, not connected with adjacent tissues and displaced during swallowing. Such goiter is characterized by elastic or dense consistence. Long-term goiter leads to formation of fibrosis and calcification, it becomes solid, and tuberous.

The shape of **diffuse goiter** resembles the butterfly. It retains the contours, its surface is smooth, consistence – mostly elastic, sometimes soft or dense. Mixed goiters combine manifestations of the nodular and diffuse one, however tactically, the mixed goiters refer to nodular group.

The separate nodes or entire goiter can partially or completely be displaced behind breastbone. Palpation of such goiter requires the special devices. The examination is performed when the patient is supine with the bolster under scapulas. During the procedure the patient must force by himself or cough, that causes the emergence of the upper pole or entire goiter above breastbone.

Variants of clinical course and complications

Features of the clinical course of endemic and sporadic goiter caused by its form (nodular, diffuse, mixed), degree of thyroid enlargement, character of functional state (euthyroid, hypothyroid, hyperthyroid), location (typical, retrosternal, ectopic, aberrant goiter), constitutional features of the patient, duration of the disease and character of previous treatment.

Complication: inflammation of the goitrous thyroid gland (strumitis), hemorrhage in the tissue of goiter, asphyxia, malignancy.

The diagnostic program

1. Physical examination of the neck, palpation of thyroid gland(fig.4.).
2. Sonography, computer tomography.
3. Determining of thyroid function (serum hormones, serum iodine, and thyroid-iodine uptake) (Fig.5;Fig.6;Fig.7;Fig.8.).
4. According to indications: X-radiography of the neck (calcification, ossified foci) with barium swallow (compression of esophagus, trachea, their shift, and deformity).

5. Chest X-radiography, particularly of mediastinum, in two plains, pneumomediastinography (intrathoracic goiter).
6. Puncture biopsy(Fig.9.)

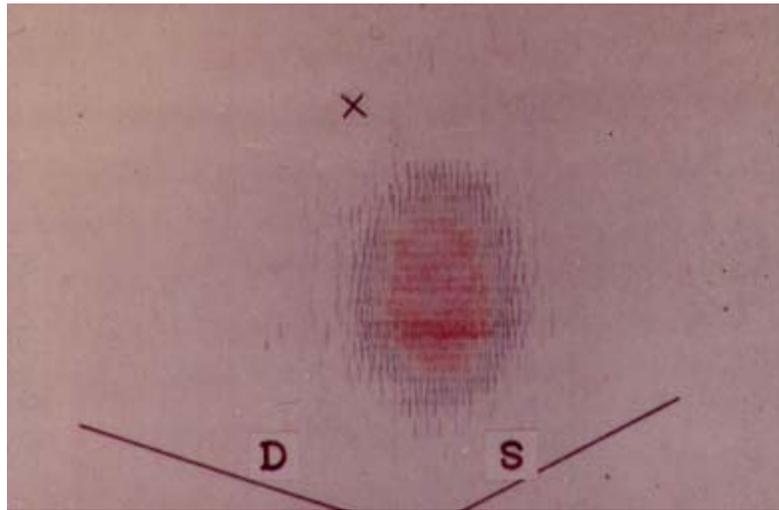

Fig.7. Scanogram of nodular goiter

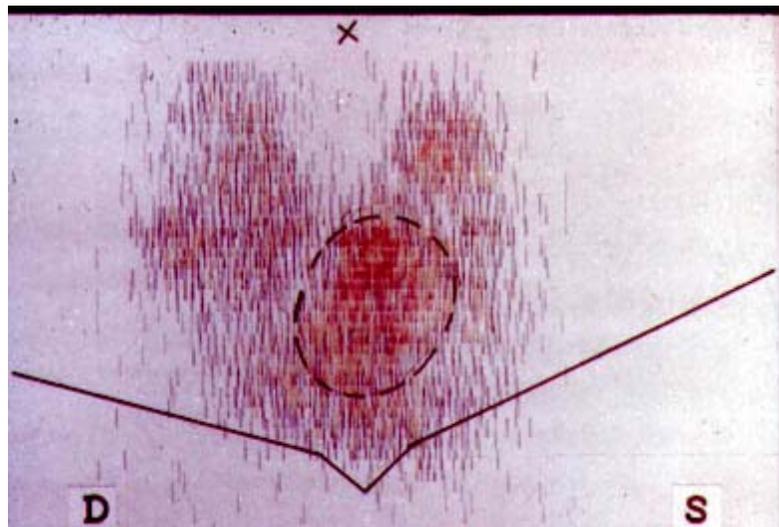

Fig.8. Scanogram of mixed goiter

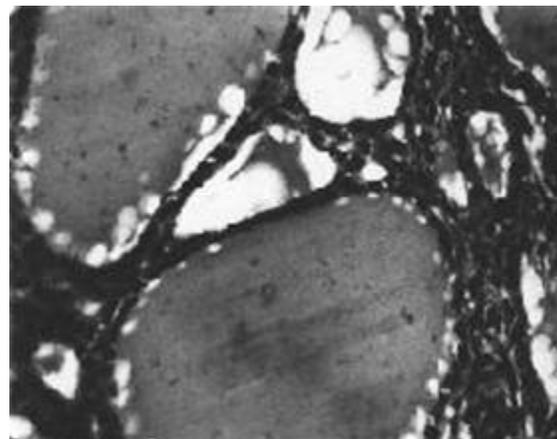

Fig.9. Endemic nontoxic goiter. Macro follicular

goiter with epithelium proliferation.

Differential diagnostics

Endemic and sporadic goiter requires the differential diagnostics with chronic autoimmune thyroiditis (Hashimoto's thyroiditis), Riedel's fibrous thyroiditis, neck cysts, lipomas and other tumours of the neck and mediastinum, malignant neoplasms of thyroid gland, metastases of tumours in cervical lymph nodes.

Hashimoto's thyroiditis is characterized by specific immunological indexes, diffuse density of thyroid, mosaic changes on sonogram and scintiscan, reducing of the goiter in response to prednisolone assay.

In case of **Riedel's goiter** the gland is tuberous, of woody consistency, quite often knitted with adjacent tissues (except skin).

The cysts, tumours of the neck, metastases in lymph nodes are well defined on sonograms, do not displace at swallowing and accumulate radioactive iodine.

The suspicion on **thyroid cancer** makes the necessity to carry out morphological verification by puncture biopsy with further cytological examination.

Tactics and choice of treatment

Endemic goiter is the subject for treatment in all its forms and all stages of the development. The choice of treatment depends on type of the goiter (diffuse, nodular, mixed), degree of enlargement of the thyroid (I-V) and character of complications of the goiter (inflammation, hemorrhage, asphyxia, and malignancy).

Conservative treatment includes the drugs of inorganic iodine, thyroidine and pure hormonal drugs (thyroxine, triiodothyronine). Thyroxine is the most effective one. The iodine drugs less effective and frequently are the cause of secondary hyperthyroidism. The medicament treatment is administered in diffuse thyroid enlargement without signs of compression of neck organs. Polynodular goiter (particularly in elder women) sometimes complicated by malignancy and consequently, even if the signs of compression of neck organs and hyperthyroidism are absent, also treated by conservative agents. The important argument of medicament treatment is their often recurrences after operation.

The **surgical approach** in endemic and sporadic goiter are determined by their spread and character of the lesion. There used the principle that all transformed into the goiter parenchyma should be removed, and healthy – preserved as much as possible.

The nodular and mixed form of the goiter, despite its function and size, is the subject for surgery. The hypothyroidism is not contraindication for operation, as the removal of the goiter results in functional normalization of unaltered, paranodular tissue. The operation, first of all, is indicated if present the signs of compression of neck organs, goiter of the major sizes, secondary hyperthyroidism and suspicion on malignancy. The goiter of additional thyroid glands (aberrant goiter) is the subject for obligatory surgical removal. The operation consists of removal of the aberrant gland with revision of the basic thyroid gland.

The intrathoracic goiter, which develops in retrosternal ectopy of thyroid gland, also requires obligatory

surgical removal(Fig.10.). The best access is the longitudinal sternotomy. The cervical goiter is possible to remove by means of cervical access without the special technical efforts.

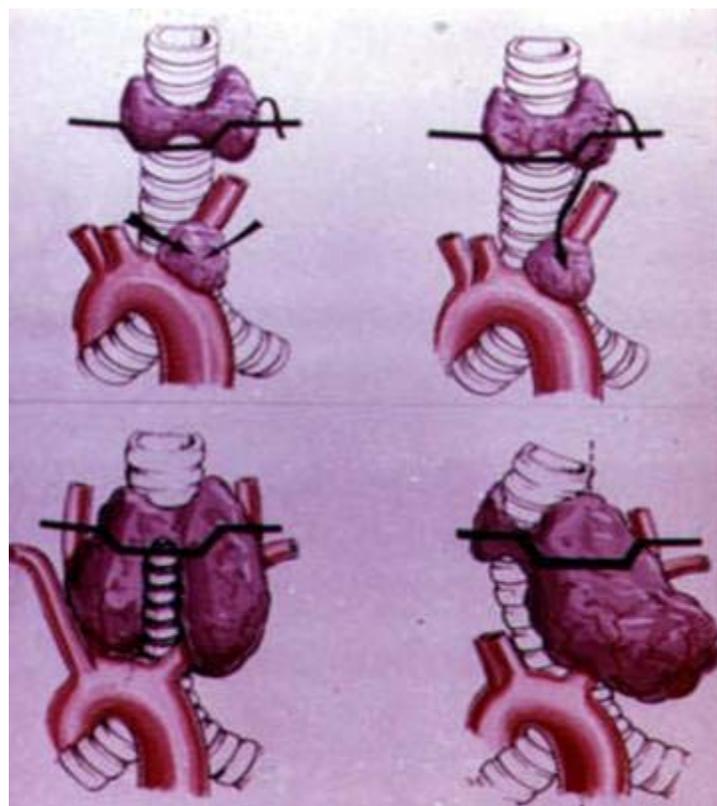

Fig.10. Scheme of goiter formation (retrosternal, intrathoracic)

In tongue ectopy if there are no severe disturbances of speech, swallow and breathe also possible observation and conservative treatment. Progressive growth of the goiter, presence of signs of compression, dysphagia, traumatic bleeding and suspicion on malignancy require the surgical treatment – removal of the goiter mostly through a lateral pharyngeal incision.

The acute disturbance of breathing (asphyxia) requires performance of urgent operation.

The optimal method of anesthesia is the endotracheal narcosis. This method prevents mechanical asphyxia during operation resulting from compression or inflection of trachea at the moment of mobilization and drawing out of the goiter. The method permits to perform careful revision of entire gland and neck spaces, first of all retrosternal, retrotracheal, retroesophageal, where there can be separate thyroid nodes. It is necessary to consider a local anesthesia, and also other methods of general anesthesia as reserve.

For removal of goiter used transversal incision by Kocher in the inferior part of the neck above the sternoclavicular junctions. Operation on thyroid gland must begin from careful revision and intraoperative diagnostics that permits to choose the adequate operative tactics. Trachea must be mobilized by means of isthmus dissection. It permits better orientation in topographic situation caused by the goiter, and to perform tracheostomy at occurrence of asphyxia. Further isthmus and pyramidal lobe must be removed as the most dangerous as for relapse of the goiter.

The volume of thyroid resection in endemic and sporadic goiter is determined individually. The resection is

performed subfascially that prevent the removal of parathyroid glands and trauma of laryngeal nerves. The node is necessary to eliminate together with paranodular tissue, as it is functionally failed. It is justified also by oncologic reasons. The operation of nodular enucleation is considered to be inadequate, thus never used. Meanwhile, in multinodular bilateral goiter, when practically entire thyroid gland is affected, it is necessary to eliminate separate nodes from healthy parenchyma, preserving its maximal amount, as the parenchyma is mainly disposed as lamina on their surface. This layer of parenchyma is necessary to dissect and draw aside by scissors out of node, having preserved its vascularization.(Fig.11-15.)

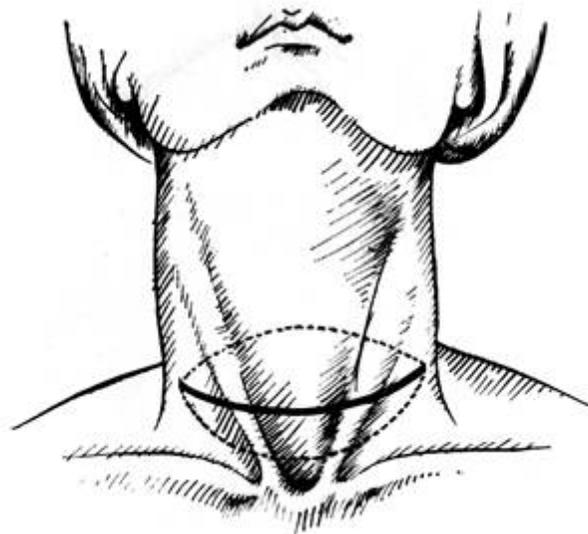

Fig.11. Operative incision

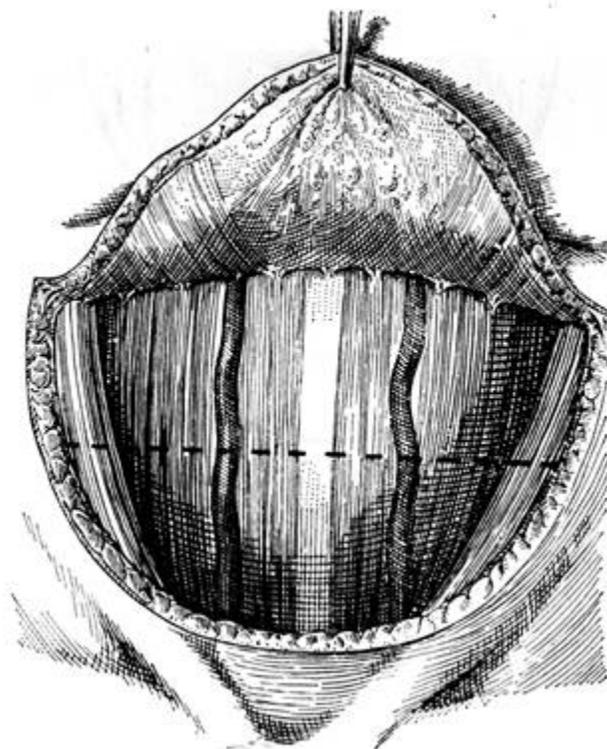

Fig.12. Preparation of upper layers of the skin

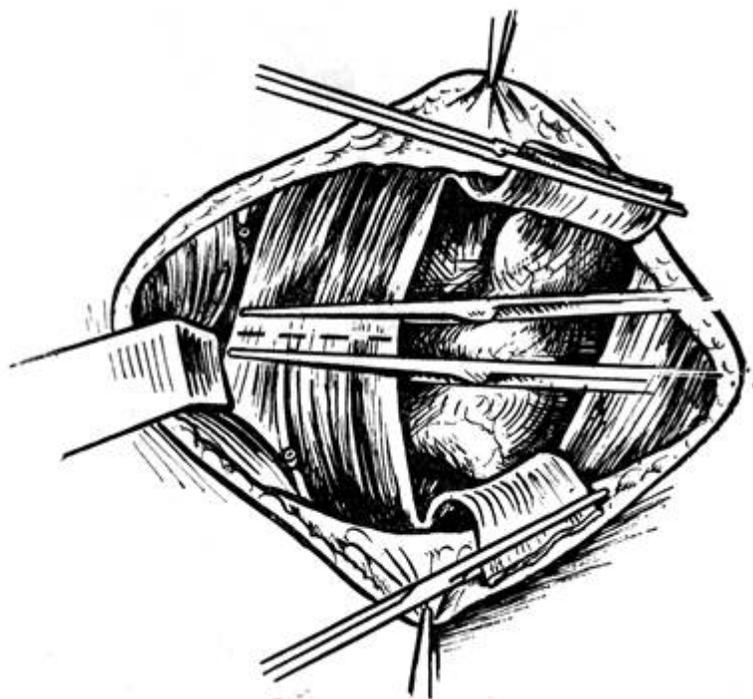

Fig.13. Transversal section of prethyroid muscles

Fig.14. Sutures imposition and closing with thyroid stump

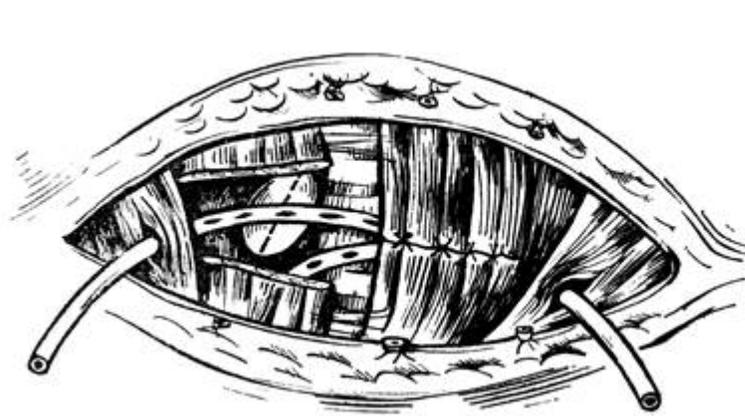

Fig.15.Sutures on prethyroid muscles
and drainage of operative wound

In endemic and sporadic goiter applied saving, extent and subtotal resection of the thyroid with obligatory indication of amount and site of leaving parenchyma.

For oncologic standpoint it is necessary in all cases to carry out intraoperative express cytology of the removed tissue.

For prophylaxis of goiter relapse after the operation necessary long-termed institution of thyroid hormones with the purpose to block thyroid stimulation by pituitary gland.

DIFFUSE GOITER WITH HYPERTHYROIDISM

Diffuse goiter with hyperthyroidism (Grave's or Basedow's disease, thyrotoxicosis, hyperthyroidism) is severe autoimmune and neuroendocrine disease resulting from excessive secretion of thyroid hormones by diffuse-enlarged thyroid gland with lesion of all organs and systems of the body.

The diffuse goiter with hyperthyroidism (thyrotoxicosis) mostly occurs at women. In 5 % of persons with hyperthyroidism develop ophthalmopathy and pretibial myxedema.

Etiology and pathogenesis

The scientific investigation and clinical examination testify that the diffuse goiter with hyperthyroidism is autoimmune disease. This disease is commonly results from infections, intoxication, craniocerebral injury, dysfunction of other endocrine glands, first of all genital, acute and chronic mental disorder, sunstroke. The disease develops under the influence of these factors directly on generically predisposed to thyrotoxicosis organism.

Pathology

The thyroid gland is 2-5 times enlarged, moderately dense, on incision pulpy, sanguineous, of grey-pink color. Histologically revealed a polymorphism of follicles. Follicular epithelium is cylindrical with papillomatous growths. The colloid is eosinophilic, contains plenty of resorptive vacuoles. In interstitial space – lot of lymphocytes, which form follicles. The severe form of thyrotoxicosis results in thyrotoxic heart, thyrotoxic liver cirrhosis, thyrotoxic ophthalmopathy, osteoporosis, and cachexia.

Classification

According to the clinical course distinguished mild, moderate and severe forms of the disease.

According to Milk's classification, there are four stages of hyperthyroidism.

I stage – neurotic, onset of thyrotoxicosis, slight enlargement of thyroid gland.

II stage – neurohormone, marked sings of thyrotoxicosis, the thyroid is noticeably enlarged in size.

III stage – visceropathic, is characterized by a thyrotoxic lesion of viscera.

IV stage – cachectic, is characterized by nonreversible dystrophy of organs and systems.

Symptomatology and clinical course

A diffuse toxic goiter affects practically all organs and systems and disturbs all types of metabolism. Except described in 1842 by Basedow classical triad (goiter, tachycardia and eye bulging), today is known about 70 signs, proper for thyrotoxicosis, which can be combined in three basic syndromes: hyperthyroidism, eye signs (ophthalmopathy) and lesion of skin (pretibial myxedema). By the may, the hyperthyroidism is the permanent phenomenon, and ophthalmopathy and pretibial myxedema occurs rather seldom (in 1-5 % of patients).

To initial sings of thyrotoxicosis can be regarded: general weakness, prompt fatigability, decreased work ability and muscular force, nervousness, irritability, sleeplessness, sweating and hyperemia of skin.

The basic signs of thyrotoxicosis are enlargement of thyroid gland (goiter), palpitation, exophthalmos, tremor and progressing loss of weight. (Fig. 16)

Fig.16. Thyrotoxicosis

The thyroid gland in the patients with thyrotoxicosis is diffuse enlarged and of moderate density. In some of them due to excessive blood supply it can pulsate. After long treatment by iodine the gland becomes dense and painless. Such long-term conservative treatment causes the development of sclerotic degenerative processes, sometimes with nodular transformation of the tissue, and the degree of thyroid enlargement frequently does not relate to the gravity of thyrotoxicosis.

Secretory activity of thyroid hyperplasia in the form of excessive releasing of its hormones (triiodothyronine and thyroxine) underlies the hyperthyroidism. The majority of effects of thyroid hyperfunction manifest through sympathetic nervous system: palpitation, tremor of fingers, tongue, and whole body (sign of "telegraphpole"), sweating. In the patients with thyrotoxicosis the protein, carbohydrate and lipid metabolism is elevated, which manifests by simultaneous excessive appetite and loss of weight.

The changes, which develop in organs of cardiovascular system and manifests by tachycardia, high systolic and low diastolic pressure, increase of pulse pressure and complete arrhythmia with the development of heart failure form a syndrome of thyrotoxic heart.

The excessive formation of heat owing to intensive metabolism, which results from the influence of thyroid hormones, leads to hyperthermal syndrome (feeling of fever, high body temperature). The signs of nervous dysfunction include irritability, anxiety, fear sensation, nervousness, sleeplessness, hyperactive tendon reflexes. The dysfunction of genitals manifests by oligo- or amenorrhea, and in the men by gynecomastia, which is the outcome of disturbed relation between estrogens and androgens. Thereafter libido and potency are reduced.

The thyrotoxicosis without treatment results in loss of weight, in advanced cases not only the subcutaneous fat disappears, but also a muscular tissue reduced, down to cachexia. Degenerative changes in muscles, and lesion of peripheral nervous system result in thyrotoxic myopathy.

In majority of patients develop characteristic eye signs. The predominant one is the exophthalmos. By the way, eye bulging, which occurs in 50 % of cases, frequently can be the initial manifestation of the disease, assigned by patient. Three types exophthalmos are distinguished: slight (14-17 mm), moderate (17-20 mm) and considerable (more than 20 mm). The exophthalmos in thyrotoxicosis is symmetric, the eye trophic and movements of does not disturbed. Except exophthalmos, there are lot of other eye signs observed in the patients with thyrotoxicosis.

- Graefe's sign – the upper lid lag when the patient looks downward;
- Stellwag's sign – infrequent winking;
- Mebius' sign – a weakness of convergence;
- Dalrymple's sign - wide palpebral fissure;
- Kocher's sign – retraction of the upper eyelid at prompt change of view.

The eye signs of diffuse toxic goiter are necessary to differentiate from ophthalmopathy (malignant exophthalmos), which observed approximately in 5 % of the patients with thyrotoxicosis. Such exophthalmos simultaneously associated with pain in the eyeballs, gritty sensation and eyewatering. Also detected lid edema, ocular injection. In considerable ophthalmopathy the eyeballs bulge from orbits, eyelids and conjunctiva are swollen, with signs of inflammation. It can result in keratitis with corneal ulceration, which finally can lead to blindness. The high orbital pressure caused by lymphoid infiltration, accumulation of fluid and edema of retroorbital tissues result in not only eye bulging – exophthalmoses, but also compression of optic nerve and loss of sight. It is necessary also to specify that the ophthalmopathy in thyrotoxicosis, as a rule, develops on the background of encephalopathy and has an autoimmune genesis. (Fig.17.)

Fig.17. Exophthalmoses

Pretibial myxedema arises on the anterior surface of lower legs. The skin becomes dense, thickened, of purple-red color, and hair follicles jut out of its surface.

Thyroid hypersecretion also negatively influences on the liver parenchyma. In severe cases it can result in toxic hepatitis, jaundice and further hepatargy. It is necessary to consider the toxic hepatitis in such patients unfavorable as for prognosis.

Under the direct cytotoxic influence of thyroid hormones on intestinal mucosa suppressed its enzymatic function that leads to intestinal hyperkinesis and osmotic diarrhea – thyrotoxic enteric syndrome. It is accompanied by gluco- and mineralocorticoid dysfunction of suprarenal gland, and leukopenia, granulocytosis and lymphocytosis in blood.

Variants of clinical course and complications

In clinical course of thyrotoxicosis distinguished the mild, moderate and severe forms.

The **mild form** of thyrotoxicosis is characterized by following signs: pulse 100 beat/min, loss of weight approximately 3-5 kg, slight sweating, eye signs absent or slightly expressed, normal arterial pressure, basal metabolism to +30 %, elevated thyroid-iodine uptake, and the maximum of iodine accumulation, which exceeds 30 % is detected after 24 hours.

The **moderate gravity** of the disease manifests by expressed symptomatology: loss of weight to 8-10 kg, tachycardia 101-120 beat/min, systolic pressure is elevated, and diastolic – decreased or normal. Frequently

observed exophthalmos, basal metabolism +31-50 %, thyroid-iodine uptake has been excessive since first hours.

The **severe form** of thyrotoxicosis is characterized by the sharply expressed symptomatology, which is caused by considerable visceral dysfunction. The pulse rate in such patients exceeds 120 per minute, and complete arrhythmia develops. Tremor and profuse sweating sharply expressed, pulse pressure considerably elevated circulatory failure and ophthalmopathy frequently observed. The loss of weight can overtop 10 kg, basal metabolism more than +50 %, the maximum of radioactive iodine accumulation detected in 4-6 hours after taking of isotope, and decreasing of accumulation curve exceed 24 hours.

According to the clinical course two forms of thyrotoxicosis distinguished: a) thyrotoxicosis with slow development; б) acute form of diffuse toxic goiter, which is characterized by an acute onset and prompt, sometimes within several hours, development. The acute thyrotoxicosis seldom occurs and in most cases ends lethally from thyrotoxic coma.

The clinics of acute thyrotoxicosis develop within some hours or days. Thus the thyroid gland is not enlarged, high temperature, vomiting, diarrhea, sharp loss of weight are observed.

The special forms of thyrotoxicosis include the thyrotoxicosis in childhood, in pregnant, in climacteric women, and people of the elderly age.

Among complications during the course of disease the most dangerous for the life is thyroid storm. It is observed in 0,02-0,05 % of the patients and develops, mainly, as the outcome of the lesion of provoking factor. Among them considered trauma (surgical intervention on thyroid gland or other organs), harsh palpation of the gland, mental trauma, emotional stress, infections, pregnancy, labors and radioiodine therapy.

The diagnostic program

1. Clinical examination, examination, palpation, auscultation of thyroid gland.
2. Detecting of basal metabolism, serum lipids, ECG.
3. Detecting of thyroid hormone concentration (common free thyroxine – T₄, common free triiodothyronine – T₃), serum iodine-binding globulin, serum thyroidstimulating hormone of hypophysis.
4. Determining of thyroidstimulating antibodies – immunoglobulins, antithyroid antibodies.
5. Sonography of thyroid gland.

Differential diagnostics

The manifestation of initial, vague and slightly expressed forms of thyrotoxicosis can resemble neuroses, rheumatic disease, tuberculosis, chroniosepsis, postcastrate syndrome, diencephalic lesions, and also malignant tumours. It particularly concerns those cases, when the enlargement of thyroid gland is slight or it is failed to detect.

All the mentioned diseases are characterized by palpitation, heart pain excessive sweating, subfebrile fever and loss of weight.

The acute development of thyrotoxicosis sometimes makes the necessity to rule out such acute infectious diseases, as dysentery, influenza or camp-fever.

The thyrotoxicosis with exophthalmos is necessary to differentiate with encephalitis, ophthalmopathy. Encephalitic exophthalmos is characterized by combination of looking upward paresis with diplopia, corneal ulceration, conjunctivitis, progressing, so-called malignant exophthalmos, which rather frequently can result in loss of eye. By the way, this type of exophthalmos is commonly unilateral.

Laboratory tests are important for differential diagnostics of thyrotoxicosis: detecting of thyroid hormones, serum protein-bounded iodine, thyroid-iodine uptake, biochemical, immunological investigations, sonography and scanning with the radioiodine or technetium.

In particularly severe cases it is advisable to apply trial antithyroid therapy.

Tactics and choice of treatment

The thyrotoxicosis revealed for the first time, and also its severe and moderate forms require institutional treatment. Three methods of treatment of thyrotoxicosis are commonly employed: a) antithyroid drugs; b) treatment by radioactive iodine; c) surgery.

The **antithyroid drug therapy** of the patients with thyrotoxicosis, first of all, should be directed to ameliorate hyperthyroidism. This is gained by the usage of iodine and thyrostatic agents, particularly mercasolil – synthetic antithyroid drug. In severe cases the treatment begins from 45-60 mg (9-12 tablets) per day, in the moderate form – from 30 mg (6 tablets), in mild – from 15 mg (3 tablets) per day. The maximal initial dose ordered within 2-4 weeks to gain expressed clinical relief of the disease (decrease of irritability, normalization of pulse rate, increase of weight). After that, if the state of the patient gradually improves, the dosage is reduced every 3-4 weeks by 1-2 tablets per day to supportive dose (1 or 1/2 tablets per day during 2-3 months). Commonly, the course of the treatment by mercasolil should be lasted for 1-1,5 years. Among complications, which can arise during the treatment, it is necessary to mention leukopenia, agranulocytosis and allergy.

In case of allergic response to mercasolil or development of complications used a reserve drug – lithium carbonate.

Such long conservative treatment of thyrotoxicosis is desirable in those patients, who gained euthyroidism in 1-3 months, that is the gradual reduce of goiter and eye signs. If during the treatment periodically exacerbation occurs, which manifests by thyroid enlargement, development of encephalopathy, activation of ophthalmopathy the surgery is indicated.

More recent studies showed that the **treatment by radioactive iodine** is a radical method of therapy of thyrotoxicosis. The radioactive iodine, which deposits in thyroid gland, irradiating its parenchyma, results in destruction of the active thyrocytes with their further replacement by connective tissue (bloodless thyroidectomy). The standard dosage is 0,1 mCi per gram of thyroid tissue, and it can be introduced at one time or partly.

Nevertheless such therapy has series of essential drawbacks. The lack of precise methods of determining the

weight of the gland results in miscalculations at selection of total dose of the isotope. It is also impossible to exclude the harmful influence of the isotope on the genetic kettle of the patient. Almost in 70 % of the patients the hypothyroidism develops after the treatment by radioactive iodine and there is a potential threat of the development of radioactive thyroid cancer. That's why the indication for application of this method rather restricted.

The treatment by radioactive iodine is commonly indicated for the patients with thyrotoxicosis after 40, with recurrent thyrotoxicosis, and after operations particularly, in combination with severe concomitant diseases and in case of refuse of surgery. It is not justified at young age, pregnancy and during lactation, thyrotoxic multinodular adenoma, expressed leukopenia, and kidney dysfunction or at severe acute thyrotoxicosis.

Sometimes introduction of radioactive iodine can cause the exacerbation of thyrotoxicosis, up to the development of thyroid storm. Thus, before administration of the radioactive iodine, particularly in patient with severe form of thyrotoxicosis in order to relieve thyrotoxicosis it is necessary to institute antithyroid drugs.

The **surgical method of treatment** is considered to be radical and the most effective. The operation almost always allows to liquidate the manifestations of hyperthyroidism together with its morphological base. The efficiency of this method in the specialized clinics reaches 95-97 %.

The indications for surgery include thyrotoxicosis of moderate gravity when the conservative treatment is inefficient during 2-3 months, severe forms of thyrotoxicosis, goiter of IV-V degree despite the gravity of thyrotoxicosis, and also nodular transformation of toxic goiter.

The surgical method is not recommended for the patients with thyrotoxicosis with severe concomitant diseases and dysfunction of vital systems.

The obligatory requirement of successful surgery of the patients with thyrotoxicosis is the careful **preoperative preparation**, which goal is the liquidation or decreasing of hyperthyroidism, that achievement of euthyroid state. Preoperative preparation should be complex, pathogenically proved and individual.

The appropriate place in preoperative period should possess psychological preparation. The patients stay in chambers together with patients recovering after operation. In severe form of thyrotoxicosis a strict bed regime is ordered. The diet should be high-caloric, rich with proteins, vitamins. The patient must take antithyroid drugs under the control of general blood analysis. To prevent leukopenia and agranulocytosis instituted leukopoetic agents. Besides antithyroid therapy, are advisable reserpin that characterized by hypotensive, sedative and antithyroid activity, beta-blockers and tranquilizers for decreasing stimulation of CNS.

In severe form of thyrotoxicosis, at presence of hypoproteinemia is advisable the intravenous infusion of protein substitute solutions (albumin, protein, plasma). With the purpose of detoxycation applied neohaemodes, neocompensan. For exhausted patients beside high-caloric diet applied parenteral infusion of glucose, intralipid, amino acids and vitamins, particularly of B-group. The patient with sings of heart failure simultaneously should take cardiac glycosides and other cardiac agents. One of the measures in preoperative preparation is the regulation of reduced function of suprarenal glands. Glycocorticoids (hydrocortisone etc.) administered in daily dosage of 25-50 mg 2-3 times per day during 3-4 days before the operation and 2-3 days after it. Preoperative preparation should also include regulation of hemostatic dysfunction (vicasol, aethamsylat, dicynon, inhibitors of proteases).

The preoperative preparation is considered to be sufficient, if the state of the patient is regarded to euthyroid or approximate to it. It is testified by normalization of pulse (90-80 per minute), increase of weight on 3-5 kg, liquidation of nervousness and irritability, disappearance of tremor, regulation of function of cardiovascular

system, liver, suprarenal glands, CNS and basal metabolism.

Anesthesia. The method of choice is endotracheal narcosis.

Operation. The most effective and rational surgery approach for thyrotoxicosis is the subtotal subfascial resection of the thyroid (O.V.Nickolayev, 1951) or thyroidectomy. The main difference of this procedure is the refuse of ligation of thyroid vessels before they enter the gland and subfascial resection of the gland. The goal of this technique is to gain bloodless and atraumatic procedure of operation, to prevent damage (removal) of parathyroid glands and laryngeal nerves. This procedure also favors the formation of a gland stumps in the site of parathyroid glands and passage of recurrent nerves. The volume of resection and, consequently, the size of the gland stamp must be based on the account of gravity of thyrotoxicosis, age of the patient, duration of the disease, previous treatment, morphology of the organ and immune state of the patient. (Fig.18)

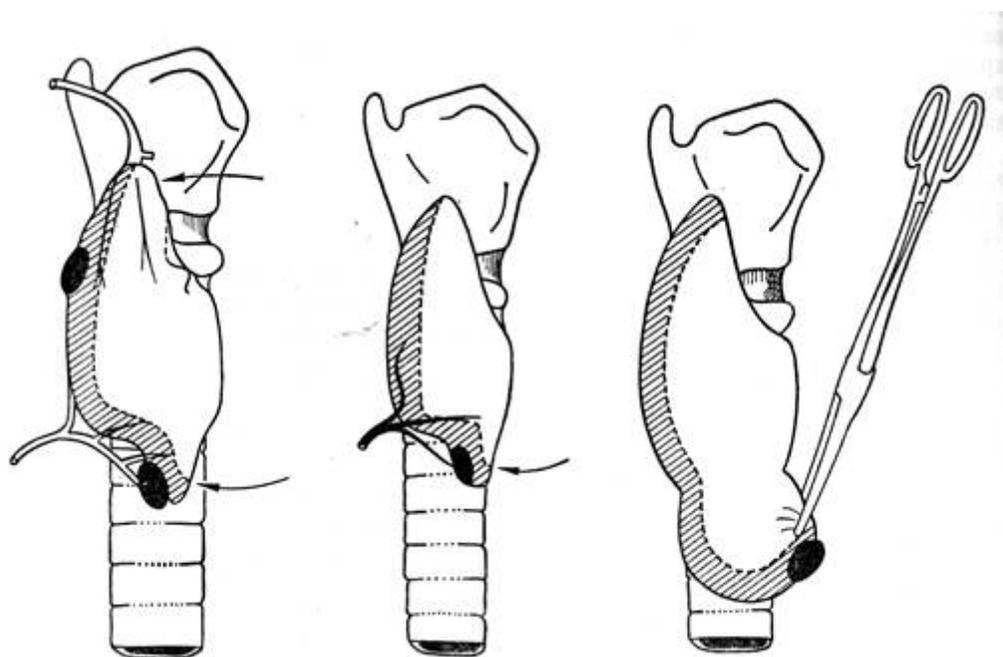

Fig.18. Subtotal resection of thyroid gland by Welti

It is generally accepted, that the more severe the form of thyrotoxicosis, more young the patient, more short duration of the disease, more intensive vascularization, more dark color of the gland, the smaller tissue remnant is necessary to leave (mainly less 6 g, on 1-3 g from each side). Morphologically in such patients revealed hyperfunctional type of histogram and autoimmune processes on initial stage of the development.

The elderly age of the patients with long conservative treatment, reduced blood supply of the gland, expressed plasmolymphatic infiltration of the tissue requires to leave greater thyroid remnant (6-10 g). Morphologically in such patients detected regenerate type of histogram.

Sometimes a long anamnesis and conservative treatment, in association with expressed sclerosis of the gland or its nodular or cystic transformation requires performing of thyroidectomy.

Postoperative period. The clinical course of early postoperative period in the patients undergone the operation mainly depends both on quality of preoperative preparation, and on technique of the surgical intervention. In some patients, particularly with severe form of thyrotoxicosis, during first days after the

operation it is possible to observe exacerbation of thyrotoxicosis – postoperative thyrotoxic response.

There are three degrees of postoperative thyrotoxic response: mild, moderate gravity and severe.

Characteristic signs of mild degree is the tachycardia up to 120 per minute, fever as high as 38°C, satisfactory state of the patient, tachypnea.

The moderate gravity of thyrotoxic response manifests by mild psychomotor excitement. They complain of general weakness, headache, fever sensation, rapid pulse to 120-140 per minute (rhythmic, tense), sometimes extrasystole. Temperature raises as high as 38,5-39°C. Characteristic the considerable sweating, tachypnea, superficial sleep.

Severe degree of thyrotoxic response is characterized by expressed psychomotor excitement. The patients are restless, frequently change positions in the bed, they complain of considerable sweating, permanent fever sensation and expressed tremor. Hyperemia of the face, pulsate vessels of the neck and cyanosis of lips are evident. The pulse rate usually exceeds 140 per minute, irregular and soft. The breathing is superficial. Body temperature is 39-40°C. The sleeplessness in such patients is almost impossible to liquidate by hypnotic and narcotics agents.

Complication of a postoperative period

1. **Thyroid storm** is the severe complication of postoperative period in the patients with thyrotoxicosis (thyrotoxic crisis, acute postoperative thyrotoxicosis). The crisis develops mainly on the second or third day after the operation. If is failed to liquidate it in a day after the onset, the patient can die.

The clinical development of such crisis is acute or fulminant. It manifests by excitement, up to psychosis and coma, motor disorders, tachycardia (pulse rate – 150-200 per minute), complete arrhythmia, fever as high as 40°C and more, hyperemia of the face, neck, limbs, cyanosis, extremely sweating, diarrhea.

Pathogenically thyroid storm is caused by excessive releasing of thyroid hormones. It can arise as the result of rough palpation of the thyroid, treatment by antithyroid drugs, radioactive iodine, infections and traumas.

The crisis requires an urgent and complex treatment. Infusion therapy includes transfusion of haemodes, solutions of glucose with vitamins, plasma, and albumin. Major doses of glucocorticoids, narcotics, neuroleptanalgesia are instituted. Also desirable administration of sedative antihistamine drugs, adrenergic blockers, cardiac glycosides, oxygenotherapy, hypothermia, particularly on regions of major vessels, medical narcosis, extracorporeal method of detoxycation.

The prophylaxis of thyroid storm suggests an adequate preoperative preparation in order to gain euthyroid state of the patient, and also atraumatic performance of surgical intervention.

2. **The damage of laryngeal nerves** is the severe complication of operations on thyroid gland. Thus the paralysis of laryngeal nerves can be unilateral or bilateral, temporary or permanent. The basic causes of the paralysis: cutting off the nerve, its crushing or ligating, distention or compression. It is also necessary to specify that the bilateral injury of inferior laryngeal nerves is particularly dangerous.

The prophylaxis of the damages of laryngeal nerves basically consists of careful technique of subfascial resection of thyroid gland. It is always necessary gently manipulate in the region of inferior poles and "dangerous zone". The hemostasis in order to obtain "dry" operative wound should be carried out only under

the visual control.

The development of asphyxia requires an urgent intubation of trachea, or tracheostomy.

3. **Asphyxia.** It is caused, except bilateral injury of inferior laryngeal nerves, by the damage of trachea, tracheomalacia, laryngeal edema or inflection of trachea.

The tracheal wall injuries must be sutured by atraumatic needle with further muscular plastics. Tracheomalacia requires supporting sutures on trachea or application of prosthetics from synthetic material. Sometimes it is necessary to perform temporary tracheostomy.

4. **Air embolism.** The cause of this infrequent complication is the entering of air in the neck veins owing to suctional activity of chest and negative venous pressure. The prophylaxis of such complications consists of clamping of veins before cutting.

5. **Parathyroid tetany** is a difficult postoperative complication, which is hardly to undergo rehabilitation. The basic cause parathyroid tetany is the removal of parathyroid glands together with thyroid tissue. Besides it can result from impaired blood supply of the glands after the operation. The tetany develops on the base of mineral metabolism disorders, first of all, extremely reduced serum calcium (less 2,5 mEq/l)

It manifests by acute attack of wide-spread or localized cramps of separate groups of muscles of the upper or lower limbs. The most dangerous in this plan is the development of laryngospasm or tonic contraction of diaphragm.

Early clinical manifestation of parathyroid tetany is the Chvostek's signs (percussion near mandible angle causes muscular contractions of the face), Trousseau (occurrence of paresthesias and the sign of "obstetrician's" hand" after applying of tourniquet on brachium.

The treatment of parathyroid tetany consists of prompt administration of calcium agents. The usage of parathormone in complex with vitamin D is usually beneficial. Simultaneously with conservative treatment also performed transplantation of bony tissue.

The careful technique of subfascial resection of thyroid gland prevents the damage of parathyroid glands (except cases of their thyroid ectopy).

6. **Bleeding.** The cause of intra- and postoperative bleedings is insufficient mechanical hemostasis.

The postoperative bleedings are observed within first hours after operation as the result of unreliable hemostasis or slipping of ligature from vessels. Bleedings are clinically characterized by the prompt enlargement of swelling in the region of neck, considerable sopping of bandage by blood. Meanwhile, the patients complain of feeling of tightness in the neck, fear, tachycardia, cyanosis and dyspnea. The treatment of this complication is only surgical. The goal consists of complete disclosure and revision of the wound, carrying out of careful hemostasis.

The prophylaxis of postoperative bleeding includes a complex of measures, the most important of which is a subfascial technique of thyroid resection, careful reliable hemostasis and anatomic operating. The special attention is necessary to pay on lateral thyroid veins (Kocher's veins), which are short and empty directly into interior jugular vein. If the vessels are sclerosed, fragile and easily broken, they should be tied at once after cutting, instead of leaving on clamps up to the end of gland removal.

The damage of larynx, esophagus, major vessels of neck, lymph duct and pleura very seldom occurs. The laryngeal defects are sewed up with further covering by muscles. The esophageal wound is sewed up tightly, and feeding of the patient during 7 days is carried out through the tube.

INFLAMMATORY DISEASES OF THYROID GLAND

PURULENT THYROIDITIS

The purulent thyroiditis is a suppurative septic lesion of thyroid parenchyma. There are also cases of purulent inflammation goitrous thyroid gland – acute purulent strumitis.

Etiology and pathogenesis

The purulent thyroiditis arises owing to invasion of the thyroid by bacterial infection which spreads by hematogenous or lymphogenous way. The infecting agent most often represented by pyogenic streptococcus or staphylococcus aureus.

Pathology

Morphologically according to the character of inflammation distinguished the plain and specific thyroiditis, according to the course – acute, subacute and chronic.

The acute thyroiditis mainly develops in one lobe. Histologically revealed formation of the necrotic foci, hemorrhages, leukocytic infiltration of stroma with admixture of lymphocytes and macrophages.

The subacute thyroiditis (de Kerven) is histologically represented by the developments granulomatous inflammation. The stroma is commonly infiltrated by lymphocytes, leukocytes and large cells, which remind the cells of foreign bodies.

The chronic thyroiditis can manifest in the form of Hashimoto's and Riedel's goiter or specific thyroiditis caused by tuberculosis, lues or actinomycosis.

Hashimoto's goiter is characterized by predominant lymphocytic infiltration with formation follicles (lymphocytic goiter). Riedel's goiter ("iron" goiter, fibrous thyroiditis) is represented by growth of fibrous tissue.

In specific thyroidites revealed specific granulomas.

Classification

Distinguished acute purulent thyroiditis as diseases, which arise in unaltered thyroid gland, and acute purulent strumitis – the lesion of the goitrous transformed thyroid gland.

Symptomatology and clinical course

The onset of the disease is usually acute. It manifests by spontaneous sharp pain in the region of the neck, which amplifies at movements, speech and swallowing, fever, chills, weakness, sweating and tachycardia. On examination it is possible to note local reddening and swelling. Palpation reveals tissue tension, thyroid enlargement, density, with fluctuation in the site of lesion. In blood observed neutrophil leukocytosis and increased erythrocyte sedimentation rate.

Variants of clinical course and complications

The clinical course of the disease is characterized by the signs of purulent septic pathology of the neck. The process spreads outside the thyroid. Late diagnostics and inappropriate treatment result in discharge of the abscess outside, development of neck phlegmon, mediastinitis and sepsis. Nevertheless, in general, the outcome is favorable, on the site of abscess replaced by fibrous tissue, and the function of gland tends to norm.

The diagnostic program

1. Clinical examination, palpation.
2. General blood analysis.
3. Sonography of thyroid gland.
4. Diagnostic puncture of thyroid gland.
5. Bacteriological investigation of exudate.

The purulent thyroidites must be differentiated from simple thyroiditis and strumitis. The stormy course and transformation of plane inflammation into purulent that detected clinically, and by means of diagnostic puncture (purulent exudate) distinguish acute thyroiditis from the other inflammatory processes in thyroid gland.

Tactics and choice of treatment

Diagnostic puncture is necessary in order to confirm the diagnosis. If present fluctuation and purulent exudate it is necessary to carry out surgical management (drainage of suppurative focus). Such patients require antibiotics, analgesics, antiinflammatory and sedative agents.

AUTOIMMUNE THYROIDITIS

Autoimmune (lymphomatous) thyroiditis is the disease described by Hashimoto in 1912. In most cases it occurs in women of age 40-50.

Etiology and pathogenesis

The basic etiologic factor in the development of autoimmune thyroiditis is the release and entering of thyroid antigens into the blood as the result of inflammatory processes and traumas combined with surgical operations on thyroid gland. It has been found the presence of antibodies to thyroglobulins, colloidal component of thyroid gland and microsomal fraction. However the presence of antithyroid antibodies not always results in the damage of the thyroid. The cytotoxic properties of these antibodies manifest only after their interaction with T-lymphocytes and HLA antigens.

Pathology

The histological sign of autoimmune thyroiditis is the diffuse or focal thyroid infiltration by lymphocytes and plasma cells, which results in destruction of follicles and their basal membranes. Further thyroid tissue is replaced by connecting that leads to the focal fibrosis, which resemble nodes.

Classification

Distinguished diffuse and focal, and also hypertrophic and atrophic form of autoimmune thyroiditis.

Symptomatology and clinical course

Hashimoto's thyroiditis is characterized by the slow growth of goiter, the thyroid density, and gradual hypothyroidism. Besides develops the symptomatology, resulting from compression of organs and tissues of the neck by goiter. The patients complain of enlargement of thyroid gland, sense of tightness in the neck, difficult swallowing and breathing, pain in the region of gland and general weakness.

Enlargement of the thyroid is symmetric, it, as a rule, of dense consistence, and on palpation detected its nodular character. During pressing on one of the lobe of thyroid gland the elevation of contralateral lobe is observed (the sign of "swing").

Variants of clinical course and complications

Autoimmune thyroiditis is characterized by the development of hypothyroidism. Nevertheless there are also atypical clinical forms of the disease: autoimmune thyroiditis with thyrotoxicosis (Hashitoxicosis) with gradual transferring into hypothyroidism, lesion of one lobe with clinical course according to the nodular type of euthyroid or hypothyroid goiter. The autoimmune thyroiditis can arise in thyroid stump after surgery for different forms of goiter. The combination of autoimmune thyroiditis with thyroid adenoma or cancer and its transferring into chronic rarely occur.

Autoimmune thyroiditis can be complicated with hypothyroidism, compression of neck organs, in some cases - malignancy.

The diagnostic program

1. Clinical examination of the patient (palpation of thyroid gland).
2. Detecting of thyroid hormone concentration and thyrotropin.
3. Sonography of thyroid gland.
4. Detecting of antibodies to different thyroid components.
5. Biopsy of thyroid gland.

Fig.19. Hashimoto's thyroiditis sonography picture

Differential diagnostics

It should be carried out with endemic and sporadic goiter, Riedel's fibrous goiter and thyroid cancer.

Symmetric enlargement of thyroid gland, its dense consistence, nodular character, presence of autoimmune diseases in family history, high antibody capacity to thyroglobulins and microsomal fraction, development of hypothyroidism, positive response as reducing of goiter at prednisolone assay (20 mg of prednisolone during 7-10 days) – all these distinguish autoimmune thyroiditis from endemic and sporadic goiter, Riedel's thyroiditis. It is usually impossible to differentiate autoimmune thyroiditis from thyroid cancer on the base of clinical, instrumental and laboratory findings. In this case exclusive value has the morphological investigation – biopsy of thyroid gland or express histological investigation during operation. Macroscopically the gland is of pale-pink- greyish color with yellowish tone (instead of red-brown in norm), with atrophic sheath and thin-walled veins.

Tactics and choice of treatment

There is no specific therapy of autoimmune thyroiditis for today. The phenomena of hypothyroidism require nominating of replaceable therapy by thyroid hormones (thyroidine, thyroxine). Glycocorticoids and antihistamine agents are used in subacute form of autoimmune thyroiditis.

Surgery is applied in case of compression of the neck organs and suspicion on malignant tumour of the thyroid. The volume of operation has been still controversial. Preserving operation (isthmusectomy in

combination with wedge-like resection of lateral lobes, resection of thyroid gland) expedient only on initial stages of the disease with maintained thyroid activity. Taking into account a reality of malignancy, often relapses of goiter after small resections, the role of thyroid remnants as the foci of autoimmune aggression, the thyroidectomy is performed. After such operation the patients till the end of life should take substitution therapy by thyroid hormones. It has been noticed, that after thyroidectomy, in comparison with thyroid resection, the patients considerably better response to substitution therapy by thyroid hormones.

RIEDEL'S THYROIDITIS

Invasive fibrous Riedel's thyroiditis (synonyms – Riedel's goiter, "woody" goiter) is the extremely rare pathology, which consist of 0,005 % of persons undergone the surgery for different thyroid lesions. The disease described by Riedel in 1894 and 1897, occurs mainly in males.

Etiology and pathogenesis

The etiology of the disease is still unknown. There is the hypothesis that the Riedel's thyroiditis is the similar to such diseases, as idiopathic fibrous mediastinitis, sclerosing cholangitis and retrobulbar fibrosis. It gives the suggestion that the fibrous lesions of different organs can be the manifestation of one disease. Some authors suggest its infectious origin, though there are no reliable findings.

Pathology

This disease is represented by the development of connective tissue in thyroid gland with further transformation into a thick-fiber fibrous tissue. Between its layers there are small foci of adenomatous parenchyma, mainly of a microfollicular structure. The fibrous connective tissue spreads outside the thyroid, penetrates into muscles of the neck, untimely adherents to esophagus and trachea, causing their constriction and deformity.

Symptomatology and clinical course

The patients complain of goiter, dysphagia, difficult respiration and changes of a voice quality (chestvoice) down to aphonia. The gland becomes of woody or iron consistence, with change of configuration. Frequently observed the signs of tracheal and esophageal compression.

The disease is characterized by severe "malignant" course with aggressive growth of a fibrous tissue, which

can go on even after thyroid resection and after repeated operations for goiter relapse.

The function of the gland commonly preserved, though occasionally the course of disease complicated with hypothyroidism.

The most common complication of the disease is compression of organs and tissues of the neck, which results in dysphagia, dyspnea, and vocal changes.

The diagnostic program

1. Clinical examination of the patient (palpation of thyroid gland).
2. Sonography of thyroid gland.
3. Scanning of thyroid gland.
4. Puncture biopsy of thyroid gland.
5. Morphological investigation of thyroid tissue during surgical management.

Differential diagnostics

Riedel's thyroiditis is necessary to differentiate with thyroid cancer. Such signs as nodular character, metastases in lymph nodes of neck and paralysis of recurrent nerves, are characteristic for cancer. Owing to high density of Riedel's thyroiditis a puncture biopsy of the thyroid is usually hardly performed. Thus, it is necessary to carry out intraoperative histological investigation.

Macroscopically the adhesion of neck muscles with thyroid capsule is observed. The tissue of the gland is grey, with pink foci, according to consistence resemble cartilage and homogeneous on incision.

Tactics and choice of treatment

The treatment of invasive fibrous Riedel's thyroiditis only surgical and consists of complete removal of affected thyroid tissue. The advantage should be given to thyroidectomy.

DISEASES OF MAMMARY GLAND

ANATOMY

Knowledge of the anatomy and embryology of the breast and the chest structures under it is required not only for the performance of surgical procedures but also in planning therapeutic radiation, predicting sites of locally recurrent disease, and assessing the adequacy of surgical procedures used in an increasing number of therapeutic trials. Embryologically, the human breast develops in the thickened portion of ectodermal tissue known as the *milk streak* coursing from the pubis to the axilla in early fetal life. Late in the first trimester, the milk streak atrophies, leaving only its pectoral portion, which continues to thicken and to form the nipple bud. The entire gland then forms as a dermally derived organ lying within the subcutaneous tissue in a manner similar to that of sweat gland development. The ductal system develops from the nipple bud by invasion and downgrowth of primitive ectodermal cells from the nipple surface. The mature breast parenchyma lies cushioned in fat between the layers of superficial pectoral fascia. Between the deep layer of the superficial fascia and the fascial investment of the pectoralis major muscle, the breast rests on a thin layer of loose areolar tissue, the retromammary space, containing lymphatics and small vessels. When a total mastectomy is performed, the correct plane is found under the pectoral fascia and includes the retromammary space as emphasized by earlier surgeons and anatomists.

Deep to the pectoralis major muscle, the pectoralis minor muscle is enclosed in the clavipectoral fascia that envelopes it and extends laterally to fuse with the axillary fascia. In a standard modified radical mastectomy, dissection along the lateral border of the pectoralis minor muscle divides the axillary fascia and exposes the contents of the axilla. The number of lymph nodes found in the axillary space of patients undergoing mastectomy varies depending on the extent of dissection and the diligence of methods used to identify these nodes. An upper limit is established by the work of Durkin and Haagensen using ethanol clearing. These investigators found an average of 50 nodes in 100 specimens obtained in the course of a Halsted-type radical mastectomy. The current approach to less radical procedures has reduced the number of nodes retrieved.

To standardize the extent of axillary dissection, the axillary space is arbitrarily divided into three levels. Level I nodes are those in the external mammary, scapular, axillary vein, and central axillary groups, which lie lateral to the lateral border of the pectoralis minor muscle. Level II nodes are those in the central axillary group, which lie under the pectoralis minor muscle. The level III nodes are difficult to visualize and remove unless the pectoralis minor muscle is sacrificed or divided and include those subclavicular nodes medial to the minor muscle. The apex of the axilla is defined by the costoclavicular ligament (Halsted's ligament), at which point the axillary vein passes into the thorax and becomes the subclavian vein. Lymph

nodes in the space between the pectoralis major and minor muscles are known as the interpectoral group, or Rotter's nodes, described by Grossman and Rotter. Unless this group is specifically exposed, they are not encompassed in surgical procedures that preserve the pectoral muscles.

The lymphatic drainage of the breast is rich, and appreciation of the major pathways allows one to predict the sites most commonly containing lymph-borne metastases. Lymphatic channels within the breast follow centrifugal pathways from the subareolar plexus along major lactiferous ducts and then along efferent veins to draining nodal beds. The major site of drainage is to central axillary nodes. The internal mammary and interpectoral nodes, although primary routes of lymph flow, are rarely the sites of nodal metastasis from breast cancer in the absence of simultaneous axillary disease. Secondly, the lymphatic spread of cancer is into the high axillary nodes in the subclavicular chain and henceforth into the supraclavicular fossa.

As the surgeon endeavors to remove the lymph nodes of the axilla, a keen knowledge of the nerve structures in the axilla is required to avoid their sacrifice. Coursing close to the chest wall on the medial side of the axilla is the long thoracic nerve, or the external respiratory nerve of Bell, which innervates the serratus anterior muscle. This muscle is important in fixation of the scapula to the chest wall during adduction of the shoulder and extension of the arm, and its denervation results in the winged scapula deformity. For this reason, the long thoracic nerve is carefully preserved during standard axillary dissection. The second major nerve trunk encountered during axillary dissection is the thoracodorsal nerve to the latissimus dorsi muscle at the lateral border of the axilla. This nerve arises from the posterior cord of the brachial plexus and enters the axillary space under the axillary vein, close to the entrance of the long thoracic nerve, and then crosses the axilla to the medial surface of the latissimus dorsi muscle. The thoracodorsal nerve is usually preserved during dissection of axillary nodes, unless its sacrifice is required for complete removal of tumor-containing nodes.

Innervation of the pectoralis major muscle has gained the attention of some who emphasize the advantage of protecting these nerves during modified radical mastectomy. Loss of innervation results in a flaccid and atrophic muscle and a diminished tissue covering over the chest wall after amputation of the breast. These investigators have named the pectoral nerves according to their actual position as encountered during axillary dissection. The lateral pectoral nerve has a variable course. In the majority of patients, the lateral pectoral nerve travels around the lateral margin of the pectoralis minor muscle and is in a vulnerable position during the division of the clavipectoral fascia and exposure of the axillary space. If possible, this branch can be saved without compromising the dissection.

The final nerves of interest to the surgeon are the large sensory intercostal brachial or brachial cutaneous nerves that span the axillary space and supply sensation to the undersurface of the upper arm and skin of the chest wall along the posterior margin of the axilla. Cutting these nerves, which is routinely done in removing the lymph node-containing tissues, causes cutaneous anesthesia in these areas. It is helpful to emphasize this to the patients before operation. Denervation of the areas supplied by these sensory nerves can cause chronic and uncomfortable pain syndromes in a small percentage of patients. Contemporary surgeons have

advocated preservation of the most superior brachial cutaneous nerve, which crosses the central axilla to supply cutaneous sensation to the posterior upper arm. This nerve can be preserved without compromising the axillary dissection in many patients.

Microscopic Anatomy of the Breast

The mature breast is composed of three principal tissue types: epithelium, fibrous stroma and supporting structures, and fat. The relative amounts tend to vary with age, but there is even greater variability among individual women. In youth, the predominant tissues are epithelium and stroma, replaced by fat in the breast of older women. For this reason, mammography in women younger than 30 years of age, whose breast tissue is dense with stroma and epithelium, produces images without much definition that are rarely useful clinically. In contrast, fat absorbs relatively little radiation and provides a contrasting background that favors detection of small density lesions in the older patient. Throughout the fat of the breast, coursing from the overlying skin to the underlying deep fascia, strands of dense connective tissue provide shape and hold the breast upward. These strands, devoid of epithelial elements, are called Cooper's ligaments. Because they are anchored into the skin, tethering of these ligaments by a small scirrhous carcinoma commonly produces a dimple or subtle deformity on the otherwise smooth surface of the breast.

The glandular apparatus of the breast is composed of a branching system of ducts, roughly organized in a radial pattern, which spread outward and downward from the nipple-areolar complex. These lactiferous ducts are so named because they carry the milk produced in the more distal lobular groupings. At the summit of the arborizing ductal system, the subareolar ducts widen to form the lactiferous sinuses, which then exit through 15 to 20 orifices on the nipple. These large ducts close to the nipple are lined with a low columnar or cuboidal epithelium that abruptly meets the squamous epithelium of the nipple surface, which invades the duct for a short distance. Awareness of this junction helps understand Paget's disease of the nipple, described later.

At the opposite end of the ductal system and after progressive generations of branching, the ducts end blindly in clusters of spaces that are called terminal ductules or acini. These are the milk-forming glands of the lactating breast and together with their small efferent ducts or ductules are known as the lobular units or lobules. The terminal ductules are invested in a specialized loose connective tissue that contains capillaries, lymphocytes, and other migratory mononuclear cells. This intralobular stroma is clearly distinguished from the denser and less cellular interlobular stroma and from the fat within the breast.

Under the luminal epithelium, the entire ductal system is surrounded by a specialized myoepithelial cell of ductal epithelial origin that has contractile properties and serves to propel secretion of milk toward the nipple. Outside the epithelial and myoepithelial layers, the ducts of the breast are surrounded by a continuous basement membrane containing laminin, type IV collagen, and proteoglycans. The basement membrane layer is extremely important in differentiating *in situ* from invasive breast cancer. Continuity of this layer around proliferations of ductal cells guarantees that progression to an invasive cancer has not yet occurred.

BREAST DEVELOPMENT AND PHYSIOLOGY

In many mammalian species, full breast development requires the stimulation of copulation or pregnancy. Humans do not require either of these two events to initiate and complete breast maturation. Appreciation of the stages of breast development is necessary to understand many benign and even malignant states that come to clinical attention. During adolescence, the breast is composed primarily of dense fibrous stroma and scattered ducts lined with epithelium. In the United States, puberty begins at about 12 years of age, during which time there is hormone-dependent maturation of the genital organs. In the breast, this process entails increased deposition of fat, formation of new ducts by branching and elongation, and the first appearance of lobular units. This process of growth entails cell division and is under the control of estrogen, progesterone, adrenal hormones, pituitary hormones, and trophic effects of insulin and thyroid hormone. There is evidence that local growth factor networks are also important, including epidermal growth factor, which can replace estrogen as a developmental mammogen. The exact timing of these events and the coordinated development of both breast buds may vary from the average in individual patients. The term *prepubertal gynecomastia* refers to the symmetrical enlargement and projection of the breast bud in a young girl before the average age of 12, unaccompanied by the other changes of puberty. This process, which may be unilateral, should not be confused with neoplastic growth and should not be subjected to biopsy.

The mature or *resting* breast contains fat, stroma, lactiferous ducts, and lobular units. During phases of the menstrual cycle or in response to exogenous hormones, the breast epithelium and lobular stroma undergo cyclic stimulation. It appears that the dominant process is hypertrophy and alteration of morphology rather than hyperplasia. In the late luteal (premenstrual) phase, there is accumulation of fluid and intralobular edema that appears to correspond to the clinical complaint of breast engorgement, which may be painful.

On physical examination, and even by mammography, this may lead to increased nodularity and even be mistaken for development of a dominant tumor. Accordingly, ill-defined masses in premenopausal women are correctly observed through the course of one or two menstrual cycles. Finally, any alteration in the periodicity of the menstrual cycle, such as anovulatory cycles, can cause accentuation of engorgement, pain, and nodularity.

[video](#)

With pregnancy, there is diminution of the fibrous stroma to accommodate the hyperplasia of the lobular units. This formation of many new acini or lobules is termed the *adenosis of pregnancy* and is influenced by high circulating levels of estrogen and progesterone and by levels of prolactin that steadily rise during gestation. After birth, there is sudden loss of the placental hormones and the continued high level of prolactin. This may be the principal trigger for lactation. The actual expulsion of milk is under hormonal control and is caused by the contraction of the myoepithelial cells that surround breast ducts and terminal ductules. There is no evidence for innervation of the myoepithelial cells; their contraction appears to be in response to the pituitary-derived peptide oxytocin. Stimulation of the nipple appears to be the

physiologic signal for continued pituitary secretion of prolactin and for the acute release of oxytocin.

When breast feeding ceases there is a fall in prolactin and no stimulus for release of oxytocin. The breast then returns to a resting state and to the cyclic changes induced when menstruation begins again. With the approach of menopause, phases of the menstrual cycle may not be as symmetrical and regular. This irregularity can induce functional nodularity and breast pain where there had been none in earlier years. Menopause is defined by a cessation in menstrual flow for a significant period of time (i.e., 6 months or more) and the variable appearance of constitutional systems such as diaphoresis, minor psychological disturbances, or even clinical depression. For the breast, menopause results in involution and a general decrease in the epithelial elements of the resting breast. These changes include increased fat deposition, diminished connective tissue, and the virtual disappearance of the lobular units. The persistence of lobules, hyperplasia of the ductal epithelium, and even cyst formation can all occur under the influence of exogenous ovarian hormones. Most commonly, hormones are administered to relieve the symptoms of menopause, to prevent demineralization of bone, or to slow the appearance of atherosclerosis. The surgeon evaluating patients at any age for breast disease should inquire about the menstrual history, establish the cessation of menses in postmenopausal women, and record the use of any exogenous hormones. It is important that the pathologist who is examining biopsy material also have this information.

Abnormal Physiology and Development

Gynecomastia. Hypertrophy of breast tissue in men is a common clinical entity for which there is frequently no identifiable cause. Haagensen distinguishes *pubertal hypertrophy*, occurring in young boys between the ages of 13 and 17 years, from *senescent hypertrophy*, which occurs in men older than 50. The enlargement in teenage boys is very common and is frequently bilateral but may be unilateral. Unless it is unilateral or painful, it passes unnoticed and regresses with adulthood. Pubertal hypertrophy is generally treated by reassurance and without operation. Surgical excision should be discussed only if the enlargement fails to regress and the breast is cosmetically unacceptable.

Hypertrophy in older men is also common and may regress spontaneously. It is frequently unilateral, although the contralateral breast may enlarge with passage of time. The discoid mass is smooth, firm, and symmetrically distributed beneath the areola. It may be tender, and patients occasionally complain of breast discomfort. A number of commonly used medications, such as digoxin, thiazides, estrogens, phenothiazines, and theophylline, may exacerbate senescent gynecomastia. In addition, gynecomastia may be a systemic manifestation of hepatic cirrhosis, renal failure, and malnutrition. There should be little confusion with carcinoma occurring in the male breast. Carcinoma is usually not tender, it is asymmetrically located either beneath or beside the areola, and may be fixed to the overlying dermis or to the deep fascia. As with pubertal hypertrophy, gynecomastia in older men is usually left untreated. A dominant mass suspected of carcinoma should be sampled or carefully observed.

Nipple Discharge. The appearance of a discharge from the nipple of a nonlactating woman

is frequently frightening to the patient and misunderstood by the physician. Nipple discharge is very common and rarely associated with an underlying carcinoma. It is important to establish whether the discharge comes from one breast or from both breasts, whether it comes from multiple duct orifices or from just one, and whether the discharge is grossly bloody or contains blood. A milky discharge from both breasts is termed *galactorrhea*. In the absence of lactation or history of recent lactation, galactorrhea may be associated with increased production of prolactin. Radioimmunoassay for serum prolactin is diagnostic. However, true galactorrhea is very rare and is diagnosed only when the discharge is milky (contains lactose, fat, and milk-specific proteins).

Unilateral non-milky discharge coming from one duct orifice is surgically significant and warrants special attention. However, the underlying cause is rarely a breast malignancy. In one review of 270 subareolar biopsy results of discharges coming from one identifiable duct, and without an associated breast mass, carcinoma was found in only 16 patients (5.9%). In each of these cases, the fluid was either grossly bloody or tested strongly positive for occult hemoglobin. In another series of 249 patients, including both multiple-duct and single-duct discharges, breast carcinoma was found in 10 (4%). In 8 of these patients, a mass lesion coexisted with the discharge. Among 67 patients with breast cancer presenting with nipple discharge and studied by Leis and colleagues, only 8 (12%) had no palpable mass and 7 (10%) had a negative mammogram. To conclude, nipple discharge that comes from a single duct and contains blood must be investigated further. However, in the absence of a palpable mass or a suspicious mammogram, this symptom is usually not associated with cancer.

The most common cause of spontaneous nipple discharge from a single duct is a solitary intraductal papilloma in one of the large subareolar ducts directly under the nipple. Fibrocystic change, or cystic mastopathy, typically produces multiple-duct discharge and is another commonly associated finding. Subareolar duct ectasia, producing inflammation and dilatation of large collecting ducts under the nipple, is a common finding in the aging breast and usually produces multiple-duct discharge. In summary, nipple discharge that is bilateral and comes from multiple ducts is usually not a surgical problem. Discharge from single ducts is not commonly associated with carcinoma in the absence of detectable blood or a palpable mass. Bloody discharge from a single duct requires surgical biopsy to establish diagnosis. Intraductal papilloma is found in the majority of cases. If an occult cancer is found, it invariably is an early intraductal lesion.

Breast Pain. Painful breast tissue is an exceedingly common symptom but is usually of functional origin and very rarely a symptom of breast cancer. Haagensen²⁴ carefully recorded the symptoms of women presenting with breast carcinoma and found pain as an unprompted symptom in only 5.4% of patients. Although not a symptom of cancer, breast pain is a common reason for patients to seek medical attention. Breast pain appears to be aggravated by abnormal menstrual cycles and may be seen in young women with menstrual irregularity, as a premenstrual symptom, or when exogenous ovarian hormones are administered during and after the menopause. In addition, fibrocystic change, in its severest forms, may cause disabling breast pain. Although many observers find painful cystic mastopathy is aggravated by excessive

intake of caffeine, nicotine, or commonly used antihistamines, other investigators disagree.

Fibrocystic Change (Cystic Mastopathy, Cystic Mastitis). Fibrocystic change, popularly referred to as *fibrocystic disease*, represents a spectrum of clinical and histologic findings and describes a loose association of cyst formation, breast nodularity, stromal proliferation, and epithelial hyperplasia. Fibrocystic change appears to represent an exaggerated response of breast stroma and epithelium to a variety of circulating and locally produced hormones and growth factors. Clinically, patients with fibrocystic change have dense, firm breast tissue with palpable lumps and frequently gross cysts. This condition is commonly painful and tender to touch. Histologically, the lesion recognized as fibrocystic complex contains macrocysts, microcysts, stromal fibrosis, adenosis, and a variable amount of epithelial metaplasia and hyperplasia. All these changes can occur alone or in combination and to a variable degree in the normal female breast. Autopsy studies have questioned whether any of these changes, except perhaps macrocysts, are abnormal. In fact, all of these lesions occur commonly in the breasts of elderly patients and appear to have no particular pathologic potential. It appears preferable to describe each of the lesions separately and comment about the extent and severity of the process. The term *fibrocystic disease* should be abandoned in the absence of any well-defined clinical and pathologic syndrome.

As discussed later, there is no consistent association between fibrocystic complex and breast cancer. It is well established that women who have undergone breast biopsy for any reason, regardless of the underlying pathology, have a slightly higher risk of developing subsequent breast cancer. Moreover, the incidence of finding fibrocystic disease in autopsied breasts from women dying of causes other than breast cancer exceeds the incidence of these same changes in cancer-containing breasts. For those patients with fibrocystic changes, higher risk appears to concentrate in those whose biopsy specimens show abnormal ductal and lobular hyperplasia and, to a lesser extent, cyst formation. Therefore, the fibrocystic complex appears to be an exaggerated or abnormal response to otherwise physiologic stimuli in most patients and represents a health risk only in certain subsets.

Galactocele. A galactocele is a milk-filled cyst that is round, well circumscribed, and easily movable within the breast. It usually occurs after the cessation of lactation or when feeding frequency has been curtailed significantly. Haagensen states that it may occur up to 6 to 10 months after breast feeding has stopped. The pathogenesis of galactocele is not known for certain, but it is thought that inspissated milk within a large lactiferous duct is responsible. The tumor is usually located in the central portion of the breast or under the nipple. Needle aspiration produces thick, creamy material that may be tinged dark-green or brown. Although it appears purulent, the fluid is sterile. The treatment is needle aspiration. Withdrawal of thick milky secretion confirms the diagnosis, operation is reserved for those cysts that cannot be aspirated or that become superinfected.

Absent or Accessory Breast Tissue. Absence of breast tissue (amastia) or absence of the nipple (athelia) are very rare anomalies. Unilateral rudimentary breast development is much more common, as is adolescent hypertrophy of one breast with more normal development of the other. In contrast, accessory breast tissue (polymastia) and accessory nipples (supernumerary

nipples) are both common. Supernumerary nipples are usually rudimentary and occur along the milk line from the axilla to the pubis in both males and females. They may be mistaken by the patient for a small mole. However, accessory nipples are removed only for cosmetic reason. True polythelia refers to more than one nipple serving a single breast and is very rare.

Accessory breast tissue is commonly located above the breast in the axilla. Rudimentary nipple development may be present, and lactation is possible with more complete development. Accessory breast tissue, which may present as an enlarging mass in the axilla during pregnancy, is treated by surgical removal if it is large, cosmetically deforming, or to prevent enlargement during future pregnancy.

Breast Imaging

The goal of any technique that seeks to image the breast is to extend the capability of physical examination to either detect smaller abnormalities or to provide more information about palpable abnormalities. Mammography is clearly the most sensitive and specific test that can be used to complement the physical examination of the breast. It is used either as a diagnostic modality that seeks to answer specific questions about the health of the breast or as a screening test that seeks to find any abnormality within the breast. A variety of other methods have been used to generate useful images of the breast. Of these, ultrasonography is the only one in common use today. Thermography, which images heat generated by the breast, was added to the Breast Cancer Detection Demonstration Project (BCDDP) to evaluate its usefulness as a screening tool. However, because of a low overall yield, thermography was dropped from the project. Computed tomography (CT) has been used by some investigators with success but can require contrast medium enhancement, has limited ability to resolve small abnormalities, and requires a larger exposure of radiation. CT appears to be the best way to image internal mammary nodes and to evaluate the chest and axilla after mastectomy. Magnetic resonance imaging (MRI) is a technique that requires expensive equipment. The long times required to construct a suitable image are acceptable for diagnostic applications but prohibit MRI as a screening tool. MRI may have a role in evaluating breasts that are difficult to image or after prosthetic implantation. Digital imaging is an evolving hybrid technology that has found application in chest radiography and may be used to store radiographic information in a digital format or to directly produce images. This technology is improving and may have application in mammography.

Diagnostic Mammography. Film-screen mammography has replaced xeromammography as the standard breast imaging technology. Xeromammography was developed by the Xerox corporation and produced a blue image viewed in ambient reflected light. Modern film-screen mammography uses a combination of an enhancing screen and a molybdenum anode tube that produces low kilovolt electron photons. The enhancing screen converts and amplifies a low-energy radiation beam into high-energy photons that, in turn, expose a standard x-ray film. This technique uses compression of the breast between plexiglass plates to lessen the thickness of the tissue through which the radiation must pass and to separate adjacent structures and improve resolution. The image, like standard x-rays, is viewed using transmitted light and is a

negative image. Film-screen mammography delivers an average glandular dose of radiation that is less than 100 mrad. (0.1 cGy. or 0.1 rad.). In comparison, the average dose to the center of the breast in patients undergoing barium swallow is more than 10-fold the dose of two-view mammography.

The mammographic features of malignancy can be broadly divided into density abnormalities (including masses, asymmetries, and architectural distortions) and microcalcifications. Each mammogram should also be assessed for the presence of abnormalities in the axillary nodes and for the presence of skin or nipple changes, such as thickening or retraction. These mammographic features can coexist in any one particular abnormality and may exist in the presence or absence of physical findings. In fact, integration of each of the radiographic features and the physical findings leads to a prediction of malignancy.

Nonpalpable Mammographic Abnormalities. Mammographic abnormalities that cannot be detected by physical examination are classified in three broad categories: (1) lesions consisting of microcalcifications only, (2) density lesions (masses, architectural distortions, and asymmetries), and (3) those with both calcifications and density abnormalities. The incidence of malignancy after biopsy depends on the characteristics of the radiographic finding. Lesions with both microcalcifications and a mass effect, spiculated masses, and linear branching calcifications carry the highest probability of being malignant. However, even well-defined densities can be malignant. To be certain, not every abnormality should undergo biopsy, and recommendations must be made by the surgeon in consultation with an experienced radiologist. For those patients not undergoing biopsy, interval mammograms must be done to ensure stability of the abnormality.

If a biopsy is performed, it is usually done after mammographic placement of a needle or hook wire. A newer alternative is automated stereotactic core-needle biopsy. This procedure requires a large and dedicated unit, which is expensive. The patient generally lies prone with the breast hanging through the table. A robotic arm and biopsy gun is positioned by computerized analysis of triangulated mammographic images. A small amount of local anesthesia is used at the point of core-needle entry into the breast. Firing the machine obtains a core biopsy through the abnormality. Many series containing hundreds of patients have shown good correlation between stereotactic biopsy and subsequent needle-placement open biopsy. For lesions with calcification, a specimen radiograph must be done to confirm the presence of the abnormality in the specimen. This is true for both stereotactic and open biopsy procedures. Cooperation is required between the radiologist, surgeon, and pathologist for the correct interpretation of biopsy material obtained by either technique. If stereotactic biopsy is available to the surgeon, judgment must be used to determine the optimal biopsy strategy. Because stereotactic biopsy does not remove the abnormality, a subsequent localization and open procedure will be required if a cancer is found and the patient wishes to attempt breast conservation. If the abnormality proves benign after stereotactic biopsy, follow-up mammography needs to be done if the lesion is indeterminate. The false-negative rate of stereotactic biopsy is low but finite.

Screening Mammography. The goals of screening mammography differ from those of diagnostic mammography. Screening studies seek to identify any abnormality, maximizing sensitivity and cost effectiveness. During the past three decades, there have been eight major randomized controlled trials that compared a screened population to women given usual care. Although screening intervals and mammographic techniques differed, each of these studies included mammography with or without clinical breast examination in the screened arms. In the United States, a single uncontrolled study was done to demonstrate the feasibility of a population-based screening program. The BCDDP screened 280,000 women annually in 29 centers throughout the United States. Each center offered free mammograms and a breast examination and taught breast self-examination. Participants in the BCDDP have been followed for 14 years, and survival data were published. Because this was not a controlled trial, comparison has been made to national statistics compiled by the Surveillance, Epidemiology, and End Results (SEER) program within the National Cancer Institute (NCI). Comparison of survival data 8 years after diagnosis of cancer in the BCDDP to corresponding data from the SEER program demonstrates improved survival in the screened population, which seems to be explained by a shift to earlier stage disease in the BCDDP.

BENIGN BREAST TUMORS AND RELATED DISEASES

Breast Cysts. Cysts within the breast are fluid-filled, epithelial-lined cavities that may vary in size from microscopic to large, palpable masses containing as much as 20 to 30 ml. of fluid. As discussed, cysts are generally discovered by physical examination and confirmed by ultrasound or needle aspiration. At least one woman in every 14 will develop a palpable cyst, and 50% of cysts are multiple or recurrent. Cysts occur as solitary abnormalities, called macrocysts or gross breast cysts, or as part of a generalized process of microscopic cyst formation. This latter disease process is frequently bilateral and the cystic transformation can be extensive. The pathogenesis of cystic formation is not well understood; however, cysts appear to arise from destruction and dilation of lobules and terminal ductules. Three-dimensional microscopic studies and extensive sectioning have shown that stricture and fibrosis at or near terminal branching of small ductules, combined with continued secretion by the distal lobule, result in expansion of a cavity containing fluid and lined by ductal epithelium.

Cysts are unquestionably influenced by ovarian hormones, a fact that explains their sudden appearance during the menstrual cycle, their rapid growth, and their spontaneous regression with completion of the menses. Most women with new cyst formation present after the age of 35 and rarely before the age of 25 years. The incidence of cyst development steadily increases until the age of menopause and sharply declines after menopause. Autopsy studies of women dying with clinically normal breasts generally confirm the age relationship of gross cyst development but do find that the breasts of older women can contain gross and microscopic cysts. New cyst formation detected clinically in older women commonly is explained by the use of exogenous hormone replacement.

When encountered during operation, cysts are frequently dark. These are often referred to as

blue dome cysts, and they reflect the dark cyst fluid contained within. Grossly, they are usually unilocular and lined by a smooth and glistening surface, although larger cystic structures may be trabeculated and multiloculated. Histologically, cysts are frequently lined by a flattened epithelium. However, the epithelial layer may display apocrine metaplasia or may have papillary features. Intracystic carcinoma is exceedingly rare. Rosemond was able to report only three examples in over 3000 cyst aspirations (0.1%), and other investigators confirm this exceedingly low incidence. Regarding the risk of developing cancer for women with cystic disease, no studies demonstrate an increased risk in women with small or microscopic cysts. For patients with large cysts, called gross cystic disease by Haagensen, there remains some controversy. Patey and Nurick found no increase in cancers subsequent to cyst aspiration. Of 810 cancers treated by Patey, only 10 had a previous history of gross cysts. Other recent reviews have emphasized that women with gross cysts have a risk of twofold to fourfold that of age-matched women without cysts. The studies of Page and associates and of Dupont and Page do not show a significant increase in cancers after long-term follow-up of over 2000 women who underwent biopsy of palpable cysts when compared with the slight increase borne by women who have had breast biopsy alone.

Fibroadenoma and Related Tumors. Fibroadenoma (adenofibroma) is a benign tumor composed of both stromal and epithelial elements in the breast. After carcinoma, fibroadenoma is the second most common solid tumor in the breast and is the most common tumor in women younger than age 30 years. The benign nature of this lesion was recognized in 1840 by Cooper, who referred to the lesions as “chronic mammary tumors.” Clinically, they present as firm, solitary tumors that may increase in size over several months of observation. They may be lobulated but will slip easily under the examining fingers. At operation, fibroadenomas appear to be well-encapsulated masses that may easily detach from the surrounding breast tissue. By history, fibroadenoma is favored over cyst in the adolescent or young adult; and on examination, these tumors are distinguished from cysts by the needle aspiration that yields no fluid. Mammography is of little help in distinguishing between cysts and fibroadenomas; however, ultrasound usually clearly shows the cavity of a cyst. The gross appearance and histopathology are distinctive of fibroadenoma. Grossly, the tumor appears well encapsulated, with smooth borders that may be lobulated. Histologically, a variable proportion of epithelial and stromal proliferation is present, and the stroma may be quite cellular or replaced by acellular swirls of collagen. In older patients, the lesions may contain deposits of calcium within dense fibrosis. The epithelium can display the entire spectrum of proliferative changes seen elsewhere in the breast. Although fibroadenomas are not considered to have a malignant potential, the epithelial elements appear to be at risk for neoplasia just as epithelium elsewhere in the breast. More than 100 invasive and noninvasive carcinomas have been reported in preexisting fibroadenomas since 1985. Most of these (50%) have been lobular carcinoma *in situ*, 35% were infiltrating carcinomas, and 15% were intraductal carcinoma. The risk of cancer in a newly discovered fibroadenoma found in the breast of a young woman is obviously exceedingly rare and is not an issue that influences treatment. A modest risk of subsequent carcinoma in women who have previously been treated for fibroadenoma has been reported, but the magnitude is about two times the general population. This is only slightly higher than the

reported excess risk for all women who have had a breast biopsy.

The treatment of fibroadenoma follows that for any unexplained solid mass within the breast. The great majority of patients in the United States are treated by excisional biopsy to remove the tumor and establish the diagnosis. It is worth recognizing that a different approach is taken by physicians in other countries. A typical fibroadenoma is frequently left untreated by European physicians when the tumor is encountered in the breast of a young women. If excision is recommended, the approach to a young women with a typical fibroadenoma on examination should be very different than the approach in older women with indeterminate masses. Cosmetic incisions around the areola with a modest amount of tunneling to remove the lesion are commonly used techniques and are proper for the treatment of fibroadenoma. Emphasis should be placed on removing a minimum amount of breast tissue adjacent to a typical fibroadenoma. If the gross appearance is that of a fibroadenoma, frozen section is superfluous, the patient can be immediately reassured, and final diagnosis can be established by inspecting permanent sections.

Juvenile Fibroadenoma, Giant Fibroadenoma. Clinicians treating breast masses should be aware of these two terms, which are sometimes confusing. *Giant fibroadenoma* is a descriptive term that applies to a fibroadenoma that attains an unusually large size, typically greater than 5 cm. Haagensen calls these lesions “massive adenofibromas in youth” to denote their common occurrence in adolescent women. *Juvenile fibroadenoma* refers to the occasional large fibroadenoma that occurs in adolescents and young adults and histologically is more cellular than the usual fibroadenoma. Both these lesions overlap, and both may display remarkably rapid growth within the breast. Although alarming to the patient and physician, prompt surgical removal is always curative. The term *benign cystosarcoma phyllodes* refers to a tumor that may be difficult to distinguish clearly from juvenile fibroadenoma. If the tumor has been completely removed, the diagnosis of benign cystosarcoma should reassure the surgeon and the patient that the risk of recurrence is low, particularly if the patient is an adolescent or a young adult. Malignant cystosarcoma phyllodes is a distinctive and aggressive tumor discussed later.

Hamartoma and Adenoma. Although probably not of the same histogenesis as fibroadenoma, these tumors are benign proliferations of variable amounts of epithelium and stromal supporting tissue. The hamartoma is a discrete nodule that contains closely packed lobules and prominent, ectatic extralobular ducts. By physical examination, mammography, and gross inspection, the hamartoma is indistinguishable from fibroadenoma. The nodule is entirely benign, and removal is curative. The mammary adenoma or tubular adenoma has been a more elusive entity to define. Page and Anderson describe this tumor as a cellular neoplasm of ductules packed closely together and forming a sheet of tiny glands without supporting stroma. During pregnancy and lactation, these tumors may increase in size and histologic examination shows secretory differentiation. Malignancy is not a feature of tubular adenoma or lactating adenoma, but biopsy is required to establish the diagnosis.

Breast Abscess and Infections. Breast abscess commonly occurs in the subareolar breast tissue and may be recurrent and difficult to treat. Although the exact cause is not known, subareolar duct ectasia and obstruction of major ducts may lead to proliferation of bacteria and subsequent abscess. Further destruction of the normal ductal openings leads to fistula formation and chronic recurrent abscess. Mammary duct ectasia, first named by Haagensen, is an inflammatory condition that causes distortion and dilation of the lactiferous sinuses under the nipple. It is a common entity and is frequently responsible for nipple inversion in older women. In understanding subareolar abscess and probably mastitis in general, it is useful to remember that the nipple and areolar complex contains secretory ducts that are exposed to the environment. Chronic inflammation, duct dilation, and obstruction may combine at the nipple to produce circumstances that favor bacterial invasion.

The treatment of acute abscess of periareolar tissue should be conservative if possible. Antibiotics with broad-spectrum coverage should be used initially. More severe infections may require hospitalization and intravenous antibiotics. A small incision with drainage is preferred if the process cannot be controlled by antibiotics alone. Needle aspiration may be attempted, but the abscess cavity is usually multiloculated. Recurrent infection is best treated by excision of the diseased subareolar ducts as described by Haagensen and others. However, recurrence is common and leads to chronic and recurring infection.

Mastitis describes a more generalized cellulitis of breast tissue that may involve a large area of the breast but may not form a true abscess. The etiology appears to be an ascending infection beginning in subareolar ducts and extending outward from the nipple. Occasionally, mastitis involves areas of cystic disease and may be sterile. Mastitis presents with erythema of the overlying skin, pain, and tenderness to palpation. There is induration of the skin and underlying breast parenchyma. Especially in young women, an apparent mastitis may develop that is dramatic in its presentation and responds poorly to antibiotics but resolves spontaneously. The etiology is unknown but may be related to menstrual cycle irregularity. More commonly, mastitis complicates lactation, possibly due to inspissation of milk, obstruction, and secondary infection. Local measures such as application of heat, ice packs, or use of a mechanical breast pump on the affected side have all been recommended. If conservative measures are not effective, administration of broad-spectrum antibiotics is usually indicated. In many situations, the differential diagnosis of acute mastitis includes inflammatory carcinoma. It is important to follow patients with mastitis and confirm that there has been a complete resolution of symptoms and signs. The erythema produced by an inflammatory carcinoma will not resolve with conservative measures and generally will worsen in a short period of follow-up.

Papilloma and Related Ductal Tumors. Solitary intraductal papillomas are true polyps of epithelial-lined breast ducts. Solitary papillomas are located under the areola in the majority of cases. In contrast, certain patients have multiple intraductal papillomas that Haagensen believes are more likely to be peripherally located and associated with an increased risk of cancer. Solitary papillomas may be located in peripheral ducts and can grow to large size, presenting as a breast mass. When papillomas attain a large size, they may appear to arise

within a cystic structure, probably representing a greatly expanded duct. In general, these lesions are less than 1 cm. but can grow to as large as 4 or 5 cm.

Tumors under the nipple and areolar complex often present with a bloody nipple discharge. Less frequently, they are discovered as a palpable mass under the areola or as a density lesion on the mammogram. Treatment is total excision through a circumareolar incision. The surgeon must keep in mind that one of the most difficult areas in differential diagnosis is between a papilloma and invasive papillary carcinoma. Because these lesions can infarct, scar, and even develop squamous metaplasia, they can appear bizarre and disordered. Most pathologists urge evaluation on permanent sections for the majority of papillary lesions before more extensive surgery is undertaken.

It is also important not to confuse the commonly used term *papillomatosis* with either solitary or multiple papillomas. Papillomatosis refers to epithelial hyperplasia that commonly occurs in younger women or is associated with fibrocystic change. This lesion is not composed of true papillomas. Hyperplastic epithelium in papillomatosis may fill individual ducts like a true polyp but has no stalk of fibrovascular tissue nor the frondlike growth. Solitary papillomas are entirely benign and do not predispose to development of cancer in the patients who have them. Page and Anderson state that the degree of subsequent risk for breast cancer in patients with either papillomatosis or with true papillomas, either solitary or multiple, relates to the degree of atypical epithelial proliferation associated with them.

MALIGNANT TUMORS OF THE BREAST

Epidemiology

The likelihood of developing breast cancer is highly dependent on both age and the interval over which an individual is at risk. Although the lifetime risk of developing breast cancer is estimated at 10%, more than one half of patients with breast cancer are older than 65. Furthermore, the 10% figure is based on a hypothetical interval that extends from birth to age 110. A more realistic view considers risk starting at a particular age and extends over a finite period of time. For instance, the chance that a woman age 35 will develop breast cancer during the next two decades of her life, until age 55, is only 2.5%. A woman who is 50 has close to a 5% chance of developing cancer before she turns 75 and a 65-year-old woman has a 5.5% chance of getting breast cancer before she turns 85 years of age. These figures apply to white women in the United States; the same idealized African-American woman has a lifetime risk of breast cancer that is 7% or 8%.

The odds of dying of breast cancer over the ideal lifetime of birth to 110 are about 3.6%. Although carcinoma of the lung has overtaken breast cancer as the leading cause of cancer-related death in American women, breast cancer remains far more common. Of 595,000 new cases of cancer among women in 1996, 186,000 occurred in the breast while 78,000 arose in the lung.

Several studies based on cancer registries in the SEER program of the NCI have reported an increasing attack rate for breast cancer in the United States. In Washington State there has been

an annual estimated increase of 2.5%. A greater increase was apparent among black and low-income women. In the Connecticut Tumor Registry the overall annual incidence rose from 53 cases per 100,000 women during the years 1935 to 1939 to an average annual rate of 86.4 per 100,000 for the years 1975 to 1979. The annual rate of increase during 1980 to 1985 averaged 3%; during the past 5 years, this rate of increase has declined to about 1% per year. Data from other studies and from other western countries confirm the increase in the incidence of breast cancer. Despite this increased incidence, the age-adjusted death rate from carcinoma of the breast was stable until 1979 and may have decreased in the 5-year period between 1979 and 1984. Although it is tempting to speculate that this is a real improvement attributable to early diagnosis or improved therapy, no direct proof can be cited.

Pathology of Breast Cancer

Modern classification of breast cancer attempts to recognize morphologic patterns that reflect both the histogenesis of the malignancy and its biologic behavior, or prognosis. As such, these classifications impose artificial divisions on diseases that are fundamentally poorly understood. As advances are made in our understanding of breast malignancies, the classifications presented today will be improved on by future generations of surgeons and pathologists. Malignancies of the breast are broadly divided into epithelial tumors of cells lining ducts and lobules and nonepithelial malignancies of the supporting stroma. A second important division of the epithelial tumors that recognizes their evolution is between noninvasive and invasive cancers. The noninvasive malignancies are proliferations of either ductal or lobular cells confined to the basement membrane. These are true carcinoma *in situ*. As in other organs, carcinoma *in situ* commonly coexists with invasive cancer. In the breast, this association is very frequent and argues for the progression of cancer through stages of noninvasive proliferation, disruption of the basement membrane, and invasion of the supporting stroma.

Most pathologists utilize the classification scheme proposed by the World Health Organization (WHO) and outlined in the fascicles of the Armed Forces Institute of Pathology. Historically, Foote and Stewart presented most of this material in 1945, including a recognition of noninvasive carcinoma and the differentiation between tumors originating in the breast lobule from those arising in the lactiferous ducts.

Ductal Carcinoma *in Situ* (DCIS), Intraductal Carcinoma. The concept of a purely noninvasive form of breast cancer and recognition of various subtypes have evolved slowly since the beginning of this century. DCIS was probably recognized first by surgeons who appreciated its favorable prognosis. Bloodgood, at the Johns Hopkins Hospital, impressed by the tumor of an early patient of Halsted, recognized a disease he termed “pure comedo tumor” that had an extremely favorable prognosis. Pathologically, breast ducts become swollen with proliferating malignant epithelium. In the solid or comedo type, the ducts can expand to visible proportions 1 or 2 mm. in diameter. The term *pure intraductal carcinoma* refers to the absence of detectable invasion of the basement membrane. Devoid of blood supply, the center of the lesion undergoes necrosis and the intraductal spaces fill with necrotic cellular debris. The

central detritus can undergo dystrophic calcification that is fine, focally clustered, and even linear and branching when seen on high-quality mammography. This process can locally produce a palpable mass if multiple ducts are involved.

Subtypes of DCIS are now well recognized and frequently reported pathologically. The solid or comedo type is most common and probably more virulent. Papillary or cribriform DCIS are characterized by papillary projections of tumor cells into the ductal lumen or by the presence of a branching, cribriform pattern filling ducts. These types are less likely to form palpable masses and uncommonly calcify to produce a mammographic abnormality. However, it is important to emphasize that these subtypes can coexist and that DCIS is best described by the pathologist in terms of its extent, multicentricity, and involvement of the surgical margin. Confusion arises in a number of ways. First, the uninitiated may confuse the term *infiltrating ductal carcinoma* with the term *intraductal carcinoma*; the former is invasive disease and the latter is noninvasive disease. Second, these two stages of tumorigenesis usually coexist, particularly when they are carefully searched for in pathologic specimens. Finally, as discussed later, the treatment and outcome for patients with intraductal disease may depend on variables such as multifocality, multicentricity, and extent of disease in a way more demanding for the pathologists and surgeons than in the past.

Lobular Carcinoma *in Situ* (LCIS) or Lobular Neoplasia. This disease of the breast lobules or acini was first clearly delineated by Foote and Stewart in 1941, who gave it the name *lobular carcinoma in situ*. Haagensen first used the term *lobular neoplasia* to emphasize its more benign course. Pathologically, it is a proliferation of small round epithelial cells within lumens of multiple breast acini. The resulting picture is multiple clusters of epithelial cells forming islands of neoplastic cells but maintaining a lobular architecture. Although the ducts expand with proliferating cells, they usually do not reach the large size seen with DCIS.

Unlike DCIS, LCIS never forms a palpable mass by itself and is therefore not recognized on physical examination. In addition, there are no mammographic findings in LCIS. It does not form a density and rarely calcifies, both of which are typical for DCIS. Therefore, this is a disease that is recognized incidentally after biopsy for another abnormality that is producing a clinical or mammographic finding. The treatment of this incidental pathologic entity remains controversial and is reviewed later.

Infiltrating Ductal Carcinoma. This is the most common malignant tumor in the breast recognized after biopsy. The term *ductal carcinoma* refers to its origin from ductal epithelium; *infiltrating* describes its growth pattern and distinguishes this lesion from noninvasive carcinoma. Some add the terms *not otherwise specified* (NOS) and *no special type* (NST) to emphasize that this disease is diagnosed after the other, more distinctive histologies have been eliminated. The tumor infiltrates into a variable amount of stroma as cords or islands of malignant epithelium. It may form primitive glandular forms, but not to the extent of a pure tubular carcinoma. As discussed, and as reflected in the WHO classification, many infiltrating carcinomas display an *in situ* component. This fact reflects its ductal origin and may be used to prove a mammary origin of the tumor. The stromal *reaction* may be intense and has led to the older term *scirrhous carcinoma* of the breast.

Clinically, most infiltrating ductal carcinomas present as a mass found on physical examination or as a density lesion on the mammogram. Microcalcifications seen mammographically are commonly found in the necrotic centers of the intraductal component but may be seen in the infiltrating component as well. The treatment of infiltrating carcinoma is discussed later, and the approach taken is generally the same regardless of the morphologic appearance. However, there is great biologic diversity among breast cancers; and after identification of an infiltrating ductal carcinoma, pathologists attempt to describe features that reflect the likely behavior of the tumor.

The evaluation of breast cancers should always specify the tumor size, the status of the surgical margin, and the content of estrogen and progesterone receptors. In addition, the nuclear and histologic grade is frequently reported and modern evaluation may include measurement of DNA content and estimation of the proliferating fraction, or S-phase. Vascular invasion, tumor necrosis, and the extent of the intraductal component are all used to make decisions about the primary or adjuvant treatment of patients with operable breast cancer. The dedicated breast surgeon must be acquainted with all of these parameters and their interpretation.

Invasive Lobular Carcinoma. This disease probably originates in the breast lobule. Invasive lobular carcinoma constitutes between 3% and 15% of all invasive breast cancers, depending on the series consulted. Histologically, the tumor is composed of small round cells that infiltrate surrounding stromal tissue in a peculiar *Indian file* fashion. Lobular carcinoma presents in an identical fashion as ordinary infiltrating ductal carcinoma and produces no distinguishing mammographic features. The treatment of lobular carcinoma is the same as for the more common ductal carcinomas and may carry a better prognosis. There may be a somewhat higher incidence of bilateral cancer or of second primary tumors in the contralateral breast. However, this is rarely used to justify prophylactic procedures in the contralateral breast in the absence of synchronous disease.

Less Common Forms of Ductal Carcinoma. These tumors, although heterogeneous, are all morphologic variants of common ductal carcinoma. In general, these less common variants have improved prognosis, reflecting their more differentiated phenotype. One exception to this rule is medullary carcinoma of the breast, which is pathologically characterized by bizarre and anaplastic tumor cells surrounded by a prominent lymphocytic infiltrate with a scant fibrous stroma. Although the epithelial component is undifferentiated, this phenotype appears to enjoy a small but significant survival advantage when compared with infiltrating ductal carcinoma NOS. Mucinous carcinoma, also called colloid carcinoma, is characterized by well-differentiated epithelial cells surrounded by a large accumulation of extracellular and extraluminal mucin that is secreted by the carcinoma cells. This histologic type enjoys a favorable prognosis in several published series. Although there are no definite clinical or mammographic signs of mucinous and medullary carcinoma, these tumor types are suggested by a well-circumscribed density with smooth borders that tend to be softer on physical examination. The final major histologic type that is distinctive and well differentiated is tubular carcinoma. This tumor is characterized by infiltrating tubular structures, lined by one

cell layer, and with an open central space. The tumor is characteristically small, is scirrhous, and has an excellent prognosis after treatment. The descriptions of these histologic variants refer to their predominant features. However, each may coexist with more undifferentiated infiltrating carcinoma of the usual type. In general, if the tumor is composed of definite infiltrating ductal carcinoma of poor differentiation, the final diagnosis reflects the poorest histologic pattern. Because tubular and mucinous variants are less likely to metastasize, some modern breast surgeons tailor their primary approach to these lesions by, for instance, omitting axillary node dissections for small and well-differentiated lesions.

Modern Surgical Procedures for Invasive Breast Cancer

The surgical treatment of breast cancer, for the most part, concerns the treatment of potentially curable cancer that is confined to the breast and regional lymph nodes. For early stages of breast cancer, surgical removal provides a reasonable chance for cure. Although the approach to operable breast cancer has changed dramatically over the past century, so, too, has the clinical presentation of breast tumors changed. In 1894, Halsted presented his first 50 patients treated by the “complete operation,” which became the radical mastectomy. Over the next 75 years, radical mastectomy was used to treat virtually every breast malignancy operated on for cure in the United States. Examination of Halsted's first cases found at least two thirds with locally advanced disease and 60% with clinically evident axillary nodal metastases. By comparison, a 1980 survey by the American College of Surgeons found that 85% of patients presented with Stage I or Stage II disease. The frequency of cases with positive axillary lymph nodes was 40%, and the average tumor presenting to physicians in the 1970s measured 2 cm. or less. In addition to these fundamental changes, realization that 90% of treatment failures will be systemic or visceral recurrences has led surgical oncologists to explore alternatives to radical mastectomy as an initial approach to operable breast cancer.

Surgical Procedures Past and Present

In 1982, the American College of Surgeons investigated surgical practice in cases of operable breast cancer and compared results with practice in earlier years. Clearly, a change in surgical practice occurred in the mid 1970s with an abrupt shift from radical mastectomy to modified radical mastectomy. Procedures that preserved the breast, as described later, were performed in only 7.2% of cases in this survey. Current estimates of conservative breast procedures range between 20% and 40%, and this procedure probably continues to increase in popularity. The following paragraphs describe procedures in widespread use now and in the past.

Radical and Extended Radical Mastectomy. In the radical mastectomy, the breast and underlying pectoralis muscles are sacrificed leaving a bare chest wall. Regional lymph nodes along the axillary vein up to the costoclavicular ligament (Halsted's ligament) are removed with the breast specimen. This procedure frequently requires a skin graft and uses incisions placed either vertically or obliquely. Prosthetic reconstruction is impossible unless muscle flaps are mobilized to cover the anterior chest defect. Cure of breast cancer can certainly be achieved by

the application of this procedure alone. Other studies document both the strengths and weaknesses of maximal local therapy represented by this procedure. The personal series of Haagensen reports results from treatment of 1036 patients; 727 patients with clinically negative nodes (Stage A, Columbia clinical staging) had a survival of 72.4% at 10 years. In contrast, only 42.3% of clinically node-positive patients (Stage B) survived at 10 years. These figures were confirmed by the National Surgical Adjuvant Breast and Bowel Project (NSABP) early trial of adjuvant thiotepa. By 10 years, 76% of patients with histologically positive nodes suffered recurrence of breast cancer and one fourth of patients with negative nodes failed surgical treatment. In contrast, *local failure* rates have been extremely low since introduction of the Halsted radical mastectomy. Published figures are generally between 5% and 7% and provide the standard against which newer procedures are judged.

The extended radical mastectomy is a standard radical mastectomy to which en bloc removal of internal mammary nodes is added. This procedure was popularized in the United States by Urban, who reported a 35.5% 10-year survival in patients undergoing extended radical mastectomy. Other studies have resulted in abandonment of the extended procedure. A large prospective trial and several uncontrolled series have failed to provide evidence of improved clinical outcome after extended radical mastectomy.

Modified Radical Mastectomy. Modified radical mastectomy refers to a procedure combining total mastectomy with removal of axillary lymph nodes in continuity with the mastectomy specimen. This is the most widely used procedure to treat operable breast cancer and is the alternative to breast-sparing procedures described later. Modified radical mastectomy leaves the pectoralis major muscle intact, providing a soft tissue covering over the chest wall and a normal-appearing junction of the shoulder with the anterior chest wall and avoiding the hollow defect inferior to the clavicle that accompanies the removal of the pectoralis muscle. The patient is left with intact musculature around the shoulder and a situation that is well suited to prosthetic reconstruction. Two forms of the procedure are in use by surgeons: the Patey procedure and modifications described by Scanlon and the procedure described by Auchincloss.

Patey, at the Middlesex Hospital in London, developed a procedure that preserves the pectoralis major muscle and sacrifices the underlying pectoralis minor muscle to remove levels I, II, and III lymph nodes in the axilla. A large number of Patey procedures performed by Handley, who wrote extensively about this procedure, were reviewed independently and reported by Donegan and associates. The survival of patients with negative axillary nodes was 82% at 10 years with a local recurrence rate of 5%. For patients with positive nodes, the survival was 48%, very similar to results with radical mastectomy. Thus, preservation of the pectoralis major muscle did not appear to produce inferior results. Scanlon modified the Patey procedure by dividing but not removing the pectoralis minor muscle, allowing removal of apical (level III) nodes and preservation of the lateral pectoral nerves to the major muscle.

The procedure described by Auchincloss differs from the Patey procedure by not removing or dividing the pectoralis minor muscle. This modification limits the complete removal of high axillary nodes but is justified by Auchincloss, who calculated that only 2% of patients will

potentially benefit by removal of the highest level nodes. It is probable that the Auchincloss mastectomy was the most popular procedure for breast cancer in the United States during the past decade.

Wide Local Excision and Primary Radiation Therapy. Excision of the primary tumor with preservation of the breast has been referred to by many names, including partial mastectomy, segmentectomy, tylectomy, or lumpectomy. *Wide local excision* seems to be the most descriptive term for the procedure, which removes the malignancy with a surrounding rim of grossly normal breast parenchyma. An even more aggressive local procedure designed to remove 1 to 2 cm. of adjacent breast and overlying skin is called *quadrantectomy*. In modern practice, these more limited surgical procedures are applied as part of a multidisciplinary approach to breast cancer and always include postoperative radiation therapy, giving at least 4500 cGy. to the whole breast and usually including a boost of radiation to the tumor bed. Axillary dissection is done through a separate incision in the majority of patients. Therefore, conservative breast surgery or breast preservation usually refers to wide local excision of the primary tumor, whole breast radiation, and a separate axillary dissection.

The Management of Noninvasive (*in Situ*) Carcinoma

Special attention to the problem of *in situ* carcinoma is justified by the increasing frequency of its recognition and the controversy surrounding the proper treatment of noninvasive cancer of the breast. Treatment decisions require appreciation of the various types and stages of *in situ* disease and demand that the surgical oncologist understand this sometimes complicated disease process. Moreover, its relationship to invasive cancer is a fascinating biologic question. Understanding these early proliferative states should give investigators a clue to the underlying cause of breast cancer. Finally, finding early malignancy is the goal of population screening. It is hoped that the high cure rate after treatment of noninvasive breast carcinoma will someday contribute to a decline in mortality from this malignancy.

Ductal Carcinoma in Situ (DCIS) or Intraductal Carcinoma

Before modern mammography, intraductal lesions presented as palpable tumors in 50% or more of patients. In the 1980s, more were recognized by the calcifications they produce, observable on mammograms, than by physical detection. The comedo or solid form fills small mammary ducts and is likely to undergo central necrosis. The central detritus within ducts undergoes dystrophic calcification, producing fine punctate and even linear calcification, which is seen first on mammography long before invasive disease develops into a palpable mass. Clearly, these are early lesions that can be approached in a different manner from that for usual invasive disease. Treatment recommendations for patients with intraductal carcinoma are based on consideration of several issues, including (1) occult invasive cancer coexisting with the *in situ* lesion, (2) multicentricity of intraductal carcinoma, (3) the occurrence of disease in the contralateral breast, and (4) the natural history after diagnosis by biopsy.

Axillary metastases are very rare in lesions that appear to be pure intraductal cancers. In the three studies just listed, a total of 316 intraductal carcinomas were studied. Axillary metastases

were present in only 5 of these; in one case a second primary invasive cancer in the ipsilateral breast was present. Although not all patients underwent axillary dissection, there were no nodal recurrences during the follow-up of these patients. Significantly, all patients with positive nodes had large tumors, palpable tumors, or microscopic invasion

Many authors who have written about intraductal carcinoma are influenced by the high incidence of multicentric, multifocal, and even bilateral disease. *Multifocal* is a term referring to disease within the vicinity or same quadrant as the dominant lesion. Multicentric refers to disease in distant sites or quadrants within the same breast. Bilateral implies the concurrent finding of disease in both breasts. The existence of multicentric disease has led many to favor mastectomy for the treatment of DCIS, and concerns about bilaterality have prompted the use of prophylactic procedures on the contralateral breast. The most widely reported figure for the incidence of multicentric disease within the ipsilateral breast is 33%, or one third of cases in which a biopsy discloses intraductal cancer as the predominant lesion. However, estimates vary depending on how extensively other quadrants of the breast are examined. For example, although a large review of NSABP material failed to find multicentric disease, only a single random section from remote quadrants was examined. In contrast, Schwartz reported an incidence of approximately 37% after examining four random sections from each remote quadrant and from under the areola. Other estimates range between the results of these two studies. The risk of multicentric disease appears to depend both on the histologic type of the intraductal tumor and on the size or extent of the primary cancer. In the study of Lagios and associates, 2 of 24 small tumors less than 2 cm. (8%) were associated with disease in other quadrants of the breast. In moderate size tumors, between 2 and 5 cm., 2 breasts of 16 examined (12.5%) had multicentric disease. In large tumors whose extent was greater than 5 cm., all 13 cases examined had disease in remote quadrants of the ipsilateral breast. The study of Patchefsky and colleagues examined multicentricity as a function of the histology of the primary tumor. In agreement with other authors, this series found that micropapillary pathology was associated with a high (80%) incidence of multicentric disease. An intermediate percentage (40%) of papillary and comedocarcinomas were associated with remote disease, and solid and cribriform types were lowest. Size was not noted in this study. Pathologic review of DCIS should include an estimate of size, a comment about pathologic margins, and assessment of multifocal disease within the surgical specimen. Histologic type should be noted and a statement made about the presence or absence of microscopic invasion.

Lobular Carcinoma in Situ

Lobular carcinoma *in situ* is a relatively uncommon disease that occurs predominantly in younger, premenopausal women. As noted earlier, this disease is rarely diagnosed before biopsy, does not form a palpable mass, and rarely calcifies. Haagensen has collected the largest series of patients, all of whom were identified by review of biopsy material. In this review, LCIS was found in 3.6% of more than 5000 biopsies done for benign disease. Haagensen prefers the term *lobular neoplasia* to emphasize that this pathologic entity predisposes to subsequent carcinoma after a long latency period. However, in a review of 297 patients with

LCIS (lobular neoplasia) treated by biopsy and careful observation, Haagensen determined the actuarial probability of developing carcinoma at the end of 35 years was 21.4%. Compared with the Connecticut Tumor Registry data, a risk ratio (observed to expected cases) of 7:1 was calculated. Significantly, 40% of the carcinomas that subsequently developed were purely *in situ* lesions and one half of all subsequent carcinomas occurred in the contralateral breast. Haagensen preferred a practice of close observation after a biopsy diagnosis of LCIS. Similar data have led others to express doubts about the need for mastectomy. These authors have recommended a conservative policy of close observation after a biopsy diagnosis of LCIS or lobular neoplasia.

METHODICAL INSTRUCTIONS FOR 4th YEAR STUDENTS

METHODOLOGICAL INSTRUCTION TO LESSON №7 "ABDOMINAL HERNIAS "

The aim. To master clinics, diagnostics, differential diagnostics of reducible and complicated abdominal hernias. To choose the treatment tactics, indications and contraindications for operative intervention, analgesia, type of plastics, principles of postoperative period course, expertise of the ability to work and the rehabilitation after operations for hernias.

Professional orientation of students. Abdominal hernias are common for 3-5% of population. Hernia limits the working ability of the hernia carrier and is a vitally dangerous illness due to eventual complications (incarceration, inflammation). The lethality at incarcerated hernias depend on many factors and therefore it ranges from 2 to 17% according to various authors.

Methodology of Practical Class 9.00-12.00.

Algorithm of communicative skills:

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened

Student's independent work program:

Theme №1. General herniology. Inguinal hernias.

1. Definitions: "Hernia", "Eventration", "Prolapse".
2. Classification of abdominal hernias. Hernias elements. Sliding hernias.
3. Causes of hernias.
4. General clinical signs of reducible hernias.
5. General principles of operative treatment of abdominal hernias.
6. Inguinal hernias. Classification. Clinical features.
7. Anatomic-topographic characteristics of inguinal area and channel.
8. Differential diagnosis of inguinal hernias.
9. Anatomic and physiological base of inguinal channel plastics in inguinal hernias treatment.
10. Peculiarities of operative treatment of congenital and sliding inguinal hernias.
11. Postoperative period after hernioplastics, prescriptions in the postoperative period.

Theme №2. Femoral, umbilical hernias, hernia of the linea alba, hernia of semilunar line (Spigelius').

1. Anatomic-topographic features of the femoral channel, linea alba, Spigelius' line and other "weak" sites of the abdominal wall.
2. Femoral hernias. Classification. Clinical features, differential diagnostics.

3. Principles of the operative treatment of femoral hernias.
4. Umbilical hernias. Classification. Clinical features, differential diagnostics.
5. Umbilical hernias. Operative treatment.
6. Hernias of the linea alba. Clinical features, differential diagnostics.
7. Hernias of the linea alba. Operative treatment principles.
8. Relapse and postoperative ventral hernias. Peculiarities of diagnostics, clinical course and curing tactics.
9. Usage of plastic materials of different origin in abdominal hernias treatment.

Theme №3. Hernial complications.

1. Classification of incarceration types.
2. Main clinical manifestation of hernial incarceration.
3. Peculiarities of diagnostics, differential diagnostics of incarceration depending on hernial localization.
4. General features of the operative treatment of hernial incarceration.
5. Peculiarities of the clinical course and curing tactics in retrograde hernial incarceration.
6. Parietal incarceration. Peculiarities of clinical course and curing tactics.
7. Peculiarities of clinical course and curing tactics in incarceration of sliding hernias.
8. Self reduction of incarcerated hernia. Curing tactics.
9. False hernia incarceration. Peculiarities of clinical course and curing tactics.
10. False reduction of incarcerated hernia. Peculiarities of clinical course and curing tactics.
11. Etiology of hernial irreducibility.
12. Clinical characteristics of the irreducible hernia.
13. Differential diagnostics of reducible and irreducible hernias.
14. Curing tactics in irreducible hernia.
15. Clinical characteristics and cause of hernial coprostasis.
16. Differential diagnostics of fecal and elastic hernial incarceration.
17. Curing tactics in hernial coprostasis.
18. Clinical characteristics and cause of inflamed hernia.
19. Differential diagnostics of inflamed and incarcerated hernias.
20. Differential diagnostics of inflamed and irreducible hernias.
21. Differential diagnostics of inflamed hernia and hernial coprostasis.
22. Curing tactics in inflamed hernia.
23. Hernia trauma. Peculiarities of diagnostics and curing tactics.

BREAK 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.

Basic level of knowledge and skills:

The student must know:

1. Anatomic and physiologic features of the anterior abdominal wall (weak sites of the abdominal wall).
2. Etiology, pathogenesis, classification of abdominal hernias and their complications.
3. Clinical characteristics of abdominal hernias of various localization.
4. Indications and contraindications for operative treatment of hernias, methods of hernial prophylaxis.
5. Typical variants of operative treatment of abdominal hernias of various localization.
6. Etiopathogenesis and classification of complications of abdominal hernias.
7. Clinics, diagnostics, differential diagnostics of the incarcerated, irreducible, inflamed, traumatic hernias, hernial

coprosthesis.

8. Indications and contraindications for conservative and operative treatment of complicated hernias.
9. Main peculiarities of operative treatment of complicated hernias.

The student has to be able to:

1. To take anamnesis of the patient's with suspicion for abdominal hernia.
2. To reveal main clinical signs of complicated and uncomplicated abdominal hernias.
3. To palpate the sites of inguinal and femoral rings, hernial protrusions.
4. To formulate the primary diagnosis.
5. To plan the examination of the patients and explain the examination data (general blood analysis, general urine analysis, X-ray examination of abdominal organs), to formulate the clinical diagnosis.
6. To define indications and contraindications for operative intervention, to choose the proper preoperative preparation, anesthesia, operative access and type of plastics according to the clinical form of the abdominal hernia.

Technical means and material provision of lectures (names and numbers of tables, compact discs, instruments quantity, subjectpatients, etc.) –

Multimedia projection of demonstration material (pictures, tables, videofilms) from compact disc “Facultative Surgery”, file “Hernias”.

TEST EVALUATION AND SITUATIONAL TASKS 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions.

(the instructor has tests & situational tasks)

1. Which of the following statements regarding unusual hernias is incorrect?
 - A. An obturator hernia may produce nerve compression diagnosed by a positive Howship-Romberg sign.
 - B. Grynfeltt's hernia appears through the superior lumbar triangle, whereas Petit's hernia occurs through the inferior lumbar triangle.
 - C. Sciatic hernias usually present with a painful groin mass below the inguinal ligament.
 - D. Littre's hernia is defined by a Meckel's diverticulum presenting as the sole component of the hernia sac.
 - E. Richter's hernia involves the antimesenteric surface of the intestine within the hernia sac and may present with partial intestinal obstruction.

2. Staples may safely be placed during laparoscopic hernia repair in each of the following structures except:
 - A. Cooper's ligament.
 - B. Tissues superior to the lateral iliopubic tract.
 - C. The transversus abdominis aponeurotic arch.
 - D. Tissues inferior to the lateral iliopubic tract.
 - E. The iliopubic tract at its insertion onto Cooper's ligament.

3. The following Nyhus classification of hernias is correct except for:
 - A. Recurrent direct inguinal hernia—Type IVa.
 - B. Indirect inguinal hernia with a normal internal inguinal ring—Type I.
 - C. Femoral hernia—Type IIIc.
 - D. Direct inguinal hernia—Type IIIa.
 - E. Indirect inguinal hernia with destruction of the transversalis fascia of Hesselbach's triangle—Type II.

4. Which of the following statements about the causes of inguinal hernia is correct?
- A. Excessive hydroxyproline has been demonstrated in the aponeuroses of hernia patients.
 - B. Obliteration of the processus vaginalis is a contributing factor for the development of an indirect inguinal hernia.
 - C. Physical activity and athletics have been shown to have a protective effect toward the development of inguinal hernias.
 - D. Elevated levels of circulating serum elastolytic activity have been demonstrated in patients with direct herniation who smoke.
 - E. The majority of inguinal hernias are acquired.
5. The following statements about the repair of inguinal hernias are true except:
- A. The conjoined tendon is sutured to Cooper's ligament in the Bassini hernia repair.
 - B. The McVay repair is a suitable option for the repair of femoral hernias.
 - C. The Shouldice repair involves a multilayer, imbricated repair of the floor of the inguinal canal.
 - D. The Lichtenstein repair is accomplished by prosthetic mesh repair of the inguinal canal floor in a tension-free manner.
 - E. The laparoscopic transabdominal preperitoneal (TAPP) and totally extraperitoneal approach (TEPA) repairs are based on the preperitoneal repairs of Cheattle, Henry, Nyhus, and Stoppa.
6. What hernia is called sliding?
- A. Which is reducible
 - B. Which contains two or more organs
 - C. Which contains intraperitoneal organ
 - D. Which contains retroperitoneal organ
 - E. One of the wall of its hernial sac is represented by mesoperitoneal organ

The answers for the self-checking tests.

1 – C.

2 – D.

3 – E.

4 – D.

5 – A.

6 – E

METHODICAL INSTRUCTIONS FOR 4th YEAR STUDENTS

METHODOLOGICAL INSTRUCTION TO LESSON №1 " ACUTE APPENDICITIS "

The aim. To master clinics, diagnostics, differential diagnostics of the acute simple, complicated and chronic appendicitis, peculiarities of acute appendicitis course in children, elderly people, pregnant women. To learn the treatment tactics, indications and contraindications for operative intervention, operative intervention, principles of postoperative period course, expertise of the working ability to and the reablement.

Professional orientation of students. Acute appendicitis is the most frequent urgent surgical illness. Its share makes up 60-70% of all urgent surgical illnesses. The lethality after appendectomy varies in the ranges of 0,1-0,15% and is determined also by diagnostic mistakes at untypical forms of the acute appendicitis, by diseases in children, elderly people and pregnant women

Methodology of Practical Class 9.00-12.00.

Algorithm of communicative skills:

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened

Student's independent work program:

Theme №1. Acute noncomplicated appendicitis.

1. Clinical and pathanatomic classification of the acute appendicitis.
2. Clinical picture of the acute simple appendicitis
3. Clinical picture of the acute destructive appendicitis
4. Differential diagnosis of the acute appendicitis with the acute cholecystitis.
5. Differential diagnosis of the acute appendicitis with the acute pancreatitis.
6. Differential diagnosis of the acute appendicitis with the acute ileus.
7. Differential diagnosis of the acute appendicitis with the perforating ulcer of the stomach and the duodenum.
8. Differential diagnosis of the acute appendicitis with the extrauterine pregnancy.
9. Differential diagnosis of the acute appendicitis with the rightsided renal colic.
10. Examination programme of the patient with the acute appendicitis before the operation.
11. Choice of anesthesia, access and tpe of intervention.
12. Postoperative period after appendectomy, prescriptions in the postoperative period.
13. Expertise of the disablement and reablement of patients after the appendectomy.

Theme №2. Acute complicated appendicitis (infiltrate, abscess, peritonitis, pylephlebitis). Untypical forms of the acute appendicitis. Peculiarities of the acute appendicitis course in children, elderly people and pregnant

women.

1. Classification of the acute appendicitis complications.
2. Clinics, diagnostics and treatment of the appendicular infiltrate.
3. Clinics, diagnostics and treatment of the appendicular abscess.
4. Clinics, diagnostics and treatment of the appendicular peritonitis.
5. Clinical features of the retrocecal appendicitis.
6. Clinical features of the acute appendicitis at the pelvic appendix.
7. Clinical features of the acute appendicitis at the subhepatic appendix.
8. Clinical features of the acute appendicitis at the medial appendix.
9. Peculiarities of clinical course of the diagnosis of the acute appendicitis in children.
10. Peculiarities of clinical course of the diagnosis of the acute appendicitis in elderly people.
11. Peculiarities of clinical course of the diagnosis of the acute appendicitis in pregnant women.

Theme №3. Chronic appendicitis.

1. Classification of the chronic appendicitis.
2. Subjective clinical signs of the chronic appendicitis.
3. Objective clinical signs of the chronic appendicitis.
4. Differential diagnosis of the chronic appendicitis with chronic disease of the abdominal cavity organs:
 - a) ulcerative disease of stomach and duodenum,
 - b) chronic cholecystitis,
 - c) chronic pancreatitis,
 - d) Krohn's disease,
 - e) unspecific ulcerative colitis,
 - f) chronic diseases of female genital organs.
5. Differential diagnosis of the chronic appendicitis with the renal lithiasis.
6. Differential diagnosis of the chronic appendicitis with the lumbosacral radiculitis.
7. Treatment of patients with the chronic appendicitis.
8. Expertise of the disablement and reablement of patients

BREAK 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.**Basic level of knowledge and skills:****The student must know:**

1. Anatomic and physiological features of the appendix.
2. Etiology, pathogenesis, classification of the acute and the chronic appendicitis and its complications.
3. Clinical characteristics of different forms of the acute and the chronic appendicitis.
4. Peculiarities the acute and the chronic appendicitis course in children.
5. Differential diagnostics of the acute and the chronic appendicitis.
6. Diagnostics peculiarities of the acute appendicitis complications (appendicular infiltrate, abscess, peritonitis, pylephlebitis, sepsis).
7. Major principles of treatment of the acute and the chronic appendicitis and their complications.
8. Principles of expertise of the disablement and reablement of patients who have undergone the appendectomy.

The student has to be able to:

1. To take the history of the patient with the suspect of the appendicitis.

2. To reveal main clinical signs and symptoms of different forms of the acute and the chronic appendicitis.
3. To argue and formulate the preliminary diagnosis.
4. To make a plan of the examination of the patient and explain the examination results (general blood test, general urine test, ultrasound diagnostics).
5. To define indications and contraindications for operative intervention, to choose properly the type anesthesia, operative access and tuype of intervention according to the clinical form of the appendicitis.

Technical means and material provision of lectures (names and numbers of tables, compact discs, instruments quantity, subjectpatients, etc.) –

Multimedia projection of demonstration material (pictures, tables, videofilms) from compact disc “Facultative Surgery”, file “Hernias”.

TEST EVALUATION AND SITUATIONAL TASKS 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions.

(the instructor has tests & situational tasks)

1. Which of the following most often initiates the development of acute appendicitis?
 - A. A viral infection.
 - B. Acute gastroenteritis.
 - C. Obstruction of the appendiceal lumen.
 - D. A primary clostridial infection.

2. The diagnosis of acute appendicitis is most difficult to establish in:
 - A. Persons aged 60 and older.
 - B. Women aged 18 to 35.
 - C. Infants younger than 1 year.
 - D. Pregnant women.

3. Once a diagnosis of acute appendicitis has been made and appendectomy decided upon, which of the following is/are true?
 - A. Prophylactic antibiotics should be administered.
 - B. Prophylactic antibiotics are not necessary unless there is evidence of perforation.
 - C. If the appendix is not ruptured and not gangrenous, antibiotics may be discontinued after 24 hours.
 - D. Multiple antibiotics are in all cases preferable to a single agent.

4. Which of the following statements about pyogenic abscess of the liver are true?
 - A. The right lobe is more commonly involved than the left lobe.
 - B. Appendicitis with perforation and abscess is the most common underlying cause of hepatic abscess.
 - C. Mortality is largely determined by the underlying disease.
 - D. Mortality from hepatic abscess is currently greater than 40%.

5. Acute appendicitis is most commonly associated with which of the following signs?
 - A. Temperature above 104c F.
 - B. Frequent loose stools.

- C. Anorexia, abdominal pain, and right lower quadrant tenderness.
D. White blood cell count greater than 20,000 per cu. mm.
6. What manifestation is predominant for retroperitoneal appendicitis?
A. Clinic of acute abdomen
B. Dyspeptic syndrome
C. Clinic of retroperitoneal phlegmon
D. Clinic of acute intestinal obstruction
E. Clinic of acute pancreatitis
7. What manifestation is predominant for pelvic appendicitis?
A. Clinic of acute abdomen
B. Clinic of irritation of pelvic organs (dysuria, pulling rectal pain, tenesmi)
C. Clinic of retroperitoneal phlegmon
D. Clinic of acute intestinal obstruction
E. Clinic of acute pancreatitis

The answers for the self-checking tests.

- 1 – C.
2 – C.
3 – A.
4 – D.
5 – C.
6 – C.
7 – B.

METHODICAL INSTRUCTIONS FOR 4th YEAR STUDENTS

METHODOLOGICAL INSTRUCTION TO LESSON №5 " ACUTE INTESTINAL OBSTRUCTION (AIO)"

The aim. To master clinics, diagnostics, differential diagnostics of various clinical forms of AIO. To learn the treatment tactics, indications and contraindications for operative intervention, operative intervention type at various clinical forms of AIO principles of postoperative period course, expertise of the working ability after operations for AIO.

Professional orientation of students. The acute intestinal obstruction makes up to 3,5% among the patients of surgical stationaries and up to 10% of patients with acute diseases of abdominal organs. The lethality at AIO according to different data, varies from 6 to 18-20%.

Methodology of Practical Class 9.00-12.00.

Algorithm of communicative skills:

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened

Student's independent work program:

Theme №1. Acute obstructive ileus.

1. Anatomic and physiologic data about the small and large intestines.
2. Definition of the concept and etiopathogenesis of the mechanical AIO.
3. Classification of AIO.
4. Reasons and types of the obstructive ileus.
5. Clinics, diagnostics, differential diagnostics of the obstructive ileus.
6. Differential diagnostics of the obstructive and strangulation intestinal obstruction
7. Verification methods of the obstructive ileus diagnosis.
8. Curing tactics choice at various clinical forms of the obstructive ileus.
9. Peculiarities of the preoperative preparation at various clinical forms of the obstructive ileus.
10. Principles of operative treatment, radical and palliative operations at the obstructive ileus.
11. Peculiarities of the postoperative period course, water-electrolytic and acid-alkaline balance correction after operations for the obstructive ileus.

Theme №2. Acute strangulate intestinal obstruction.

1. Classification of the strangulation intestinal obstruction.
2. Phases of clinical course of the strangulation intestinal obstruction.
3. Peculiarities of etiopathogenesis of the strangulation intestinal obstruction.

4. Clinics, diagnostics, differential diagnostics of various types of the strangulation intestinal obstruction.
5. Differential diagnosis of the strangulation intestinal obstruction.
6. Modern verification methods of diagnosis (ultrasonic examination, laparoscopy, roengenologic methods).
7. Curing tactics at the strangulation intestinal obstruction.
8. Choice of scope and method of operative interventions at various clinical types of the strangulation intestinal obstruction.
9. Peculiarities of the preoperative preparation and postoperative period course at the strangulation intestinal obstruction.
10. Principles of operative treatment of the strangulation intestinal obstruction.
11. Peculiarities of the postoperative period course.

Theme №3. Paralytic intestinal obstruction.

1. Concept definition, reasons of the paralytic intestinal obstruction.
2. Classification of the paralytic intestinal obstruction.
3. Clinics, diagnostics, differential diagnostics of various clinical forms of the paralytic intestinal obstruction.
4. Differential diagnosis of mechanical and dynamic paralytic intestinal obstruction.
5. Methods of diagnosis verification of the paralytic intestinal obstruction.
6. Curing tactics and method choice of paralytic intestinal obstruction depending on a clinical version.
7. Stimulation methods of motor-evacuative intestinal function.

BREAK 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.

Basic level of knowledge and skills:

The student must know:

1. Anatomic and physiologic features of various intestines sections.
2. Topography of abdominal organs.
3. Etiopathogenesis of the intestinal obstruction. Classification of AIO.
4. Phases of clinical course of the acute mechanical intestinal obstruction.
5. Reasons, clinics, diagnosis, differential diagnosis of the obstructive ileus.
6. Types, clinics, diagnostics, differential diagnostics of the strangulation intestinal obstruction.
7. Verification methods of diagnosis of the acute mechanical intestinal obstruction.
8. Peculiarities of water-electrolytic balance violations at AIO.
9. Curing tactics at AIO.
10. Choice of methods of conservative and operative treatment of patients with mechanical AIO.
11. Peculiarities of the preoperative preparation and principles of operative treatment of patients with mechanical AIO.
12. Correction principles of water-electrolytic and acid-alkaline balance violations and energetic balance in patients with AIO.
13. Expertise principles of the patients after operations for AIO.
14. Reasons, clinics, diagnosis, differential diagnosis of paralytic AIO.
15. Reasons, clinics, diagnosis, differential diagnosis of spastic AIO.

The student has to be able to:

- 1.To take the history of the patient with the suspect for AIO.
- 2.To reveal main clinical features and symptoms at various clinical forms of the obturative ileus.
- 3.To reveal main clinical features and symptoms at various clinical forms of the strangulation AIO.
- 4.To reveal main clinical features and symptoms at various clinical forms of the dynamic AIO.
- 5.To define free and limited liquid in the abdominal cavity, splash noise, characteristics of peristaltic violations.
- 6.To argue and explain the preliminary diagnosis.
- 7.To make a plan of patient examination and explain the examination results (general blood test, general urine test, roentgenologic examination of the alimentary tract, general view roentgenogram, barium passage, irriography, ultrasonic examination, biochemical blood test).
- 8.To define indications and contraindications for operative intervention, to choose properly the preoperative preparation, anesthesia type, operative access and type of intervention according to the clinical form of mechanical AIO.
- 9.To define principles of conservative treatment of the dynamic AIO.

TEST EVALUATION AND SITUATIONAL TASKS 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions.
(the instructor has tests & situational tasks)

1. History and physical examination permit the diagnosis of intestinal obstruction in most cases. Which of the following are important for the clinical diagnosis of small bowel obstruction?
 - A. Crampy abdominal pain.
 - B. Fever.
 - C. Vomiting.
 - D. Abdominal distention.
 - E. Leukocyte count above 12,000.
 - F. Abdominal tenderness.
2. Patients with established, complete, simple, distal small bowel obstruction usually have the following findings on plain and upright abdominal radiographs:
 - A. Distended small bowel identifiable by the valvulae conniventes.
 - B. Multiple air-fluid levels.
 - C. Modest amount of gas in the pelvis.
 - D. Peripheral, rather than central, distribution of gas.
 - E. Prominent haustral markings.
 - F. Free air.
3. Which of the following statement(s) about gallstone ileus is/are not true?
 - A. The condition is seen most frequently in women older than 70.
 - B. Concomitant with the bowel obstruction, air is seen in the biliary tree.
 - C. The usual fistula underlying the problem is between the gallbladder and the ileum.
 - D. When possible, relief of small bowel obstruction should be accompanied by definitive repair of the fistula since there is a significant incidence of recurrence if the fistula is left in place.
 - E. Ultrasound studies may be of help in identifying a gallstone as the obstructing agent.
4. Complete mechanical small bowel obstruction can cause dehydration by:

- A. Interfering with oral intake of water.
- B. Inducing vomiting.
- C. Decreasing intestinal absorption of water.
- D. Causing secretion of water into the intestinal lumen.
- E. Causing edema of the intestinal wall.

The answers for the self-checking tests.

1 – A,B,C,D,F.

2 – A,B.

3 – C.

4 – A,B,C,D,E.

METHODICAL INSTRUCTIONS FOR 4th YEAR STUDENTS

METHODOLOGICAL INSTRUCTION TO LESSON №2 " ACUTE CHOLECISTITIS, CHOLELITHIASIS "

The aim. To master clinics, diagnostics, differential diagnostics of various clinical forms of the cholelithiasis and pancreatitis. To learn to choose the treatment tactics, indications and contraindications for operative intervention, analgesia type, operative intervention type, principles of postoperative period course, expertise of the working ability after operations for biliary ducts and pancreas.

Professional orientation of students. Cholelithiasis and pancreatitis is the most frequent surgical illness of outer biliary ducts. The disease is constantly growing and is covering now up to 10-15% of the population; it is especially common for women after 40-50. Cholecystectomy still remains the main surgical treatment method. During the recent years endoscopic (laparoscopic) operative interventions on biliary ducts have become widely used in surgical practice.

Methodology of Practical Class 9.00-12.00.

Algorithm of communicative skills:

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints. Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened.

Student's independent work program:

Theme №1. Acute and chronic calculous cholecystitis.

1. Anatomic and physiologic data about extrahepatic biliary ducts.
2. Concept definition of etiopathogenesis of cholelithiasis.
3. Classification of the cholelithiasis.
4. Classification of the acute calculous cholecystitis.
5. Clinics, diagnostics, differential diagnostics of the acute simple calculous cholecystitis.
6. Clinics, diagnostics, differential diagnostics of the acute destructive calculous cholecystitis.
7. Clinics, diagnostics, differential diagnostics of the acute complicated calculous cholecystitis (perivesical infiltrate, abscess, gallbladder empyema, perforating cholecystitis, peritonitis, cholangitis, obstructive jaundice, cholepancreatitis).
8. Choice of treatment tactics at various clinical forms of the acute calculous cholecystitis.
9. Scope and methods of conservative and operative treatment of the acute calculous cholecystitis.
10. Peculiarities of the postoperative period course.
11. Classification of the chronic calculous cholelithiasis.
12. Clinical characteristics, diagnosis, differential diagnostics of the noncomplicated chronic calculous cholecystitis.
13. Clinical characteristics, diagnosis, differential diagnostics of the complicated chronic calculous cholecystitis (chronic empyema, gallbladder hydrops).

14. Modern methods of verification of chronic calculous cholecystitis diagnosis.
15. Choice of scope and methods of operative interventions at various clinical forms of chronic calculous cholecystitis.
16. Methods of intraoperative examination of biliary ducts
17. Peculiarities of the postoperative period course.
18. Disablement expertise after operations for the chronic calculous cholecystitis.

Theme №2. Obstructive jaundice.

1. Biochemical peculiarities of the bilirubin metabolism.
2. Jaundice classification.
3. Obstructive jaundice classification.
4. Differential diagnosis of the mechanical and parenchymatous jaundice.
5. Differential diagnosis of the mechanical and hemolytic jaundice.
6. Verification methods of obstructive jaundice reasons.
7. Peculiarities of the preoperative preparation of patients with obstructive jaundice.
8. Types of operative interventions which are used at various clinical versions of the obstructive jaundice.
9. Peculiarities of the postoperative period course after operations for obstructive jaundice.

Theme №3. Acute pancreatitis.

1. Anatomic and physiologic features of the pancreas.
2. Concept definition and pathogenesis of the acute pancreatitis.
3. Classification of the acute pancreatitis.
4. Clinics, diagnostics, differential diagnostics of the acute edematous pancreatitis.
5. Clinics, diagnostics, differential diagnostics of the acute hemorrhagic pancreatitis. 6. Cholecystopancreatitis. Clinics, diagnostics.
7. Curing tactics choice at various clinical forms of the acute pancreatitis.
8. Methods of conservative treatment of the acute pancreatitis.
9. Classification of the acute pancreatitis complications.
10. Clinical characteristics, diagnostics, differential diagnostics of the pancreatogenic fermentative peritonitis.
11. Clinical characteristics, diagnostics, differential diagnostics of the necrotic pancreatitis (pancreonecrosis).
12. Modern verification methods of diagnosis (ultrasonic examination, laparocentesis, laparoscopy).
13. Curing tactics at the acute complicated pancreatitis.
14. Choice of the scope and operative intervention method at various clinical forms of the acute complicated pancreatitis.
15. Clinical characteristics, diagnostics, differential diagnostics of the false cyst of the pancreas and its complications.
16. Choice of the scope and methods of conservative and operative treatment of patients with the false cyst of the pancreas.
17. Peculiarities of the postoperative period course.

BREAK 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.

Basic level of knowledge and skills:

The student must know:

1. Anatomic and physiologic data about the liver and the outer biliary ducts.
2. Modern theories and stages of biliary lithogenesis.
3. Definition and classification of various clinical forms of the cholelithiasis.
4. Modern pre-, intra- and postoperative examination methods of biliary ducts.
5. Clinical and biochemical characteristics of violations of hepatic functions at cholelithiasis.
6. Clinics, diagnostics, differential diagnostics of various clinical forms of the cholelithiasis (acute and chronic calculous cholecystitis, choledocholithiasis, biliodigestive fistula).
7. Indications and contraindications for conservative or operative treatment of various clinical versions of the cholelithiasis.
8. Peculiarities of the preoperative preparation.
9. Types of operative interventions at various clinical forms of the cholelithiasis.
10. Peculiarities of the postoperative period course.
11. Anatomic and physiologic features of the pancreas.
12. Modern theories of appearance of acute and chronic pancreatitis.
13. Acute pancreatitis classification.
14. Chronic pancreatitis classification.
15. Clinical and biochemical characteristics of secretory and excretory functions of the pancreas.
16. Clinics, diagnostics, differential diagnostics and curing tactics choice at various clinical forms of acute pancreatitis.
17. Clinics, diagnostics, differential diagnostics and curing tactics choice at various clinical forms of chronic pancreatitis.
18. Curing tactics at the acute pancreatitis.
19. Indications and contraindications for conservative and operative treatment of various clinical forms of acute pancreatitis.
20. Complex of conservative treatment of acute pancreatitis.
21. Types of operative interventions at various clinical forms of acute pancreatitis.
22. Complex of conservative treatment of chronic pancreatitis.
23. Types of operative interventions at various clinical forms of chronic pancreatitis.
24. Peculiarities of postoperative period course after operations at acute and chronic pancreatitis.

The student has to be able to:

1. To take the history of the patient with the suspect for the cholelithiasis.
2. To reveal main clinical features and symptoms at various clinical forms of the cholelithiasis.
3. To perform the palpation of the gallbladder.
4. To argue and formulate the preliminary diagnosis.
5. To make a plan of the examination of the patient and explain the examination results (general blood test, general urine test, duodenal intubation, roentgenologic examination of biliary ducts, ultrasonic examination, biochemical blood test).
6. To define indications and contraindications for operative intervention, to choose properly the preoperative preparation, anesthesia type, operative access and type of intervention according to the clinical form of the cholelithiasis.
7. To reveal main clinical features and symptoms at various clinical forms of acute pancreatitis.
8. To perform palpation of the pancreas.
9. To argue and formulate the preliminary diagnosis.
10. To make a plan of the examination of the patient and explain the examination results (general blood test, general urine test, duodenal intubation, roentgenologic examination of biliary ducts and pancreas, ultrasonic examination, biochemical blood test < KT).
11. To define curing tactics, indications and contraindications for operative intervention, to choose properly the preoperative preparation, anesthesia type, operative access and type of intervention according to the clinical form of acute and chronic pancreatitis.

TEST EVALUATION AND SITUATIONAL TASKS 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions.

(the instructor has tests & situational tasks)

1. Which of the following statements about the diagnosis of acute calculous cholecystitis are true?
 - A. Pain is so frequent that its absence almost precludes the diagnosis.
 - B. Jaundice is present in a majority of patients.
 - C. Ultrasonography is the definitive diagnostic test.
 - D. Cholescintigraphy is the definitive diagnostic test.

2. Which statements about acute acalculous cholecystitis are correct?
 - A. The disease is often accompanied by or associated with other conditions.
 - B. The diagnosis is often difficult.
 - C. The mortality rate is higher than that for acute calculous cholecystitis.
 - D. The disease has been treated successfully by percutaneous cholecystostomy.

3. True statements about the surgical management of patients with acute calculous cholecystitis include:
 - A. Operation should be performed in all patients as soon as the diagnosis is made.
 - B. Antibiotic therapy should be initiated as soon as the diagnosis is made.
 - C. Dissection of the gallbladder is facilitated by decompression of the organ with the use of a trocar.
 - D. An operative cholangiogram should be done in every patient.

4. Which of the following are indications for cholecystectomy?
 - A. The presence of gallstones in a patient with intermittent episodes of right-side upper quadrant pain.
 - B. The presence of gallstones in an asymptomatic patient.
 - C. The presence of symptomatic gallstones in a patient with angina pectoris.
 - D. The presence of asymptomatic gallstones in a patient who has insulin-dependent diabetes.

5. Which of the following statements about laparoscopic cholecystectomy are correct?
 - A. The procedure is associated with less postoperative pain and earlier return to normal activity.
 - B. The incidence of bile duct injury is higher than for open cholecystectomy.
 - C. Laparoscopic cholecystectomy should be used in asymptomatic patients because it is safer than open cholecystectomy.
 - D. Pregnancy is a contraindication.

6. Which of the following statements about cholangitis are correct?
 - A. Charcot's triad is always present.
 - B. Associated biliary tract disease is always present.
 - C. Chills and fever are due to the presence of bacteria in the bile duct system.
 - D. The most common cause of cholangitis is choledocholithiasis.

7. The initial goal of therapy for acute toxic cholangitis is to:
 - A. Prevent cholangiovenous reflux by decompressing the duct system.
 - B. Remove the obstructing stone, if one is present.

- C. Alleviate jaundice and prevent permanent liver damage.
E. Prevent the development of gallstone pancreatitis.
8. Which of the following parameters is/are not included in the Ranson's prognostic signs useful in the early evaluation of a patient with acute pancreatitis?
A. Elevated blood glucose.
B. Leukocytosis.
C. Amylase value greater than 1000 U per dl.
D. Serum lactic dehydrogenase (LDH) greater than 350 IU per dl.
E. Alanine aminotransferase greater than 250 U per dl.
9. Standard supportive measures for patients with mild pancreatitis include the following:
A. Intravenous fluid and electrolyte therapy.
B. Withholding of analgesics to allow serial abdominal examinations.
C. Subcutaneous octreotide therapy.
D. Nasogastric decompression.
E. Prophylactic antibiotics.
10. Which of the following statements about chronic pancreatitis is/are correct?
A. Chronic pancreatitis is the inevitable result after repeated episodes of acute pancreatitis.
B. Patients with chronic pancreatitis commonly present with jaundice, pruritus, and fever.
C. Mesenteric angiography is useful in the evaluation of many patients with chronic pancreatitis.
D. Total pancreatectomy usually offers the best outcome in patients with chronic pancreatitis.
E. For patients with disabling chronic pancreatitis and a dilated pancreatic duct with associated stricture formation, a longitudinal pancreaticojejunostomy (Peustow procedure) is an appropriate surgical option.
11. Which of the following statements about pancreatic ascites is/are correct?
A. Patients typically present with painful ascites, reflecting the release of toxic pancreatic enzymes into the peritoneal cavity.
B. The standard evaluation of a patient with new-onset ascites includes abdominal paracentesis. In cases of pancreatic ascites, the peritoneal fluid contains high concentrations of both amylase and protein.
C. Pancreatic ascites can follow an episode of acute pancreatitis.
D. Patients with pancreatic ascites may fail to improve with nonoperative therapy and require surgical procedures. At abdominal exploration an acceptable approach to the pancreatic duct disruption involves suture ligation with omental patching.
12. Which of the following statements about adenocarcinoma of the pancreas is/are correct?
A. It is the fifth most common cause of cancer death in the U.S.
B. Most cases occur in the body and tail of the pancreas, making distal pancreatectomy the most commonly performed resectional therapy.
C. For cancers of the head of the pancreas resected by pancreaticoduodenectomy, prognosis appears to be independent of nodal status, margin status, or tumor diameter.
D. The most accurate screening test involves surveillance of stool for carbohydrate antigen (CA 19-9).

The answers for the self-checking tests.

1 – A,D.

2 – A,B,C,D.

3 – B,C.

4 – A.

5 – A,B.

6 – B,C,D.

7 – A.

8 – C,E.

9 – A.

10 – E.

11 – B.

12 – A.

METHODICAL INSTRUCTIONS FOR 4th YEAR STUDENTS

METHODOLOGICAL INSTRUCTION TO LESSON №12 " DISEASES OF THE RECTUM AND THE COLON "

The aim. To master clinics, diagnostics, differential diagnostics of diseases of rectum and colon: hemorrhoids, anal fissures, acute and chronic paraproctitis, Crohn's disease, nonspecific ulcerative colitis, rectal prolapse. To learn the treatment tactics, indications and contraindications for conservative and operative treatment, analgesia type, operative intervention type, principles of the pre- and postoperative periods, expertise of the working ability after operations on rectum and colon.

Professional orientation of students. Diseases of the rectum and the colon are very common for people regardless their sex, especially in mature and elderly age. Say, 10-20% of the population suffer with hemorrhoids, 0,5-6,1% of people of able to work age have rectal fistulas. Therefore, a doctor of any profile, especially a family one, must be accustomed with the peculiarities of curing-diagnostic tactics at those illnesses.

Methodology of Practical Class 9.00-12.00.

Algorithm of communicative skills:

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints. Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened.

Student's independent work program:

Theme №1. Hemorrhoids. Anal fissures.

1. Anatomic and physiologic data about the rectum.
2. Topography of cellular spaces of the pelvis.
3. Semiotics of the rectum diseases.
4. Hemorrhoids. Concept definition. Classification.
5. Clinical characteristics of the hemorrhoids.
6. Hemorrhoids complications (prolapse, thrombosis, strangulation, bleeding). Clinical characteristics.
7. Curing tactics at the hemorrhoids.
8. Methods of the conservative treatment of the hemorrhoids.
9. Indications and methods of the operative treatment of the hemorrhoids.
10. Peculiarities of the preoperative preparation and the postoperative period course in patients with the hemorrhoids.
11. Anal fissure. Concept definition, classification.
12. Clinical features of anal fissures depending on the clinical form.
13. Curing tactics and treatment of anal fissures depending on the clinical form.

Theme №2. Acute and chronic paraproctitis.

1. Acute paraproctitis. Concept definition, classification.
2. Clinics, diagnostics and differential diagnostics of the acute subcutaneous paraproctitis.
3. Clinics, diagnostics and differential diagnostics of the acute ischiorectal paraproctitis.
4. Clinics, diagnostics and differential diagnostics of the acute pelvirectal paraproctitis.
5. Curing tactics choice at the acute paraproctitis depending on the clinical form and the stage of the inflammatory process.
6. Chronic paraproctitis. Concept definition, classification.
7. Clinical signs, diagnostics of the chronic paraproctitis depending on the clinical form.
8. Fistulography – the main method of diagnosis verification: preparation, performance techniques, results assessment.
9. Features of the preoperative preparation and operative treatment of patients with the chronic paraproctitis.
10. Expertise of the disablement of patients after operations for acute and chronic paraproctitis.

Theme №3. Nonspecific ulcerative colitis (NUC).

1. Concept definition. Classification.
2. Clinical characteristics of the NUC depending on the clinical form and course stage.
3. Clinics, diagnostics and differential diagnosis of NUC complications.
4. Diagnosis verification methods (irrigography, colonoscopy, biopsy).
5. Curing tactics at NUC.
6. Principles of conservative and operative treatment of patients with NUC.
7. Clinics, diagnostics and differential diagnosis of various clinical forms of Crohn's disease.
8. Clinical characteristics of surgical complications of Crohn's disease.
9. Modern methods of diagnosis verification.
10. Curing tactics choice depending on the clinical form and complications of Crohn's disease.

BREAK 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.**Basic level of knowledge and skills:****The student must know:**

1. Anatomic and physiologic features of the rectum and the colon.
2. Topography of the rectum and the colon.
3. Classification of diseases of the rectum and the colon.
4. Hemorrhoids. Concept definition and classification.
5. Clinical characteristics, diagnostics and differential diagnostics of hemorrhoids depending on the clinical form and complications.
6. Curing tactics choice and treatment method of hemorrhoids depending on the clinical form and complications.
7. Methods of conservative and operative treatment of hemorrhoids.
8. Anal fissures. Classification.
9. Clinical characteristics of anal fissures depending on the clinical form.
10. Curing tactics and methods of conservative and operative treatment of anal fissures.
11. Acute paraproctitis. Concept definition and classification.
12. Clinics, diagnostics and differential diagnostics of the acute paraproctitis depending on the clinical form and stage of the inflammatory process.
13. Curing tactics and treatment methods of the acute paraproctitis depending on the clinical form and stage of the

inflammatory process.

14. Chronic paraproctitis. Concept definition and classification.

15. Clinical characteristics, diagnostics and differential diagnostics and diagnosis verification methods of chronic paraproctitis.

16. Curing tactics and treatment method of chronic paraproctitis depending on the clinical form.

17. Crohn's disease. Classification.

18. Clinical characteristics of Crohn's disease depending on the clinical form and course stage, complications.

19. Curing tactics and methods of conservative and operative treatment of Crohn's disease depending on the clinical form, course stage and complications.

20. Nonspecific ulcerative colitis (NUC). Concept definition and classification.

21. NUC clinics depending on the allocation, clinical course, complications.

22. Verification methods of NUC diagnosis.

23. Curing tactics and principles of conservative and operative treatment of NUC depending on the clinical form, course and complications.

24. Rectal prolapse. Concept definition and classification.

25. Clinics of the rectal prolapse depending on the course stage.

26. Curing tactics and treatment methods of the rectal prolapse depending on the course stage.

The student has to be able to:

1. To take the history of the patient with the rectum and the colon diseases.

2. To elicit major clinical signs and symptoms of diseases of the rectum and the colon.

3. To perform rectal examination of the rectum.

4. To make a plan of patient's examination and to explain the examination results (general blood test, general urine test, roentgenologic examinations (irrigoscopy, irrigography, fistulography), ultrasonic examination, biochemical blood test, anoscopy, colonoscopy, biopsy, rectoromanoscopy).

5. To define curing tactics, indications and contraindications for an operative intervention to choose properly the preoperative preparation, anesthesia type, operative access and type of intervention according to the clinical form of the disease, its course, inflammatory process stage, complications.

TEST EVALUATION AND SITUATIONAL TASKS 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions.

(the instructor has tests & situational tasks)

1. Which of the following statements about hemorrhoids is/are not true?

A. Hemorrhoids are specialized "cushions" present in everyone that aid continence.

B. External hemorrhoids are covered by skin whereas internal hemorrhoids are covered by mucosa.

C. Pain is often associated with uncomplicated hemorrhoids.

D. Hemorrhoidectomy is reserved for third- and fourth-degree hemorrhoids.

2. Which answers are true? In contrast to ulcerative colitis, Crohn's disease of the colon:

A. Is not associated with increased risk of colon cancer.

B. Seldom presents with daily hematochezia.

C. Is usually segmental rather than continuous.

D. Has a lower incidence of perianal fistulas.

E. Never develops toxic megacolon.

3. Which of the following statements about the etiology of chronic ulcerative colitis are true?
- A. Ulcerative colitis is 50% less frequent in nonwhite than in white populations.
 - B. Psychosomatic factors play a major causative role in the development of ulcerative colitis.
 - C. Cytokines are integrally involved in the pathogenesis of ulcerative colitis.
 - D. Ulcerative colitis has been identified with a greater frequency in family members of patients with confirmed inflammatory bowel disease.
 - E. Ulcerative colitis is two to four times more common in Jewish than in non-Jewish populations.
4. Surgical alternatives for the treatment of ulcerative colitis include all of the following except:
- A. Colectomy with ileal pouch–anal anastomosis.
 - B. Left colectomy with colorectal anastomosis.
 - C. Proctocolectomy with Brooke ileostomy or continent ileostomy.
 - D. Subtotal colectomy with ileostomy and Hartmann closure of the rectum.
5. The initial management of toxic ulcerative colitis should include:
- A. Broad-spectrum antibiotics.
 - B. 6-Mercaptopurine.
 - C. Intravenous fluid and electrolyte resuscitation.
 - D. Opioid antidiarrheals.
 - E. Colonoscopic decompression.
6. Which finding(s) suggest(s) the diagnosis of chronic ulcerative colitis as opposed to Crohn's colitis?
- A. Endoscopic evidence of backwash ileitis.
 - B. Granulomas on biopsy.
 - C. Anal fistula.
 - D. Rectal sparing.
 - E. Cobblestone appearance on barium enema.
7. Axial twisting of the right colon or cecal volvulus has been shown to be associated with each of the following except:
- A. A history of abdominal operation.
 - B. A mobile cecum.
 - C. An obstructing lesion in the transverse or left colon.
 - D. Inflammatory bowel disease.

The answers for the self-checking tests.

1 – C.

2 – B,C.

3 – A,C,D,E.

4 – B.

5 – A,C.

6 – A.

7 – D.

Therefore, a doctor of any profile, especially a family one, must be accustomed with the peculiarities of curing-diagnostic tactics at those illnesses.

Methodology of Practical Class 9.00-12.00.

Algorithm of communicative skills:

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints. Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened.

Student's independent work program:

Theme №1. Hemorrhoids. Anal fissures.

1. Anatomic and physiologic data about the rectum.
2. Topography of cellular spaces of the pelvis.
3. Semiotics of the rectum diseases.
4. Hemorrhoids. Concept definition. Classification.
5. Clinical characteristics of the hemorrhoids.
6. Hemorrhoids complications (prolapse, thrombosis, strangulation, bleeding). Clinical characteristics.
7. Curing tactics at the hemorrhoids.
8. Methods of the conservative treatment of the hemorrhoids.
9. Indications and methods of the operative treatment of the hemorrhoids.
10. Peculiarities of the preoperative preparation and the postoperative period course in patients with the hemorrhoids.
11. Anal fissure. Concept definition, classification.
12. Clinical features of anal fissures depending on the clinical form.
13. Curing tactics and treatment of anal fissures depending on the clinical form.

Theme №2. Acute and chronic paraproctitis.

1. Acute paraproctitis. Concept definition, classification.
2. Clinics, diagnostics and differential diagnostics of the acute subcutaneous paraproctitis.
3. Clinics, diagnostics and differential diagnostics of the acute ischiorectal paraproctitis.
4. Clinics, diagnostics and differential diagnostics of the acute pelvirectal paraproctitis.
5. Curing tactics choice at the acute paraproctitis depending on the clinical form and the stage of the inflammatory process.
6. Chronic paraproctitis. Concept definition, classification.
7. Clinical signs, diagnostics of the chronic paraproctitis depending on the clinical form.
8. Fistulography – the main method of diagnosis verification: preparation, performance techniques, results assessment.
9. Features of the preoperative preparation and operative treatment of patients with the chronic paraproctitis.
10. Expertise of the disablement of patients after operations for acute and chronic paraproctitis.

Theme №3. Nonspecific ulcerative colitis (NUC).

1. Concept definition. Classification.
2. Clinical characteristics of the NUC depending on the clinical form and course stage.
3. Clinics, diagnostics and differential diagnosis of NUC complications.
4. Diagnosis verification methods (irrigography, colonoscopy, biopsy).
5. Curing tactics at NUC.
6. Principles of conservative and operative treatment of patients with NUC.
7. Clinics, diagnostics and differential diagnosis of various clinical forms of Crohn's disease.
8. Clinical characteristics of surgical complications of Crohn's disease.
9. Modern methods of diagnosis verification.
10. Curing tactics choice depending on the clinical form and complications of Crohn's disease.

BREAK 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.**Basic level of knowledge and skills:****The student must know:**

1. Anatomic and physiologic features of the rectum and the colon.
2. Topography of the rectum and the colon.
3. Classification of diseases of the rectum and the colon.
4. Hemorrhoids. Concept definition and classification.
5. Clinical characteristics, diagnostics and differential diagnostics of hemorrhoids depending on the clinical form and complications.
6. Curing tactics choice and treatment method of hemorrhoids depending on the clinical form and complications.
7. Methods of conservative and operative treatment of hemorrhoids.
8. Anal fissures. Classification.
9. Clinical characteristics of anal fissures depending on the clinical form.
10. Curing tactics and methods of conservative and operative treatment of anal fissures.
11. Acute paraproctitis. Concept definition and classification.
12. Clinics, diagnostics and differential diagnostics of the acute paraproctitis depending on the clinical form and stage of the inflammatory process.
13. Curing tactics and treatment methods of the acute paraproctitis depending on the clinical form and stage of the

inflammatory process.

14. Chronic paraproctitis. Concept definition and classification.

15. Clinical characteristics, diagnostics and differential diagnostics and diagnosis verification methods of chronic paraproctitis.

16. Curing tactics and treatment method of chronic paraproctitis depending on the clinical form.

17. Crohn's disease. Classification.

18. Clinical characteristics of Crohn's disease depending on the clinical form and course stage, complications.

19. Curing tactics and methods of conservative and operative treatment of Crohn's disease depending on the clinical form, course stage and complications.

20. Nonspecific ulcerative colitis (NUC). Concept definition and classification.

21. NUC clinics depending on the allocation, clinical course, complications.

22. Verification methods of NUC diagnosis.

23. Curing tactics and principles of conservative and operative treatment of NUC depending on the clinical form, course and complications.

24. Rectal prolapse. Concept definition and classification.

25. Clinics of the rectal prolapse depending on the course stage.

26. Curing tactics and treatment methods of the rectal prolapse depending on the course stage.

The student has to be able to:

1. To take the history of the patient with the rectum and the colon diseases.

2. To elicit major clinical signs and symptoms of diseases of the rectum and the colon.

3. To perform rectal examination of the rectum.

4. To make a plan of patient's examination and to explain the examination results (general blood test, general urine test, roentgenologic examinations (irrigoscopy, irrigography, fistulography), ultrasonic examination, biochemical blood test, anoscopy, colonoscopy, biopsy, rectoromanoscopy).

5. To define curing tactics, indications and contraindications for an operative intervention to choose properly the preoperative preparation, anesthesia type, operative access and type of intervention according to the clinical form of the disease, its course, inflammatory process stage, complications.

TEST EVALUATION AND SITUATIONAL TASKS 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions.

(the instructor has tests & situational tasks)

1. Which of the following statements about hemorrhoids is/are not true?

A. Hemorrhoids are specialized "cushions" present in everyone that aid continence.

B. External hemorrhoids are covered by skin whereas internal hemorrhoids are covered by mucosa.

C. Pain is often associated with uncomplicated hemorrhoids.

D. Hemorrhoidectomy is reserved for third- and fourth-degree hemorrhoids.

2. Which answers are true? In contrast to ulcerative colitis, Crohn's disease of the colon:

A. Is not associated with increased risk of colon cancer.

B. Seldom presents with daily hematochezia.

C. Is usually segmental rather than continuous.

D. Has a lower incidence of perianal fistulas.

E. Never develops toxic megacolon.

3. Which of the following statements about the etiology of chronic ulcerative colitis are true?
- A. Ulcerative colitis is 50% less frequent in nonwhite than in white populations.
 - B. Psychosomatic factors play a major causative role in the development of ulcerative colitis.
 - C. Cytokines are integrally involved in the pathogenesis of ulcerative colitis.
 - D. Ulcerative colitis has been identified with a greater frequency in family members of patients with confirmed inflammatory bowel disease.
 - E. Ulcerative colitis is two to four times more common in Jewish than in non-Jewish populations.
4. Surgical alternatives for the treatment of ulcerative colitis include all of the following except:
- A. Colectomy with ileal pouch–anal anastomosis.
 - B. Left colectomy with colorectal anastomosis.
 - C. Proctocolectomy with Brooke ileostomy or continent ileostomy.
 - D. Subtotal colectomy with ileostomy and Hartmann closure of the rectum.
5. The initial management of toxic ulcerative colitis should include:
- A. Broad-spectrum antibiotics.
 - B. 6-Mercaptopurine.
 - C. Intravenous fluid and electrolyte resuscitation.
 - D. Opioid antidiarrheals.
 - E. Colonoscopic decompression.
6. Which finding(s) suggest(s) the diagnosis of chronic ulcerative colitis as opposed to Crohn's colitis?
- A. Endoscopic evidence of backwash ileitis.
 - B. Granulomas on biopsy.
 - C. Anal fistula.
 - D. Rectal sparing.
 - E. Cobblestone appearance on barium enema.
7. Axial twisting of the right colon or cecal volvulus has been shown to be associated with each of the following except:
- A. A history of abdominal operation.
 - B. A mobile cecum.
 - C. An obstructing lesion in the transverse or left colon.
 - D. Inflammatory bowel disease.

The answers for the self-checking tests.

1 – C.

2 – B,C.

3 – A,C,D,E.

4 – B.

5 – A,C.

6 – A.

7 – D.

METHODICAL INSTRUCTIONS FOR 4th YEAR STUDENTS

METHODOLOGICAL INSTRUCTION TO LESSON №12 "DISEASES OF THE THYROID AND MAMMARY GLAND"

The aim. To master clinics, diagnostics, differential diagnostics of various clinical forms of goiter, thyroiditis. To learn the treatment tactics, indications and contraindications for operative intervention, operative intervention type at various clinical forms of goiter, principles of postoperative period course, expertise of the working ability after operations for endemic, sporadic, diffuse toxic goiters, thyroidites.

Professional orientation of students. Thyroid gland diseases (endemic, sporadic, diffuse, toxic goiters, thyroidites) occupy the leading place among surgical illnesses of endocrine glands. The actuality of the problem is connected with the endemic character of many geographical regions of Ukraine and also with the accident at Chernobyl Power Atomic Station.

Methodology of Practical Class 9.00-12.00.

Algorithm of communicative skills:

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints. Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened.

Student's independent work program:

Theme №1. Endemic, sporadic goiter.

1. Anatomic and physiologic data about the thyroid gland.
2. Topography of the neck.
3. Definition of concepts of endemic area, stages of endemic gravity, endemic and sporadic goiter.
4. Concept definition and classification of endemic, sporadic goiter.
5. Classification of the thyroid gland enlargement stages.
6. Characteristics of various clinical versions of the endemic and sporadic goiter.
7. Peculiarities of the clinical picture of endemic goiter depending on the availability of violations of thyroid gland function, on compressive signs, morphologic characteristics.
8. Differential diagnostics of the endemic and sporadic goiter.
9. Verification methods of endemic goiter diagnosis.
10. Curing tactics at the thyroid gland diseases.
11. Principles of treatment method choice of patients with endemic goiter, indications for operative treatment.
12. Methods of operative treatment of patients with the endemic goiter.
13. Postoperative period course in patients with endemic, sporadic goiter.

Theme №2. Diffuse toxic goiter (DTG).

1. Concept definition, etiopathogenesis of DTG.
2. Classification of DTG.
3. Clinics, diagnostics, differential diagnostics of DTG.
4. Verification methods of DTG diagnosis.
5. Treatment tactics and curing method choice at DTG, indications for operative treatment.
6. Peculiarities of preoperative preparation of patients with DTG depending on the gravity stage of the thyroiditis.
7. Principles of operative treatment of patients with DTG.
8. Peculiarities of postoperative period course in patients with DTG.
9. Early and late complications after operations for DTG (reasons, clinics, prophylaxis, treatment).
10. Thyrotoxic crisis –reasons, classification, clinics, prophylaxis and treatment.
11. Disablement expertise after the subtotal resection of the thyroid gland.

Theme №3. Strumites, thyroidites.

1. Concept definition. Classification.
2. Clinics, diagnostics, differential diagnostics of the acute purulent thyroiditis (strumitis).
3. Clinics, diagnostics, differential diagnostics of the chronic Riedel's thyroiditis.
4. Clinics, diagnostics, differential diagnostics of chronic Hashimoto's and De Kerven's thyroidites.
5. Curing tactics at acute and chronic thyroidites, strumites.
6. Principles of conservative and operative treatment of patients with acute and chronic thyroidites.

BREAK 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.

Basic level of knowledge and skills:

The student must know:

1. Anatomic and physiologic features of the thyroid gland.
2. Topography of the neck (thyroid gland, cellular spaces).
3. Definition of concepts "goiter", "strumitis", "thyroiditis",.

4. Classification of the thyroid gland diseases.
5. Etiopathogenesis, clinics, diagnostics, differential diagnostics of the diffuse toxic goiter.
6. Etiopathogenesis, clinics, diagnostics, differential diagnostics of the endemic goiter.
7. Diagnostics and tactics at the acute thyroiditis.
8. Diagnostics and tactics at the chronic thyroiditis (Riedel's, Hashimoto's, de Kerven's).
9. Treatment tactics at the thyroid gland diseases.
10. Peculiarities of the preoperative preparation of patients with the thyroid gland diseases.
11. Principles of operative treatment of patients with various clinical forms of the goiter.
12. Peculiarities of the postoperative period course in patients after the resection of the thyroid gland, thyroidectomy.
13. Expertise principles of the disablement of patients after operations on the thyroid gland.

The student has to be able to:

1. To take the history of the patient with the suspect for the thyroid gland diseases.
2. To palpate the thyroid gland.
3. To elicit major clinical signs and symptoms at various clinical forms of the endemic goiter.
4. To elicit major clinical signs and symptoms at various clinical forms of the diffuse goiter.
5. To elicit major clinical signs of the acute and chronic thyroiditis.
6. To argue and explain the preliminary diagnosis.
7. To make a plan of patient's examination and to explain the examination results (general blood test, general urine test, roentgenologic examinations of the neck (general view roentgenogram), ultrasonic examination, biochemical blood test (hepatic probes, electrolytes, thyroxin, TTG).
8. To define indications and contraindications for an operative intervention to choose properly the preoperative preparation, anesthesia type, operative access and type of intervention according to the clinical form of the goiter and the gravity stage of the thyrotoxicosis.

TEST EVALUATION AND SITUATIONAL TASKS 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions. (the instructor has tests & situational tasks)

1. When progressive enlargement of a multinodular goiter causes symptomatic tracheal compression, the preferred management in otherwise good-risk patients is:
 - A. Iodine treatment.
 - B. Thyroid hormone treatment.
 - C. Surgical resection of the abnormal thyroid.
 - D. Radioactive iodine treatment.
2. The most precise diagnostic screening procedure for differentiating benign thyroid nodules from malignant ones is:
 - A. Thyroid ultrasonography.
 - B. Thyroid scintiscan.
 - C. Fine-needle-aspiration biopsy (FNAB).
 - D. Thyroid hormone suppression.
3. Therapy for Hashimoto's disease includes:
 - A. Radioiodine.
 - B. Antithyroid medications.
 - C. Subtotal thyroidectomy.
 - D. None of the above.
4. Which of the following statements is true about the synthesis of thyroid hormone and its physiology?
 - A. The iodine utilized in hormone synthesis is derived principally from dietary sources.
 - B. The role of thyroid-stimulating hormone (TSH) in thyroid physiology is limited to regulation of the release of thyroid hormone in plasma.
 - C. Enough thyroxine (T₄) is stored in the normal thyroid to provide a euthyroid state for 3 weeks despite absence of iodine intake.
 - D. The regulation of thyroid function involves pituitary, but not hypothalamic, input.
5. Correct statements about thyroid function tests include which of the following?
 - A. Contraceptive pills and pregnancy increase the amount of thyroxin-binding globulin (TBG), and, consequently, the total T₄ level.
 - B. Anticonvulsive medications and chronic debilitating illnesses decrease the amount of TBG and, consequently, the total T₄ level.
 - C. Intravenous pyleography can lower the rate of active iodine uptake by the thyroid.
 - D. A triiodothyronine (T₃) suppression test that demonstrates nonsuppressibility of thyroid function is compatible with the diagnosis of Graves' disease, toxic adenoma, or functioning carcinoma.
 - E. An increased serum cholesterol level in a hypothyroid patient indicates a thyroid cause.
6. Hyperthyroidism can be caused by all of the following except:
 - A. Graves' disease.
 - B. Plummer's disease.
 - C. Struma ovarii.
 - D. Hashimoto's disease.
 - E. Medullary carcinoma of the thyroid.
7. Arrange the following complications of thyroid surgery (bilateral subtotal thyroidectomy) in decreasing order of incidence in patients with Graves' disease.
 - A. Laryngeal nerve paralysis.
 - B. Hypoparathyroidism.
 - A. Hypothyroidism.
 - B. Recurrent hyperthyroidism.

The answers for the self-checking tests.

- 1 – C.
- 2 – C.
- 3 – D.
- 4 – A,C.
- 5 – A,B,C,D.
- 6 – E.
- 7 – A,B,C,D.

EMPLOYMENT № 13 (Practical - 7 hours.)
NEW TECHNOLOGIES IN SURGERY. MODERN METHODS OF DIAGNOSTIC AND TREATMENT

- Themes: 1. Endoscopic surgery, prospects and possibilities of modern endoscopic technologies.
2. X-Ray surgery. Surgery under the control sonography.
3. Telesurgery.

Purpose: to learn the modern approaches to operative medical treatment with the use of endoscopic technologies. To know prospects, possibilities and to be able to ground testimonies to implementation of endoscopic operative interferences. Learn modern approaches to operative medical treatment with the use of sonography and X-Ray control. To know prospects, possibilities and to be able to ground a testimony to implementation of operative interferences under the control sonography and X-Ray control. To know diagnostic potential of modern medical telecommunication equipment. To familiarize with the basic systems vehicles, which is used in remote diagnostics of surgical pathology. Learn the principles of action, testimonies and contra-indications to application and diagnostic value of modern telemedical equipment.

Professional orientation of students: subsequent development of surgery largely will be determined by endoscopic technologies. Laparoscopic cholecystectomy is today named a «gold standard». Progress in endoscopic surgery is connected with the improvement of apparatus, optical systems and instruments, provide which implementation of these operations. Development of hardware necessary for endoscopic operative interferences takes place the parallel with the improvement of methods. Pre- and intraoperative diagnostics has the important value at the decision of testimonies, choice of methods and volume of endoscopic operative interferences.

X-Ray surgery is a new perspective direction of clinical medicine. Main point of it consists in conducting of diagnostic inspections and medical manipulations under the X-Ray control. Successfully made X-Ray endovascular interferences can only experienced specialists, who well know X-Ray anatomy of the vessels, is able thinly to conduct the diagnostic and medical stages of procedure, acquainted with possible complications and ways of their removal. Only high-quality preparation is conducted, clear determination of testimonies and contra-indications for every patient can justify the potential risk, connected with the use of this method. Modern possibilities of BONDS allow expressly to localize a pathological process and conduct medical manipulation, not damaging here surrounding fabrics.

Telemedicine provides for use telecommunication technologies for the grant of medicare. Last years there is a tendency to appearance of specialists in narrow industries of medicine. It led to certain centralization of medicare and often necessary specialist it is now possible to find gust in big town. Due to telemedicine a necessity in the physical presence of certain specialists diminishes considerably, and a patient can be consulted in the distance. Thus become possible access of more skilled consultation, that especially it is important at the using new dear diagnostic procedures (Computer tomography, densitometry, Dopplersonography and etc). Carefully using neat new technologies allows to accelerate the reduce the price of consultation from one or a few experts, in spite of physical distance from him, as by way of Internet it is possible to unite with a specialist even, who is on other continent.

Method of implementation of practical work.

Methodology of Practical Class 9.00-12.00.

Algorithm of communicative skills:

1. To greet and name itself.

2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints. Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened.

I. Theme №1 practical employments

Work 1. After the introductory word of teacher and control of basic level of knowledge and abilities of students (verbal questioning and writing control) it is necessary to made the following group settings:

- A) determinations and grounds of indications and contra-indications of endoscopic operative interferences;
- B) a student collects complaints, anamnesis of disease and lives, conducts the objective inspection, reveal, discover the basic clinical signs of disease of patient, estimates clinical-laboratory information of stationary card of patient, determines and grounds a indications and contra-indications for endoscopic operative interferences which are possible.

After it making individual settings, directed on setting of medical treatment to the patients after endoscopic operative interferences.

II. Theme №2 practical employments

Work 2. Making the following group of settings:

- A) determinations and grounds of testimonies and contra-indications for X-Ray endovascular manipulations;
- B) near the patient a facts student sick on the basis of clinical-laboratory determines and grounds a indication and contra-indication for operative interferences under the control sonography and X-Ray control. The inspection is conducted X-Ray controle, the sonography, a student interprets findings, determines their diagnostic value.

After it making individual settings, directed on setting of medical treatment to the patients after X-Ray endovascular operative interferences.

III Theme №3 practical employments

Work 3. Making following group settings:

- A) determination and ground of indication for the conducting of remote consultations: by phone, to the e-mail, video conference communication;
- B) a student collects complaints, anamnesis of disease and lives, conducts the objective inspection, reveal, discover the basic clinical signs of disease of patient, estimates clinical-laboratory information of stationary card of patient, are formulated by the request for remote consultation.

After it making individual settings: a student sets a diagnosis on the basis of digital facts about a patient, grounds and formulates the request for the additional methods of inspection and determines medical tactic.

After the sum of implementation of all settings estimation is proposed to every student.

Program of selftraining of students

Questions on wich a student must give answers:

I. Theme № 1 practical employments

1. Types of endoscopic surgery.
2. Advantages and lacks of endoscopic operations.
3. Endoscopic equipment and tool.
4. Technique of execution of laparoscopy.
5. Method of laparoscopic revision and its informing.

6. Laparoscopic anatomy of hepatopancreaticoduodenal area.
7. Intraoperative laparoscopic specific complications.
8. Specific and unspecific complications of early and late postoperative periods.
9. Indication and contra-indication for laparoscopic operations on bilious ways.
10. Method of laparoscopic cholecystectomy.
11. Invasive and noninvasive methods of laparoscopic intraoperative inspections of bilious ways.
12. Laparoscopic medical treatment of the complicated forms of cholecystitis (one- and two-stapes methods).
13. Laparoscopic methods of hepaticocholechocheal drenaging.
14. endoscopy, bronkhoscopy, kolonoscopy. Method of conducting, possibilities.

II. Theme № 2 practical employments

1. Types of X-Ray surgery and directions for using.
2. X-Ray endovascular surgery. Prospects. General principles, equipment.
3. X-Ray endovascular dilatation. General principles, mechanism dilatation.
4. X-Ray endovascular dilatation of coronal arteries. Testimony, method of conducting.
5. X-Ray endovascular dilatation of kidney arteries. Testimony, method of conducting.
6. X-Ray endovascular occlusion. General principles, mechanism of occlusion.
7. X-Ray endovascular occlusion at the pulmonary bleeding.
8. X-Ray endovascular occlusion at pathology of organs of abdominal region.
9. X-Ray endovascular occlusion at the pathological function of bud.
10. X-Ray endovascular prosthesis.
11. Raising of driver of rhythm under the control x-ray photography. Indication and method of implementation.
12. Endoscopic retrograde pancreatocholangiography. Indication and method of implementation.
13. Puncture under the control sonography. Indication and method of implementation.
14. Types of lithotripsy under the control sonography and X-Ray control. Indication and method of implementation.

III. Theme № 3 practical employments

1. Diagnostic, consultation and medical possibilities of telemedycine.
2. Types of telesurgery. Directions of application.
3. Telesurgery as newest link of medicine. Apparatus and rigging.
4. Telesurgical consultations as an effective method of the diagnostics urgent condition.
5. X-Ray endovascular in the distance as a stage of grant of the first aid is important.
6. Sonography in the distance as a stage of grant of the first aid is important.
7. Features of conducting of telesurgical operative interferences.
8. Telesurgical assisting at operative interferences.
9. Using of teleconsultations at operative interferences for the prophylaxis of intraoperative and postoperative complications, choice of tactic of medical treatment.
10. Using of digital records of hospital chart at the grant of stage medicare.
11. Features of formulation of query for remote teleconsultation.
12. Robotosurgery. Possibilities of application. Advantages and failings.

Break 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.

Seminar discussion of theoretical questions

The basic level of knowledges and abilities is checked up by the undoing of situation tasks to every theme, by answers for tests and structural questions.

(presence of complete sets of tests and situation tasks at a teacher)

A student must know:

1. Troubleshooting routines at preparation of patients to endoscopic interferences.
2. Sequence of physical and clinical inspections of patients.
3. Indications and contraindications for endoscopic interferences.
4. Variants of norm of endoscopic anatomy.
5. What apparatus and tool is used for the different types of laparoscopic operations and manipulations.
6. What equipment is used for the different types of telesurgery.
7. What equipment is used for X-Ray surgery.
8. Variants of the norm X-Ray anatomy.

A student must be able:

1. To prepare a patient to the inspections: endoscopy, colonoscopy, sonography, sciagraphies, tomography, angiography, cystoscopy, gysteroscopy, thoracoscopy, bronkhoscopy.
2. On the basis of clinico-laboratory findings to define and ground a indications and contraindications for endoscopic operative interferences.
3. To estimate sonography, sciagrams, tomogram, information endoscopy, bronkhoscopy and kolonoscopy.
4. To be able work with medical databases and electronic hospital charts.
5. To be able to formulate the request for remote teleconsultation.
6. To give remote teleconsultation from help of different communication facilities (e-mail, telephone message, vydeoteleconsultations).

Test evaluation and situational tasks 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions.

(the instructor has tests & situational tasks)

1. Patient To., 46 years, first days after laparoscopic operation concerning chronic calculous cholecystitis grumbles about a general weakness, nausea, multiple vomiting by a bile, pain and swelling of stomach. To the peristalsis is hearkened, gases do not depart. On a X-Ray film is free gas in an abdominal region.

Clinical diagnosis?

Medical tactic?

2. At a patient, 40 years, about of 5 month after carried laparoscopic cholecystectomy there recover the cramping hepatic colic, which was accompanied icteric of the skin covers, excrement of color of argil. What method of diagnostics will be most informing?

Answers:

- A. Peroral cholangiography
- B. Retrograde pankreatocholangiography
- C. Ultrasonography hepatobiliary area

Д. Radionuclide scanning

Е. Laparoscopy

3. A patient 78 years is hospitalized in the planned order with complaints about jaundice making progress, which appeared over 3 weeks to that ago, without a pain syndrome, general weakness, bad appetite. Objectively: temperature of body 36,8°C, pulse of 78/мин, a stomach is soft painless, symptoms of irritation of the peritoneum not exposed. From data of sonography tumular education in the area of gate of liver by sizes 4*6 см, intrahepatic bilious duct is extended. On the X-Ray sciagram of organs of pectoral cavity extended plural metastases in both 0,5 - 1 см easy by sizes. What operative medical treatment will be most optimum?

Answers:

A. Cholecystoenterostomy

B. Hepatoenteroanastomosis on a excluded loop for Ru

C. cholecystectomy, external drenagine of choledoch

Д. Choledochoduodenostomy

Е. Throughskin throughhepatic drenagine of intrahepatic bilious ducts under the control sonography

4. Patient of 53 years, entered a clinic concerning the gastro-intestinal bleeding of unclear etiology. During laparotomy there is a reveal big vascular tumour, which coverage on a duodenum, the Treyts copula and head of the pancreas. Deleting a tumour is not possible. During postoperative period it is conducted to the angiography gastroduodenal artery. On angiography was determined characteristic picture of vascular tumour.

What next medical tactic in relation to this patient?

A. Embolization systems of gastroduodenal artery.

B. Conservative hemostatic therapy.

C. Chemotherapy.

Д. Radial therapy.

Е. Embolization of abdominal trunk branches of aorta.

5. During telemedical vydeoteleconsultations you advise a domestic doctor, who is appealed to the patient in 62, during 10 years is ill gallstone illness. Three days to that ago he fell dull pain in right hypochondriac region, almost at once at a patient the turn of sclera and skin covers appeared yellow, at the same time of patient marked the complete lighting up of color of excrement the masses almost. Your recommendations?

А. Urgent hospitalization in surgical permanent establishment

B. Setting of diet № 5 for Pevznerom

C. Supervision after a patient in the conditions of polyclinic

Д. Conservative therapy in ambulatory terms

Е. Conducting of diagnostic measures for clarification of diagnosis

6. To your electronic address came a latter from a patient 50 years, in which she grumbles about pain in right hypochondriac region, nausea, arose up after the reception of rich food. After 6 hours of spasmolytics using she fell better. Similar to pain colic it was to 3 mounts that before. A patient did sonography - in a gall-bladder find out the concretion in diameter of 30 mm. What can be advised this patient?

A. To apply medicinal dissolution of stone

B. To offer conservative medical treatment

C. Ambulatory supervision following to new pain colic

Д. To apply extracorporal lithotripsy

Е. To offer cholecystectomy

METHODICAL INSTRUCTION FOR 5th YEAR STUDENTS

METHODOLOGICAL INSTRUCTION FOR LESSON №1 "PURULENT DISEASES OF LUNG AND PLEURA"

The aim: To be able to diagnose the acute and chronic abscess of lung depending on their localization and complications, to give urgent help to the patients with the acute abscess of lung complicated by the pulmonary bleeding, to diagnose and liquidate complications, indications for conservative and operative treatment, to know the methods of their operative treatment.

Professional orientation of students:

Over the past 40 years, the frequency of lung abscesses has declined in 10 times, whereas the mortality rate among patients decreased only on 5-10 % and consists of 4-7 %. In aspiration of fluid, which contains microflora, the mortality can reach 20 % and more, especially if the reaction of the liquid is acid. Most deaths in lung abscess associated with *Pseudomonas aeruginosa*, *Staphylococcus aureus* and *Klebsiella pneumoniae*. Late and inappropriate antibiotic therapy, inadequate drainage of the abscess, inadequate use of bracing treatment leads to the formation of chronic abscess and consequently its surgical treatment, with mortality rate more than 5 %.

Complications of suppurative processes of the lungs and pleura are difficult to treat and have a serious prognosis.

Methodology of Practical Class 9.00-12.00.

Algorithm of communicative skills:

To greet and name itself.

Friendly behaviour.

To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.

Correct and quiet conversation with a patient.

To get the agreement of patient for the performance of the examination. To take complaints. Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened.

Student's independent work program:

Work 1. A student collects complaints, anamnesis of disease and life of patient, performs the objective examination, exposes the basic clinical signs of acute abscess of lung, makes a troubleshooting routine, formulates a diagnosis. On the basis of complaints, anamnesis of disease and life, information of objective examination, laboratory and roentgenologic researches performs the differential diagnosis of patient with different variants of intrapleural complications.

A student must give a question on which to the answer.

Work 2. Students independently inspect sick purulent diseases of lung, meet with a medical document, confirm diagnosis and methods of treatment. After it the survey sciagrams of organs of thorax are analysed, differential diagnostics is performed with urgent thoracic pathology.

Work 3. Students independently inspect patients with different types of purulent diseases of lung, meet with the methods of diagnostics, by a medical document, confirm diagnosis and methods of treatment, the survey sciagrams of organs of thorax are analysed, CT, information of clinical methods of examination, differential diagnostics is performed with urgent thoracic pathology.

Individual Students Program.

1. Reasons of origin of acute abscess of lung.
2. Clinical forms of gangrene of lung.
3. Clinical symptoms of acute abscess of lung in a stage “before opening”.
4. Clinical symptoms of acute abscess of lung in a stage “after opening”.
5. Clinic of chronic abscess of lung.
6. Additional methods of examination of patients with the purulent diseases of lung.
7. Differential diagnostics of chronic abscess of lung and cancer.
8. Differential diagnostics of air cyst and chronic abscess of lung.
9. 11. Treatment of gangrenous abscess of lung.
10. Treatment of acute abscess of lung. Indication to operative treatment.
11. Tactic of treatment of the complicated acute abscess of lung.

Work 4. Students independently examine patients with the purulent diseases of pleura, meet with the methods of diagnostics, by a medical document, confirm diagnosis and methods of treatment, information of the survey sciagrams is analysed, clinical methods of examination, differential diagnostics is performed with urgent thoracic pathology.

Individual Students Program.

1. Acute empyema of pleura: Etiology, pathogeny, clinic.
2. Clinical signs of the limited empyema pleura: roentgenologic picture.
3. Clinic of limited piopneumothorax: roentgenologic signs.
4. Reasons of origin and clinic of total piopneumothorax.
5. Additional methods of examination at the chronic purulent processes of pleura.
6. Differential diagnostics of empyema pleura and piopneumothorax.
7. Clinic of chronic empyema.
8. Additional methods of examination at piopneumothorax.
9. Tactic of treatment of patients with piopneumothorax.
10. Indication to puncture of pleura cavity.
11. Technique of execution of pleura puncture.
12. Indication to drainage of pleura cavity.
13. Technique of execution of drainage of pleura cavity.
14. Features of conservative treatment of piopneumothorax.

Break 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.

1. Reasons of origin of acute abscess of lung.
2. Clinical forms of gangrene of lung.
3. Clinical symptoms of acute abscess of lung in a stage “before opening”.
4. Clinical symptoms of acute abscess of lung in a stage “after opening”.
5. Clinic of chronic abscess of lung.
6. Additional methods of examination of patients with the purulent diseases of lung.
7. Differential diagnostics of chronic abscess of lung and cancer .
8. Differential diagnostics of air cyst and chronic abscess of lung.
9. Methods of sanation of bronchial tree.
10. Treatment of gangrenous abscess of lung.

11. Treatment of acute abscess of lung. Indication to operative treatment.
12. Tactic of treatment of the complicated acute abscess of lung.
13. Acute empyema of pleura: Etiology, pathogeny, clinic.
14. Clinical displays of the limited pleura empyema: roentgenologic picture.
15. Clinic of limited pyopneumothorax: roentgenologic signs.
16. Reasons of origin and clinic of total pyopneumothorax.
17. Additional methods of examination at the chronic purulent processes of pleura.
18. Differential diagnostics of empyema pleura and pyopneumothorax.
19. Clinic of chronic empyema.
20. Additional methods of examination at pyopneumothorax.
21. Tactic of treatment of patients with pyopneumothorax.
22. Indication to puncture of pleura cavity.
23. Technique of execution of pleura puncture .
24. Indication to drainage of pleura cavity.
25. Technique of execution of drainage of pleura cavity.
26. Features of conservative treatment of pyopneumothorax

Test evaluation and situational tasks 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions.
(the instructor has tests & situational tasks)

The tests for self-checking of knowledge, skills.

1. What is the predominant factor which causes the lung abscess?
 - A. Increased cholesterol, dyslipoproteinemia
 - B. Pulmonary hypertension
 - C. Rheumatism, endocarditis
 - D. Myocardial infarction
 - E. Disturbances of bronchial permeability with the development of atelectasis

2. What is the cause of pyopneumothorax?
 - A. Bronchiectatic disease
 - B. Obstructive bronchitis
 - C. Pulmonary embolism
 - D. Bronchial asthma
 - E. Pulmonary emphysema

3. For the clinical manifestation of pyopneumothorax is typical:
 - A. Chest pain
 - B. Vomiting
 - C. Regurgitation
 - D. Dysphagia
 - E. Dilated cervical veins

4. What acute complication is characteristic for lung abscess?

- A. Emphysema
 - B. Pulmonary bleeding
 - C. Rib fracture
 - D. Malignancy
 - E. Esophageal bleeding
5. What acute complication is characteristic for lung abscess?
- A. Rib fracture
 - B. Emphysema
 - C. Pyopneumothorax
 - D. Malignancy
 - E. Esophageal bleeding
6. What complication is characteristic for lung abscess?
- A. Esophageal bleeding
 - B. Rib fracture
 - C. Emphysema
 - D. Sepsis
 - E. Malignancy
7. What complication is characteristic for lung abscess?
- A. Esophageal bleeding
 - B. Rib fracture
 - C. Bronchogenic dissemination
 - D. Emphysema
 - E. Malignancy
8. In the patient of 35 years old during physical exertion have appeared a sharp pain in the left half of the chest. On examination: the patient is covered with cold sweat, difficult breathing on the left side. A tachycardia. By percussion: the bandbox sound from the left side. By auscultation: respiration on the right side is vesicular, on the left side is absent. The probable diagnosis?
- A. Spontaneous pneumothorax
 - B. Angina on exertion
 - C. Acute myocardial infarction
 - D. Left pleurisy
 - E. Pneumonia
9. The patient A., 37 years old, has entered with the complaints of cough with daily excretion of a purulent sputum to 150 ml, pain in the right half of the chest, increase of temperature to 38°C. Has been ill for 2 weeks. Before the day of entrance in clinic appeared expectoration of 300 ml of purulent sputum during cough. On examination: a shortening of percussion pulmonary sound and harsh breathing with coarse rales over the right scapula. What is the previous diagnosis?

- A. Acute bronchitis
- B. Acute abscess of lung
- C. Exacerbation of a chronic abscess
- D. Exacerbation of bronchiectatic disease
- E. Pleural empyema

10. The patient A., 42 years old entered the clinic. During two months was treated for acute abscess of the upper lobe of the right lung. The treatment included intramuscular injections of antibiotics. Improvement inappreciable as there stayed a cough with expectoration of a purulent fetid-odor sputum to 80-100 ml per day, high temperature. The diagnosis?

- A. Acute abscess of the right lung
- B. Tubercular cavern
- C. The cavity form of a lung cancer
- D. Chronic abscess of lung
- E. Purulent polycystosis

A student must know:

1. Reasons of origin of acute abscess of lung.
2. Clinical forms of gangrene of lung.
3. Clinical symptoms of acute abscess of lung in a stage “before opening”.
4. Clinical symptoms of acute abscess of lung in a stage “after opening”.
5. Clinic of chronic abscess of lung.
6. Additional methods of examination of patients with the purulent diseases of lung.
7. Differential diagnostics of chronic abscess of lung and cancer .
8. Differential diagnostics of air cyst and chronic abscess of lung.
9. Methods of sanation of bronchial tree.
10. Treatment of gangrenous abscess of lung.
11. Treatment of acute abscess of lung. Indication to operative treatment.
12. Tactic of treatment of the complicated acute abscess of lung.
13. Acute empyema of pleura: Etiology, pathogeny, clinic.
14. Clinical displays of the limited pleura empyema: roentgenologic picture.
15. Clinic of limited pyopneumothorax: roentgenologic signs.
16. Reasons of origin and clinic of total pyopneumothorax.
17. Additional methods of examination at the chronic purulent processes of pleura.
18. Differential diagnostics of empyema pleura and pyopneumothorax.
19. Clinic of chronic empyema.
20. Additional methods of examination at pyopneumothorax.
21. Tactic of treatment of patients with pyopneumothorax.
22. Indication to puncture of pleura cavity.
23. Technique of execution of pleura puncture .
24. Indication to drainage of pleura cavity.
25. Technique of execution of drainage of pleura cavity.
26. Features of conservative treatment of pyopneumothorax.

A student must be able:

1. To expose the basic clinical signs of the uncomplicated and complicated trauma of thorax, ground and formulate a clinical diagnosis, to perform a differential diagnosis, to ground surgical tactic of treatment.

2. To expose the basic variants of clinical display of acute and chronic abscess of lung, ground and formulate a diagnosis, to perform a differential diagnosis, to ground conservative and operative treatment.
3. To expose the basic clinical signs of acute empyema of pleura and pyopneumothorax, to formulate a clinical diagnosis, to perform a differential diagnosis, to ground the shows and methods of operative treatment.
4. To expose the basic clinical aspects of purulent processes of lung.
5. To ground and formulate a clinical diagnosis.
6. To perform a differential diagnosis.
7. To formulate the shows to surgical and conservative treatment.

The answers for the self-checking tests.

- 1 – E.
- 2 – A.
- 3 – A.
- 4 – B.
- 5 – C.
- 6 – D.
- 7 – C.
- 8 – A.
- 9 – B.
- 10 – D.

„Medical cure of patient with pancreatitis

ALGORITHM „ Examination of patient with pancreatitis”

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination.To take complaints
6. To take anamnesis (to pay attention to the onset of the disease, the error in the alcohol intake, development of the pain irradiation)
7. To examine the patient (palpation of the pancreas, determination of particular symptoms)
8. Interpretation of laboratory and instrumental methods of investigation, establishment of the diagnosis

„Medical cure of patient with chronic cholecystitis, gallstone disease”

ALGORITHM „ Examination of patient with chronic cholecystitis”

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination.To take complaints
6. To take anamnesis (to pay attention to the onset of the disease, the error in the alcohol intake, development of the pain irradiation, presence in anamnesis of the similar symptoms)
7. To examine the patient (palpation, percussion of the abdomen , determination of particular symptoms)
8. Interpretation of laboratory and instrumental methods of investigation, establishment of diagnosis

„Medical cure of patient with the incarcerated hernia”

ALGORITHM „ Examination of patient with incarcerated hernia”

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.

4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention to the onset of the disease, period from the moment of strangulation, presence of clinic of intestinal obstruction)
7. To examine the patient (palpation of patient in horizontal and vertical positions, palpation of inguinal channel, scrotum, the sign of coughing push)
8. Interpretation of laboratory and instrumental methods of investigation, establishment of diagnosis

„Medical cure of patient with acute appendicitis”

ALGORITHM „ Examination of patient with acute appendicitis”

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention to the onset of the disease, irradiation of pain, presence of the dysuric phenomena)
7. To examine the patient (palpation, percussion of abdomen, determination of particular symptoms)
8. Interpretation of laboratory and instrumental methods of investigation, establishment of diagnosis

„Medical cure of patient with the acute urine delay”

ALGORITHM „ Examination of patient with the acute urine delay”

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention to the period of the onset of complaints; frequency of urination, especially in a night time, presence of haematouria in anamnesis)
7. To examine the patient (examination, palpation and percussion of suprapubic area, determination of Pasternack's sign, digital rectal examination)

8. To detect the cause of acute urine delay

„To perform the catheterization of urinary bladder by a soft catheter”

ALGORITHM „To perform the catheterization of urinary bladder by a soft catheter”

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. The position of the patient – horizontal, thereafter to prepare the instruments, necessary for performance of this manipulation
6. To wash up the external pudenda foramen of urethra by antiseptic solution
7. To perform catheterization of urinary bladder by a soft catheter with according to the rules of the introduction of the last.

"Medical cure of the patient with atherosclerosis of the lower extremities"

ALGORITHM "Examination of the patient with atherosclerosis of lower extremities"

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention on the character, period of onset of complaints, presence of the intermittent claudication)
7. To examine the patient (Examination of skin covers, presence of destructive changes, presence of pulsation at different levels of the arterial system of lower extremities)
8. To detect the degree of arterial insufficiency of lower extremities)

"Medical cure of the patient with endarteriitis of the lower extremities"

ALGORITHM "Examination of the patient with endarteriitis of the lower extremities"

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.

5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention on the character, period of the onset of complaints, presence of the intermittent claudication)
7. To examine the patient (examination of the skin, presence of destructive changes, presence of pulsation on different levels of the arterial system of the lower extremities)
8. To detect the degree of arterial insufficiency of the lower extremities

"Determination of pulsation of the lower extremities"

ALGORITHM "Determination of pulsation of the lower extremities"

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To ask the patient to lie down and relax the muscles
6. Determination of pulsation on a. femoralis
7. Determination of pulsation on a. poplitea
8. Determination of pulsation on a. tibialis post
9. Determination of pulsation on a. dorsalis pedis

"Medical cure of the patient with thrombophlebitis of the lower extremities"

ALGORITHM "Examination of the patient with thrombophlebitis of the lower extremities"

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (feeling of heaviness of the lower extremities, presence of acute pain in the lower extremity, the onset of the painful cord along the great saphenous vein, swelling of the ankles)
7. To examine the patient (examination of skin, presence of destructive changes, presence of the painful cord along the great saphenous vein, test on the patency of the deep veins)

8. To interpret the indexes of коагулограми

"Medical cure of the patient with varicosity of the lower extremities"

ALGORITHM "Examination of patient with varicosity of the lower extremities"

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention on the onset of the complaints, presence: feeling of heaviness, painfulness in the region of varicosity, muscular cramps, swelling of the ankles, trophic ulcers)
7. To examine the patient (examination of skin, presence of the varicose veins, swelling of the ankles, presence of trophic ulcers, test on valvular incompetence of perforative and deep veins)
8. To detect the degree of venous insufficiency of the lower extremities.

"Determination of the valvular function of subcutaneous and deep veins of the lower extremities"

ALGORITHM "Determination of the valvular function of subcutaneous and deep veins of the lower extremities"

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. Troyanov-Trendelenburg's test
6. Gakkenbruch's test
7. Pratt's test
8. Sheinice test
9. Talman's test

„Medical cure of the patient with the purulent destructive diseases of lungs"

ALGORITHM „Examination of the patient with the purulent destructive diseases of lungs"

1. 1. To greet and name itself.

2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention to the onset of the disease, development of purulent destructive processes in pulmonary tissue, clinical course of the pathological process before to and after discharge into bronchial tube)
7. To examine the patient (physical examination, palpation, percussion, auscultation)
8. Interpretation of laboratory and instrumental methods of investigation, establishment of diagnosis

„Medical cure of the patient with pleurisy”

ALGORITHM „Examination of patient with pleurisy”

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention to the onset of the disease, development of pleurisy, clinical course of pathological process)
7. To examine the patient (physical examination, palpation, percussion, auscultation)
8. Interpretation of laboratory and instrumental methods of investigation, establishment of diagnosis

„Medical cure of the with the chest trauma”

ALGORITHM „ Examination of patient with the chest trauma”

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention to the onset of the disease, development of pleurisy, clinical course of pathological process)
7. To examine the patient (physical examination, palpation, percussion, auscultation)

8. Interpretation of laboratory and instrumental methods of investigation, establishment of diagnosis

METHODICAL INSTRUCTIONS FOR 4th YEAR STUDENTS

METHODOLOGICAL INSTRUCTION TO LESSON №6 " PERITONITIS "

The aim. To master clinics, diagnostics, differential diagnostics of various clinical forms of peritonitis. To learn the treatment tactics, indications and contraindications for operative intervention, operative intervention type at various clinical forms of peritonitis, principles of postoperative period course.

Professional orientation of students. The course of acute surgical illnesses of peritoneal organs is complicated with peritonitis development in 20-30% of the cases. The lethality at the extensive forms of peritonitis depends on the skilled early diagnosis and in-time complex treatment.

Methodology of Practical Class 9.00-12.00.

Algorithm of communicative skills:

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints. Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened.

Student's independent work program:

Theme №1. Acute extensive purulent peritonitis.

1. Anatomic and physiologic data about of the peritoneum.
2. Topography of the peritoneum.
3. Concept definition and classification of the acute peritonitis.
4. Phases of clinical course of the acute extensive purulent peritonitis.
5. General clinical characteristics of the acute extensive purulent peritonitis.
6. Peculiarities of the clinical picture of acute extensive purulent peritonitis depending on reasons and phases of the clinical course.
7. Differential diagnosis of the acute extensive purulent peritonitis.
8. Violations of water-electrolytic and acid-alkaline balance at the acute extensive purulent peritonitis.
9. Verification methods of diagnosis of the acute extensive purulent peritonitis.
10. Curing tactics at peritonitis.
11. Peculiarities of the preoperative preparation at the extensive peritonitis.
12. Principles of operative treatment of patients with the acute extensive peritonitis depending on phases (stages) of the clinical course.
13. Postoperative period course in patients with the acute extensive peritonitis.

Theme №2. Encapsulated peritonitis. Specific clinical forms of peritonitis.

1. Concept definition. Encapsulated peritonitis.
2. Classification of encapsulated peritonitis (as per allocation, clinical course phase).
3. Subdiaphragmatic abscess. Classification.
4. Clinics, diagnostics, differential diagnostics and treatment of the subdiaphragmatic abscess.
5. Clinics, diagnostics, differential diagnostics of Douglas space abscess.
6. Clinics features, diagnostics, differential diagnostics of interintestinal abscesses.
7. Modern verification methods of diagnosis of the encapsulated peritonitis (general view roentgenogram, ultrasonic examination, laparoscopy, roentgenologic methods).
8. Curing tactics at the encapsulated peritonitis.
9. Choice of scope and method of conservative and operative treatment at various clinical forms of the encapsulated peritonitis.
10. Disablement expertise and patients reablement after the operations for encapsulated peritonitis.
11. Concept definition. Classification.
12. Clinics, diagnostics, differential diagnostics of the adhesive tuberculous peritonitis.
13. Clinics, diagnostics, differential diagnostics of the exsudative tuberculous peritonitis.
14. Clinics, diagnostics, differential diagnostics of the caseous tuberculous peritonitis.
15. Curing tactics choice at tuberculous peritonitis.
16. Principles of conservative and operative treatment of patients with various forms of tuberculous peritonitis.

Theme №3. Correction principles of water-electrolytic and acid-alkaline balance. Pre- and postoperative periods course in patients with acute extensive peritonitis.

1. Classification of dehydration and electrolytic violations.
2. Clinical characteristics of water-electrolytic violations at various course phases of the acute extensive peritonitis.
3. Classification of blood substitutes, hydroionic solutions which are used to correct the hydroionic violations.
4. Major principles of intravascular dehydration correction.
5. Principles of intravascular and mixed dehydration correction.
6. Concrete example of calculation of hyponatremia correction.
7. Concrete example of calculation of hypopotassiumemia correction.
8. General rules of infusion therapy.

BREAK 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.**Basic level of knowledge and skills:****The student must know:**

1. Anatomic and physiologic features of the peritoneum.
2. Topography of the peritoneum.
3. Definition of "the acute peritonitis" concept. Etiopathogenesis of the acute peritonitis.
4. Classification of the peritonitis.
5. Clinics, diagnostics, differential diagnostics of the acute extensive peritonitis depending on reasons and stages of clinical course.
6. Clinics, diagnostics, differential diagnostics of the encapsulated peritonitis (infiltrate, peritoneal abscess).
7. Diagnostics and curing tactics at the tuberculous peritonitis.

8. Peculiarities of clinical course and differential diagnosis of the false peritonitis (at diabetes mellitus, uremia, Schonlein-Henoch disease).
9. Peculiarities of the preoperative preparation in patients with the extensive peritonitis.
10. Principles of operative treatment of patients with various clinical versions of the peritonitis.
11. Peculiarities of the postoperative course in patients with the peritonitis.

The student has to be able to:

1. To take the history of the patient with the suspect for the peritonitis.
2. To reveal main clinical features and symptoms at various clinical forms of the extensive peritonitis.
3. To reveal main clinical features and symptoms at various clinical forms of the encapsulated peritonitis.
4. To reveal main clinical features and symptoms at various clinical forms of the tuberculous and false peritonitis.
5. To define free and limited liquid and gas in the abdominal cavity, splash noise, characteristics of peristaltic violations.
6. To argue and explain the preliminary diagnosis.
7. To make a plan of patient examination and explain the examination results (general blood test, general urine test, roentgenologic examination of the alimentary tract general view roentgenogram), ultrasonic examination, biochemical blood test, clinical, biochemical and bacteriologic examination of the peritoneal content).
8. To define curing tactics, indications and contraindications for operative intervention, to choose properly the preoperative preparation, anesthesia type, operative access and type of intervention according to the clinical form and course phase of peritonitis.
9. To define principles of conservative treatment of the peritonitis.

TEST EVALUATION AND SITUATIONAL TASKS 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions.
(the instructor has tests & situational tasks)

1. The following statement about peritonitis are all true except:
 - A. Peritonitis is defined as inflammation of the peritoneum.
 - B. Most surgical peritonitis is secondary to bacterial contamination.
 - C. Primary peritonitis has no documented source of contamination and is more common in adults than in children and in men than in women.
 - D. Tuberculous peritonitis can present with or without ascites.
2. The most common indication for surgery secondary to acute diverticulitis is:
 - A. Abscess.
 - B. Colonic obstruction.
 - C. Colovesical fistula.
 - D. Free perforation.
 - E. Hemorrhage.
3. Which of the following statements most accurately describes the current therapy for pyogenic hepatic abscess?
 - A. Antibiotics alone are adequate for the treatment of most cases.
 - B. All patients require open surgical drainage for optimal management.
 - C. Optimal treatment involves treatment of not only the abscess but the underlying source as well.
 - D. Percutaneous drainage is more successful for multiple lesions than for solitary ones.

4. Which of the following statements characterize amebic abscess?
- A. Mortality is higher than that for similarly located pyogenic abscesses.
 - B. The diagnosis of amebic abscess may be based on serologic tests and resolution of symptoms.
 - C. In contrast to pyogenic abscess, the treatment of amebic abscess is primarily medical.
 - D. Patients with amebic abscess tend to be older than those with pyogenic abscess.

The answers for the self-checking tests.

1 – C.

2 – A.

3 – C.

4 – B,C.

METHODICAL INSTRUCTIONS FOR 5th YEAR STUDENTS
METHODOLOGICAL INSTRUCTION TO LESSON №8

POSTRESECTION AND POSTVAGOTOMIC SYNDROMES. POSTCHOLECYSTECTOMIC SYNDROME

I. AIM. To be able to diagnose, to know symptoms of diseases of operated stomach, depending on clinical type of the disease. Principles of conservative and surgical treatment. To be able to diagnose, to know symptoms and principles of conservative and surgical treatment of of postcholecystectomic syndrome.

II. Professional orientation of the student.

Knowledge of symptoms, appearing after performed stomach resections and vagotomies, causes proper approach to choosing of operative intervention and the techniques of its performing.

Cholecystectomy is one of frequently performed operations in surgical clinics. Knowledge of symptoms, clinical signs and diagnosing of the diseases, that are grouped into the term "PCES", gives us a possibility to prevent its appearing in one cases, and to determine the expediency of conservative or surgical treatment in another ones.

Methodology of Practical Class 9.00-12.00.

Algorithm of communicative skills:

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints. Correct and quiet conversation with a patient. A patient is in vertical position persons to the doctor, neck and shoulders of patient is maximally weakened.

Student's independent work program:

Theme №1. POSTRESECTION AND POSTVAGOTOMIC SYNDROMES

1. Anatomical, morphological and functional peculiarities of stomach (anatomy, topographical anatomy, anatomical pathology, histology).
2. Etiology, pathogenesis and classification of diseases of operated stomach (pathological physiology, propaedeutical therapy, faculty surgery).
3. Estimation of x-ray, endoscopic, laboratory findings (rhoetgenology, functional diagnostics).
4. Mechanism of antiulcerogenic agents action, correction of electrolytes metabolism violation, use of digestive enzymes, hormones, vitamins, methods of operative intervention (pharmacology, faculty surgery).
5. Rontgenoscopy, estimation of x-ray reports, gastric juices test.

Theme №2. POSTCHOLECYSTECTOMIC SYNDROME

1. Anatomical, morphological and functional peculiarities of biliary tracts (anatomy, topographical anatomy, anatomical pathology).
2. Classification of postcholecystectomic syndrome (propaedeutical therapy)
3. Estimation of clinical and laboratory, x-ray, ultrasonographical, endoscopic, findings (rhoetgenology, infectious diseases, biochemistry).
4. Mechanism of antiinflammatory, spasmolytic, detoxicative, replacement agents action, methods of operative intervention on biliary tracts (pharmacology, topographical anatomy and operative surgery).

5. Constants of biochemical blood and urine tests.

Break 12.00-12.30

Seminar discussion of theoretical issues 12.30-14.00.

Basic level of knowledge and skills:

The student must know:

1. Surgical anatomy of stomach and duodenum.
2. Types of stomach resections at ulcerous disease.
3. Types of draining operations on stomach at ulcerous disease.
4. Choosing the method of surgical treatment of duodenum ulcer.
5. Types of vagotomies, their characteristics: indications, contraindications to their performing.
6. Classification of postresection syndromes.
7. Reasons of dumping syndrome appearing.
8. Theories of dumping syndrome appearing.
9. Clinical variants of dumping syndrome passing.
10. X-ray and clinical criteria of disease severeness degree estimation.
11. Conservative treatment of dumping syndrome.
12. Indications to surgical treatment of dumping syndrome. Types of operations.
13. Methods of stomach resection, that prevent dumping syndrome.
14. Afferent loop syndrome: its reasons, classification.
15. Afferent loop syndrome: clinical variants, diagnosis.
16. Peptic ulcer of gastroenteroanastomosis: its reasons, complications, diagnosis.
17. Peptic ulcer of gastroenteroanastomosis: types of surgical interventions.
18. Coloventricular fistula: clinical and X-ray diagnosis.
19. Coloventricular fistula: methods of surgical interventions.
20. Zollinger-Ellison syndrome: diagnosis and treatment.
21. Factors of stomach and duodenum ulcer relapsing after vagotomy.
22. Clinical variants of relapsing ulcer after vagotomy.
23. X-ray and endoscopic signs of stomach and duodenum ulcer relapsing.
24. Conservative methods of postvagotomic relapsing ulcers treatment.
25. Surgical treatment of postvagotomic relapsing ulcers.
26. Postvagotomic diarrhoea: reasons, classification by severeness degrees.
27. Treatment of postvagotomic diarrhoea.
28. Postvagotomic gastrostasis: its degrees, treatment.
29. Surgical anatomy of biliary tracts.
30. Instrumental methods of examination at PCES.
31. Classification of PCES by Shalimov.
32. Types of external draining of common bile duct.
33. Types of internal draining of common bile duct.
34. PCES, determined by changes, not corrected during cholecystectomy.
35. PCES, that has appeared as a result of cholecystectomy.
36. PCES: diseases of hepatobiliary system, that were not corrected by cholecystectomy.
37. PCES: organic and functional disorders of organs and systems, that are not connected with cholecystectomy.
38. PCES: Nerve-kinetic disorders of hepatic ducts and duodenum.
39. Cicatric biliary stricture. Types of operations.
40. Differential diagnosis of obstructive jaundice.

The student has to be able to:

1. Reveal basic clinical signs of diseases of operated stomach.
2. Substantiate and formulate the clinical diagnosis.
3. Make differential diagnosis.
4. Substantiate pharmacotherapy, indications for surgical treatment.
5. Reveal basic reasons and clinical signs of postcholecystectomic syndrome.
6. Substantiate and formulate the clinical diagnosis.
7. Make differential diagnosis.
8. Substantiate pharmacotherapy, indications for surgical treatment.

Technical means and material provision of lectures (names and numbers of tables, compact discs, instruments quantity, subjectpatients, etc.) –

Multimedia projection of demonstration material (pictures, tables, videofilms) from compact disc “Clinical Surgery”, videofilms with operations.

Test evaluation and situational tasks 14.00-15.00.

Initial level of knowledge and skills are checked by solving situational tasks for each topic, answers in test evaluations and constructive questions.

(the instructor has tests & situational tasks)

1. 40-years old patient, 3 years ago had an operation of stomach resection by Hoffmeister-Finsterer because of duodenum ulcer with petetration into the head of pancreas. Duting the last year notices everyday pain in right subcostal region, that are attended by bile vomiting up to 1 l in volume. After vomiting pain disappears. The patient several times have passed treatment courses in surgical department, but there was no improving of his state. The patient has lost 16 kg of weight. During x-ray examination the contrast gets into the afferent loop.

Your diagnosis?

Surgeon's tactics?

2. 45-year old patient, 3 years ago had an operation of 2/3 stomach resection by Hoffmeister-Finsterer because of stenosing ulcer of the antrum. Now the expressed dumping syndrome of severe degree with ptogressive weight loss is observed, despite repeated courses of in-patient and health resort treatment. Psychoneurological disorders are expressed slightly. There is no bile vomiting. At x-ray examination of gastric stump the accelerated evacuation is observed.

Your diagnosis?

Surgeon's tactics?

3. 48-years old patient, that has undergone an operation of cholecystectomy 3 years ago, has complaints on cramping pains, that were followed by raised temperature up to 38⁰C, scleral and mucous membranes icteritiousness. Whole bilirubin 128,0 mkmol/l, leukocites – 15,0x10⁹/l, stab neutrophils – 16 %.

What methods of examination should be used?

Your diagnosis?

Treatment tactics?

4. 35-year old female patient, a month ago had an operation of cholecystectomy. Now she complains on circumferential pain in abdomen, nausea, vomiting, icteritiousness of scleras and visible mucous membranes. Whole bilirubin is 60,0 mkmol/l. While palpation the patient feels pain in left mesogastral region. Symptoms of rebound stomach tenderness are absent.

Your diagnosis?

Surgeon's tactics?

„Medical cure of patient with acute cholecystitis”

ALGORITHM „ Examination of patient with acute cholecystitis”

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention to the onset of the disease, the error in the alcohol intake, development of the pain irradiation, presence in anamnesis of the similar symptoms)
7. To examine the patient (palpation, percussion of the abdomen , determination of particular symptoms)
8. Interpretation of laboratory and instrumental methods of investigation, establishment of diagnosis

Practical skill "Determination of the symptoms of peritoneal irritation"

ALGORITHM for "Determination of the symptoms of peritoneal irritation"

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
To ask a patient to lie down on the back and relax the muscles of front abdominal wall
6. The external examination of abdomen is performed, the doctor marks the
7. symmetry, presence of outpouching and participation of front abdominal wall in the act of breathing
8. The right arm of the doctor on the front abdominal wall (any area) slowly presses by 4 fingers of doctor (to estimate the degree of pain)
9. All hand is quickly taken off from abdominal wall to estimate the increase of pain degree (Schotkin – Blumberg's sign)
10. By the fingers tips of right arm the doctor performs dosed percussion of front abdominal wall (Rozdolsky's sign).

„Medical cure of patient with acute intestinal obstruction

ALGORITHM „To determine the symptoms of the acute intestinal obstruction”

1. To greet and name itself.

2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention to the onset of the disease, defecation, swelling of the abdomen, development of the pain irradiation)
7. To examine the patient (palpation of the large and small intestine, auscultation of peristalsis, determination of particular symptoms)
8. Interpretation of laboratory and instrumental methods of investigation, establishment of the diagnosis (X-Ray films)

Practical skill "To determine the symptoms of the perforative ulcer"

ALGORITHM for "To determine the symptoms of the perforative ulcer "

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints. Correct and quiet conversation with a patient. To ask a patient to lie down on the back and relax the muscles of front abdominal wall.
6. The external examination of abdomen is performed, the doctor marks the symmetry, presence of outpouching and participation of front abdominal wall in the act of breathing
7. Before the palpation epigastric region on a front abdominal wall is determined
8. Determination of wooden abdomen, ulcer anamnesis and knife-like pain (Mondore sign)
9. Confirming diagnosis by finding gas on X-Ray film which performed on vertical position of the patient.

„Medical cure of patient with acute appendicitis”

ALGORITHM „ Examination of patient with acute appendicitis”

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention to the onset of the disease, irradiation of pain,

presence of the dysuric phenomena)

7. To examine the patient (palpation, percussion of abdomen, determination of particular symptoms)
8. Interpretation of laboratory and instrumental methods of investigation, establishment of diagnosis

„Medical cure of patient with acute pancreatitis

ALGORITHM „To determine the symptoms of the acute pancreatitis”

9. To greet and name itself.
10. Friendly behaviour.
11. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
12. Correct and quiet conversation with a patient.
13. To get the agreement of patient for the performance of the examination. To take complaints
14. To take anamnesis (to pay attention to the onset of the disease, the error in the alcohol intake, development of the pain irradiation)
15. To examine the patient (palpation of the pancreas, determination of particular symptoms)
16. Interpretation of laboratory and instrumental methods of investigation, establishment of the diagnosis

Practical skill "To perform digital examination of rectum"

ALGORITHM for "To perform digital examination of rectum"

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
Examination of perianal area in knee-elbow position or in position of patient on a side with the flexed knees.
6. The index finger, dressed into the glove and smeared by solution of lubricant enters the rectum.
7. Estimated: tonus of anal sphincter, wall of the rectum, presence of compressions, excrescences, overhanging, pain syndrome, pathological maintenance.
8. After rectal examination the character of maintenance is estimated on a glove.

„Medical cure of patient with the incarcerated and non-incarcerated hernia”

ALGORITHM „ Curation of patient with incarcerated and non-incarcerated hernia”

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
1. To get the agreement of patient for the performance of the examination. To take complaints
2. To take anamnesis (to pay attention to the onset of the disease, period from the moment of strangulation, presence of clinic of intestinal obstruction)
3. To examine the patient (palpation of patient in horizontal and vertical positions, palpation of inguinal channel, scrotum, the sign of coughing push)
4. Interpretation of laboratory and instrumental methods of investigation, establishment of diagnosis

„To perform the catheterization of urinary bladder by a soft catheter”**ALGORITHM „To perform the catheterization of urinary bladder by a soft catheter”**

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. The position of the patient – horizontal, thereafter to prepare the instruments, necessary for performance of this manipulation
6. To wash up the external pudenda foramen of urethra by antiseptic solution
7. To perform catheterization of urinary bladder by a soft catheter with according to the rules of the introduction of the last.

„Medical cure of patient with the acute urine delay”**ALGORITHM „ Examination of patient with the acute urine delay”**

1. To greet and name itself.
2. Friendly behaviour.
3. To explain to the patient a purpose of the visit, duration of conversation and to get his agreement.
4. Correct and quiet conversation with a patient.
5. To get the agreement of patient for the performance of the examination. To take complaints
6. To take anamnesis (to pay attention to the period of the onset of complaints; frequency of urination, especially in a night time, presence of haematouria in

anamnesis)

7. To examine the patient (examination, palpation and percussion of suprapubic area, determination of Pasternacky's sign, digital rectal examination)
8. To detect the cause of acute urine delay

TOPIC №18. SYNDROME OF LIMB ISCHEMIA. CAUSES. CONSERVATIVE AND SURGICAL TREATMENT OF ARTERIAL OCCLUSIONS OF THE LOWER EXTREMITIES.

General Approach to the Vascular Patient

Because the vascular system involves every organ system in our body, the symptoms of vascular disease are as varied as those encountered in any medical specialty. Lack of adequate blood supply to target organs typically presents with pain; for example, calf pain with lower extremity (LE) claudication, postprandial abdominal pain from mesenteric ischemia, and arm pain with axillosubclavian arterial occlusion. In contrast, stroke and transient ischemic attack (TIA) are the presenting symptoms from middle cerebral embolization as a consequence of a stenosed internal carotid artery (ICA). The pain syndrome of arterial disease usually is divided clinically into acute and chronic types, with all shades of severity between the two extremes. Sudden onset of pain can indicate complete occlusion of a critical vessel, leading to more severe pain and critical ischemia in the target organ, resulting in lower limb gangrene or intestinal infarction. Chronic pain results from a slower, more progressive atherosclerotic occlusion, which can be totally or partially compensated by developing collateral vessels. Acute on chronic is another pain pattern in which a patient most likely has an underlying arterial stenosis that suddenly occludes; for example, the patient with a history of calf claudication who now presents with sudden, severe acute limb-threatening ischemia. The clinician should always try to understand and relate the clinical manifestations to the underlying pathologic process.

Vascular History

Appropriate history should be focused on the presenting symptoms related to the vascular system (Table 1). Of particular importance in the previous medical history is noting prior vascular interventions (endovascular or open surgical), and all vascular patients should have inquiry made about their prior cardiac history and current cardiac symptoms. Approximately 30% of vascular patients will be diabetic. A history of prior and current smoking status should be noted.

Table 1. Pertinent Elements in Vascular History

- History of stroke or transient ischemic attack
- History of coronary artery disease, including previous myocardial infarction and angina
- History of peripheral arterial disease
- History of diabetes
- History of hypertension
- History of tobacco use
- History of hyperlipidemia

The patient with carotid disease in most cases is completely asymptomatic, having been referred based on the finding of a cervical bruit or duplex finding of stenosis. Symptoms of carotid territory TIAs include transient monocular blindness (amaurosis), contralateral weakness or numbness, and dysphasia. Symptoms persisting longer than 24 hours constitute a stroke. In contrast, the patient with chronic mesenteric ischemia is likely to present with postprandial abdominal pain and weight loss. The patient fears eating because of the pain, avoids food, and loses weight. It is very unlikely that a patient with abdominal pain who has not lost weight has chronic mesenteric ischemia.

The patient with LE pain on ambulation has intermittent claudication that occurs in certain muscle groups; for example, calf pain upon exercise usually reflects superficial femoral artery (SFA) disease, while pain in the buttocks reflects iliac disease. In most cases, the pain manifests in one muscle group below the level of the affected artery, occurs only with exercise, and is relieved with rest only to recur at the same location, hence the term *window gazers disease*. Rest pain (a manifestation of severe underlying occlusive disease) is constant and occurs in the foot (not the muscle groups), typically at the metatarsophalangeal junction, and is relieved by dependency. Often, the patient is prompted to sleep with their foot hanging off one side of the bed to increase the hydrostatic pressure.

Vascular Physical Examination

Specific vascular examination should include abdominal aortic palpation, carotid artery examination, and pulse examination of the LE (femoral, popliteal, posterior tibial, and dorsalis pedis arteries). The abdomen should be palpated for an abdominal aortic aneurysm (AAA), detected as an expansile pulse above the level of the umbilicus. It also should be examined for the presence of bruits. Because the aorta typically divides at the level of the umbilicus, an aortic aneurysm is most frequently palpable in the epigastrium. In thin individuals, a normal aortic pulsation is palpable, while in obese patients even large aortic aneurysms may not be

detectable. Suspicion of a clinically enlarged aorta should lead to the performance of an ultrasound scan for a more accurate definition of aortic diameter.

The carotids should be auscultated for the presence of bruits, although there is a higher correlation with coronary artery disease (CAD) than underlying carotid stenosis. A bruit at the angle of the mandible is a significant finding, leading to follow-up duplex scanning. The differential diagnosis is a transmitted murmur from a sclerotic or stenotic aortic valve. The carotid is palpable deep to the sternocleidomastoid muscle in the neck. Palpation, however, should be gentle and rarely yields clinically useful information.

Upper extremity examination is necessary when an arteriovenous graft is to be inserted in patients who have symptoms of arm pain with exercise. Thoracic outlet syndrome can result in occlusion or aneurysm formation of the subclavian artery. Distal embolization is a manifestation of thoracic outlet syndrome; consequently, the fingers should be examined for signs of ischemia and ulceration. The axillary artery enters the limb below the middle of the clavicle, where it can be palpated in thin patients. It usually is easily palpable in the axilla and medial upper arm. The brachial artery is most easily located at the antecubital fossa immediately medial to the biceps tendon. The radial artery is palpable at the wrist anterior to the radius.

For LE vascular examination, the femoral pulse usually is palpable midway between the anterior superior iliac spine and the pubic tubercle. The popliteal artery is palpated in the popliteal fossa with the knee flexed to 45° and the foot supported on the examination table to relax the calf muscles. Palpation of the popliteal artery is a bimanual technique. Both thumbs are placed on the tibial tuberosity anteriorly and the fingers are placed into the popliteal fossa between the two heads of the gastrocnemius muscle. The popliteal artery is palpated by compressing it against the posterior aspect of the tibia just below the knee. The posterior tibial pulse is detected by palpation 2 cm posterior to the medial malleolus. The dorsalis pedis is detected 1 cm lateral to the hallucis longus extensor tendon, which dorsiflexes the great toe and is clearly visible on the dorsum of the foot. Pulses can be graded using either the traditional four-point scale or the basic two-point scale system (Table 2). The foot also should be carefully examined for pallor on elevation and rubor on dependency, as these findings are indicative of chronic ischemia. Note should also be made of nail changes and loss of hair. Ulceration and other findings specific to disease states are described in relevant sections below.

Table 2 Grading Scales for Peripheral Pulses

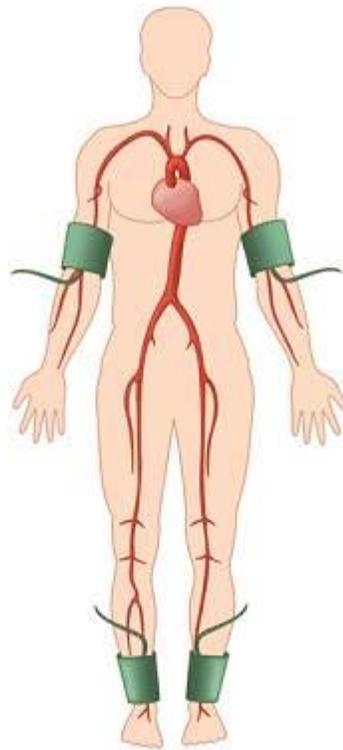

Traditional Scale		Basic Scale	
4+	Normal	2+	Normal
3+	Slightly reduced	1+	Diminished
2+	Markedly reduced	0	Absent
1+	Barely palpable	—	—
0	Absent	—	—

After reconstructive vascular surgery, the graft may be available for examination, depending on its type and course. The in situ LE graft runs in the subcutaneous fat and can be palpated along most of its length. A change in pulse quality, aneurysmal enlargement, or a new bruit should be carefully noted. Axillofemoral grafts, femoral-to-femoral grafts, and arteriovenous access grafts usually can be easily palpated as well.

Noninvasive Diagnostic Evaluation of the Vascular Patient

Ankle-Brachial Index

There is increasing interest in the use of the ankle-brachial index (ABI) to evaluate patients at risk for cardiovascular events. An ABI <0.9 correlates with increased risk of myocardial infarction and indicates significant, although perhaps asymptomatic, underlying peripheral vascular disease. The ABI is determined in the following ways. Blood pressure (BP) is measured in both upper extremities using the highest systolic BP as the denominator for the ABI. The ankle pressure is determined by placing a BP cuff above the ankle and measuring the return to flow of the posterior tibial and dorsalis pedis arteries using a pencil Doppler probe over each artery. The ratio of the systolic pressure in each vessel divided by the highest arm systolic pressure can be used to express the ABI in both the posterior tibial and dorsalis pedis arteries (Fig. 1). Normal is more than 1. Patients with claudication typically have an ABI in the 0.5 to 0.7 range, and those with rest pain are in the 0.3 to 0.5 range. Those with gangrene have an ABI of <0.3 . These ranges can vary depending on the degree of compressibility of the vessel. The test is less reliable in patients with heavily calcified vessels. Due to noncompressibility, some patients such as diabetics and those with end-stage renal disease may have an ABI of 1.40 or greater and require additional noninvasive diagnostic testing to evaluate for peripheral arterial disease (PAD). Alternative tests include toe-brachial pressures, pulse volume recordings, transcutaneous oxygen measurements, or vascular imaging (duplex ultrasound).

**Right ABI = ratio of**

Higher of the right ankle systolic pressures (posterior tibial or dorsalis pedis)

Higher arm systolic pressure (left or right arm)

Left ABI = ratio of

Higher of the left ankle systolic pressures (posterior tibial or dorsalis pedis)

Higher arm systolic pressure (left or right arm)

Fig. 1. Ankle-Brachial Index

Segmental Limb Pressures

By placing serial BP cuffs down the LE and then measuring the pressure with a Doppler probe as flow returns to the artery below the cuff, it is possible to determine segmental pressures down the leg. These data can then be used to infer the level of the occlusion. The systolic pressure at each level is expressed as a ratio, with the highest systolic pressure in the upper extremities as the denominator. Normal segmental pressures commonly show high thigh pressures 20 mmHg or greater in comparison to the brachial artery pressures. The low thigh pressure should be equivalent to brachial pressures. Subsequent pressures should fall by no more than 10 mmHg at each level. A pressure gradient of 20 mmHg between two subsequent levels is usually indicative of occlusive disease at that level. The most frequently used index is the ratio of the ankle pressure to the brachial pressure, the ABI. Normally the ABI is >1.0 , and a value <0.9 indicates some degree of arterial obstruction and has been shown to be correlated

with an increased risk of coronary heart disease.¹ Limitations of relying on segmental limb pressures include: (a) missing isolated moderate stenoses (usually iliac) that produce little or no pressure gradient at rest; (b) falsely elevated pressures in patients with diabetes and end-stage renal disease; and (c) the inability to differentiate between stenosis and occlusion.² Patients with diabetes and end-stage renal disease have calcified vessels that are difficult to compress, thus rendering this method inaccurate, due to recording of falsely elevated pressure readings. Noncompressible arteries yield ankle systolic pressures of 250 mmHg or greater and an ABI of >1.40 . In this situation, absolute toe and ankle pressures can be measured to gauge critical limb ischemia. Ankle pressures <50 mmHg or toe pressures <30 mmHg are indicative of critical limb ischemia. The toe pressure is normally 30 mmHg less than the ankle pressure, and a toe-brachial index of <0.70 is abnormal. False-positive results with the toe-brachial index are unusual. The main limitation of this technique is that it may be impossible to measure pressures in the first and second toes due to pre-existing ulceration.

Pulse Volume Recording

In patients with noncompressible vessels, segmental plethysmography can be used to determine underlying arterial occlusive disease. Cuffs placed at different levels on the leg detect changes in leg volume and produce a pulse volume recording (PVR) when connected to a plethysmograph (Fig. 2). To obtain accurate PVR waveforms the cuff is inflated to 60 to 65 mmHg to detect volume changes without causing arterial occlusion. Pulse volume tracings are suggestive of proximal disease if the upstroke of the pulse is not brisk, the peak of the wave tracing is rounded, and there is disappearance of the dicrotic notch.

A

Fig. 2 A Pulse volume recording is done by connecting blood pressure cuffs and plethysmograph to various levels of the leg

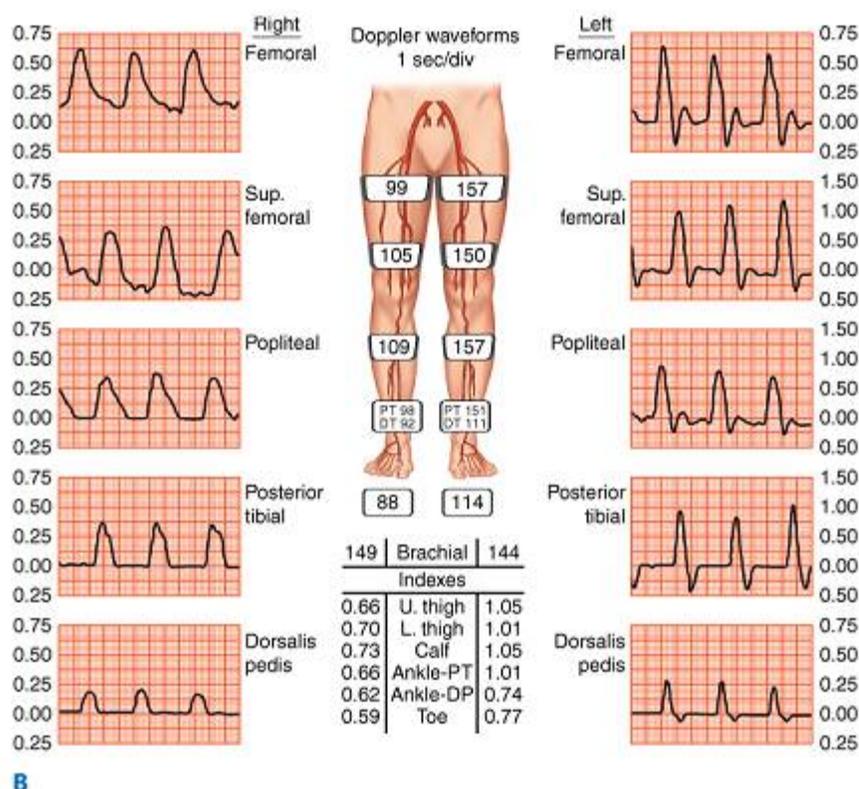

Fig. 2 B Typical report of peripheral vascular study with arterial segmental pressure measurement plus Doppler evaluation of the lower extremity.

Although isolated segmental limb pressures and PVR measurements are 85% accurate when compared with angiography in detecting and localizing significant atherosclerotic lesions, when used in combination, accuracy approaches 95%.³ For this reason, it is suggested that these two diagnostic modalities be used in combination when evaluating PAD.

Radiological Evaluation of the Vascular Patient

Ultrasound

Ultrasound examinations are relatively time consuming, require experienced technicians, and may not visualize all arterial segments. Doppler waveform analysis can suggest atherosclerotic occlusive disease if the waveforms in the insonated arteries are biphasic,

monophasic, or asymmetrical. B-mode ultrasonography provides black and white, real-time images. B-mode ultrasonography does not evaluate blood flow; thus, it cannot differentiate between fresh thrombus and flowing blood, which have the same echogenicity. Calcification in atherosclerotic plaques will cause acoustic shadowing. B-mode ultrasound probes cannot be sterilized. Use of the B-mode probe intraoperatively requires a sterile covering and gel to maintain an acoustic interface. Experience is needed to obtain and interpret images accurately. Duplex ultrasonography entails performance of B-mode imaging, spectral Doppler scanning, and color flow duplex scanning. The caveat to performance of duplex ultrasonography is meticulous technique by a certified vascular ultrasound technician, so that the appropriate 60° Doppler angle is maintained during insonation with the ultrasound probe. Alteration of this angle can markedly alter waveform appearance and subsequent interpretation of velocity measurements. Direct imaging of intra-abdominal vessels with duplex ultrasound is less reliable because of the difficulty in visualizing the vessels through overlying bowel. These disadvantages currently limit the applicability of duplex scanning in the evaluation of aortoiliac and infrapopliteal disease. In a recent study, duplex ultrasonography had lower sensitivity in the calculation of infrapopliteal vessel stenosis in comparison to conventional digital subtraction or computer tomography angiography.⁴ Few surgeons rely solely on duplex ultrasonography for preoperative planning in LE revascularizations. However, in the hands of experienced ultrasonographers, LE arteries can be assessed accurately by determining the significance of velocity criteria across the arterial stenosis. Duplex scanning is unable to evaluate recently implanted polytetrafluoroethylene (PTFE) and polyester (Dacron) grafts because they contain air, which prevents ultrasound penetration.

Computed Tomography Angiography

Computed tomography angiography (CTA) is a noninvasive, contrast-dependent method for imaging the arterial system. It depends on IV infusion of iodine-based contrast agents. The patient is advanced through a rotating gantry, which images serial transverse slices. The contrast-filled vessels can be extracted from the slices and rendered in three-dimensional format (Fig. 3). The extracted images can also be rotated and viewed from several different directions during postacquisition image processing. This technology has been advanced as a consequence of aortic endografting. CTA provides images for postprocessing that can be used to display the aneurysm in a format that demonstrates thrombus, calcium, lumen, and the outer wall, and allows "fitting" of a proposed endograft into the aneurysm (Fig. 4). CTA is increasingly being used to image the carotid bifurcation, and as computing power increases, the

speed of image acquisition and resolution will continue to increase. The major limitations of multidetector CTA are use of contrast and presence of artifacts caused by calcification and stents. CTA can overestimate the degree of instant stenosis, while heavy calcification can limit the diagnostic accuracy of the method by causing a "blooming artifact."⁵ The artifacts can be overcome with alteration in image acquisition technique. There are no randomized trials to document the superiority of multidetector CTA over traditional angiography, but there is emerging evidence to support the claim that multidetector CTA has sensitivity, specificity, and accuracy that rival invasive angiography.

Fig. 3 A. A multidetector computed tomographic angiogram with three-dimensional reconstruction of the iliofemoral arterial circulation in two patients with lower leg claudication. A 50-year-old man with an occluded right superficial femoral artery (*single long arrow*) with reconstituted superficial femoral artery at the level of mid thigh. Arterial calcifications (*short arrows*) in the bilateral distal superficial femoral arteries.

Fig. 3 B. A multidetector computed tomographic angiogram with three-dimensional reconstruction of the iliofemoral arterial circulation in two patients with lower leg claudication.

Fig. 4. Three-dimensional computed tomographic angiogram of an abdominal aortic aneurysm that displays various aneurysm components, including thrombus, aortic calcification, blood circulation, and aneurysm wall.

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) has the advantage of not requiring iodinated contrast agents to provide vessel opacification (Fig. 5). Gadolinium is used as a contrast agent for MRA studies, and as it is generally not nephrotoxic, it can be used in patients with elevated creatinine. MRA is contraindicated in patients with pacemakers, defibrillators, spinal cord stimulators, intracerebral shunts, cochlear implants, and cranial clips. Patients with claustrophobia may require sedation to be able to complete the test. The presence of metallic stents causes artifacts and signal dropout; however, these can be dealt with using alternations in image acquisition and processing. Nitinol stents produce minimal artifact.⁶ Compared to other modalities, MRA is relatively slow and expensive. However, due to its noninvasive nature and decreased nephrotoxicity, MRA is being used more frequently for imaging vasculature in various anatomic distributions.

Fig. 5. Magnetic resonance angiogram of aortic arch and carotid arteries. This study can provide a three-dimensional analysis of vascular structures such as aortic arch branches, as well as carotid and vertebral arteries

Diagnostic Angiography

Diagnostic angiography is considered the gold standard in vascular imaging. In many centers, its use is rapidly decreasing due to the development of noninvasive imaging modalities such as duplex arterial mapping, CTA, and MRA. Nevertheless, contrast angiography still remains in widespread use. The essential aspects of angiography are vascular access and catheter placement in the vascular bed that requires examination. The imaging system and the contrast agent are used to opacify the target vessel. Although in the past this function has largely been delegated to the interventional radiology service, an increasing number of surgeons are performing this procedure and following the diagnostic imaging with immediate surgical or endovascular intervention. There are several considerations when relying on angiography for imaging.

Approximately 70% of atherosclerotic plaques occur in an eccentric location within the blood vessel; therefore, images can be misleading when trying to evaluate stenoses because angiography is limited to a uniplanar "lumenogram." With increased use of intravascular stent deployment, it has been also noted that assessment of stent apposition and stent position in relation to surrounding branches may be inaccurate. Furthermore, angiography exposes the

patient to the risks of both ionizing radiation and intravascular contrast. Nevertheless, contrast angiography remains the most common invasive method of vascular investigation for both diagnostic and therapeutic intervention. The angiogram usually provides the final information needed to decide whether or not to proceed with operation or endovascular interventions.

Digital subtraction angiography (DSA) offers some advantages over conventional cut-film angiography, such as excellent visualization despite use of lower volumes of contrast media. In particular when multilevel occlusive lesions limit the amount of contrast reaching distal vessels, supplemental use of digital subtraction angiographic techniques may enhance visualization and definition of anatomy. Intra-arterial DSA uses a portable, axially rotatable imaging device that can obtain views from different angles. DSA also allows for real-time video replay (Fig. 6). An entire extremity can be filmed with DSA, using repeated injections of small amounts of contrast agent to obtain sequential angiographic images, the so-called *pulse-chase technique*.

Fig. 6. Digital subtraction angiography provides excellent visualization of intravascular circulation with intra-arterial contrast administration. As depicted in this digital subtraction

angiography study, multilevel lesions are demonstrated that include a focal left iliac artery stenosis (*large arrow*), right superficial femoral occlusion (*curved arrows*), left superficial femoral stenosis (*small arrow*), and multiple tibial artery stenoses (*arrowheads*).

Preoperative Cardiac Evaluation

The most important and controversial aspect of preoperative evaluation in patients with atherosclerotic disease requiring surgical intervention is the detection and subsequent management of associated CAD. Several studies have documented the existence of significant CAD in 40 to 50% or more of patients requiring peripheral vascular reconstructive procedures, 10 to 20% of whom may be relatively asymptomatic largely because of their inability to exercise. Myocardial infarction is responsible for the majority of both early and late postoperative deaths. Most available screening methods lack sensitivity and specificity to predict postoperative cardiac complications. There have been conflicting reports regarding the utility of preoperative dipyridamole-thallium nuclear imaging or dobutamine-echocardiography to stratify vascular patients in terms of perioperative cardiac morbidity and mortality. In nearly one half of patients, thallium imaging proves to be unnecessary because cardiac risk can be predicted by clinical information alone. Even with coronary angiography, it is difficult to relate anatomic findings to functional significance, and hence, surgical risk. There are no data confirming that percutaneous coronary interventions or surgical revascularization before vascular surgical procedures impacts mortality or incidence of myocardial infarctions. In fact, coronary angiography is associated with its own inherent risks, and patients undergoing coronary artery bypass grafting or coronary percutaneous transluminal angioplasty (PTA) before needed aortoiliac reconstructions are subjected to the risks and complications of both procedures.

The Coronary Artery Revascularization Prophylaxis trial showed that coronary revascularization in patients with peripheral vascular disease and significant CAD, who are considered high risk for perioperative complications, did not reduce overall mortality or perioperative myocardial infarction. Additionally, patients who underwent prophylactic coronary revascularization had significant delays before undergoing their vascular procedure and increased limb morbidity compared to patients who did not. Studies do support improvement in cardiovascular and overall prognosis with medical optimization of patients. Therefore, use of perioperative beta blockade, as well as use of antiplatelet medication, statins,

and angiotensin-converting enzyme (ACE) inhibitors is encouraged in vascular patients

AORTOILIAC OCCLUSIVE DISEASE

The distal abdominal aorta and the iliac arteries are common sites affected by atherosclerosis. The symptoms and natural history of the atherosclerotic process affecting the aortoiliac arterial segment are influenced by the disease distribution and extent. Atherosclerotic plaques may cause clinical symptoms by restricting blood flow due to luminal obstruction or by embolizing atherosclerotic debris to the LE circulation. If the aortoiliac plaques reach sufficient mass that impinge on the arterial lumen, obstruction of blood flow to lower extremities occurs. Various risk factors exist that can lead to the development of aortoiliac occlusive disease. Recognition of these factors and understanding this disease entity will enable physicians to prescribe the appropriate treatment strategy that may alleviate symptoms and improve quality of life.

Diagnostic Evaluation

On clinical examination, patients often have weakened femoral pulses and a reduced ABI. Verification of iliac occlusive disease is usually made by color duplex scanning that reveals either a peak systolic velocity ratio of 2.5 or greater at the site of stenosis and/or a monophasic waveform. Noninvasive tests such as pulse volume recording (PVR) of the LE with estimation of the thigh-brachial pressure index may be suggestive of aortoiliac disease. MRA and multidetector CTA are increasingly being used to determine the extent and type of obstruction. DSA offers the interventionalist the benefit of making a diagnosis and the option of performing an endovascular treatment in a single session. Angiography provides important information regarding distal arterial runoff vessels as well as the patency of the profunda femoris artery (PFA). Presence of pelvic and groin collaterals is important in providing crucial collateral flow in maintaining lower limb viability. It must be emphasized, however, that patients should be subjected to angiography only if their symptoms warrant surgical intervention.

Differential Diagnosis

Degenerative hip or spine disease, lumbar disc herniation, spinal stenosis, diabetic neuropathy, and other neuromuscular problems can produce symptoms that may be mistaken

for vascular claudication. Such cases can be distinguished from true claudication by the fact that the discomfort from neuromuscular problems often is relieved by sitting or lying down, as opposed to cessation of ambulation. In addition, complaints that are experienced upon standing suggest nonvascular causes. When confusion persists, the use of noninvasive vascular laboratory testing modalities, including treadmill exercise, can help establish the diagnosis.

Collateral Arterial Network

The principal collateral pathways in severe aortoiliac artery occlusive disease or chronic aortic occlusion that may provide blood flow distal to the aortoiliac lesion include: (a) the SMA to the distal IMA via its superior hemorrhoidal branch to the middle and inferior hemorrhoidals to the internal iliac artery (39%); (b) the lumbar arteries to the superior gluteal artery to the internal iliac system (37%); (c) the lumbar arteries to the lateral and deep circumflex arteries to the common femoral artery (CFA) (12%); and (d) Winslow's pathway from the subclavian to the superior epigastric artery to the inferior epigastric artery to the external iliac arteries at the groin (Fig. 7). In general, treatment indications for aortoiliac artery occlusive disease include disabling claudication, ischemic rest pain, nonhealing LE tissue wound, and LE microembolization that arise from aortoiliac lesions.

Fig. 7. Pertinent collateral pathways are developed in the event of chronic severe aortoiliac occlusive disease. As illustrated in this multidetector computed tomography angiography, these collaterals include epigastric arteries (*large white arrows*), an enlarged inferior mesenteric artery (*white arrowhead*), and enlarged lumbar arteries (*black arrows*).

Disease Classification

Based on the atherosclerotic disease pattern, aortoiliac occlusive disease can be classified into three various types (Fig. 8). Type I aortoiliac disease, which occurs in 5 to 10% of patients, is confined to the distal abdominal aorta and common iliac vessels (Fig. 9). Due to the localized nature of this type of aortic obstruction and formation of collateral blood flow around the occluded segment, limb-threatening symptoms are rare in the absence of more distal disease (Fig. 10). This type of aortoiliac occlusive disease occurs in a relatively younger group of patients (aged in their mid-50s), compared with patients who have more femoropopliteal disease. Patients with a type I disease pattern have a lower incidence of hypertension and diabetes, but a significant frequency of abnormal blood lipid levels, particularly type IV hyperlipoproteinemia. Symptoms typically consist of bilateral thigh or buttock claudication and fatigue. Men report diminished penile tumescence and may have complete loss of erectile function. These symptoms in the absence of femoral pulses constitute Leriche's syndrome. Rest pain is unusual with isolated aortoiliac disease unless distal disease coexists. Occasionally patients report a prolonged history of thigh and buttock claudication that recently has become more severe. It is likely that this group has underlying aortoiliac disease that has progressed to acute occlusion of the terminal aorta. Others may present with "trash foot" that represents microembolization into the distal vascular bed (Fig. 11).

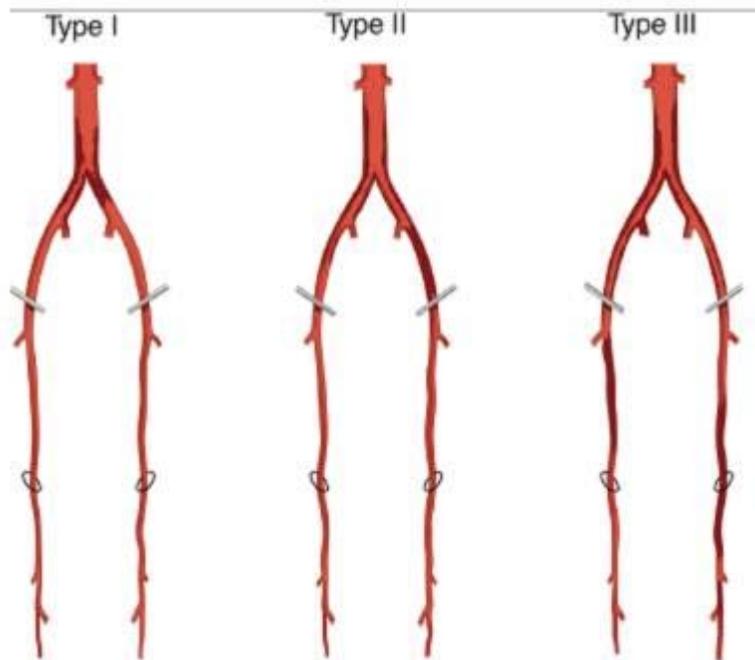

Fig. 8. Aortoiliac disease can be classified into three types. Type I represents focal disease affecting the distal aorta and proximal common iliac artery. Type II represents diffuse aortoiliac disease above the inguinal ligament. Type III represents multisegment occlusive disease involving aortoiliac and infrainguinal arterial vessels.

Fig. 9. Type I aortoiliac disease is confined to the distal abdominal aorta (*long arrow*) or proximal common iliac arteries. Due to the localized nature of this type of aortic obstruction and formation of collateral blood flow around the occluded segment (*short arrows*), limb-threatening symptoms are rare in the absence of more distal disease.

Fig. 10. Multidetector computed tomography angiography of the aortoiliac artery circulation in a 63-year-old man with buttock claudication. Three-dimensional image reconstruction showing intra-arterial calcification of the aorta (*large arrows*) and right common iliac artery (*small arrows*). This is consistent with a type I aortoiliac occlusive disease.

Fig. 11. Atherosclerotic disease involving the aortoiliac segment can result in microembolization of the lower leg circulation, resulting in trash foot or digital gangrene of toes.

Type II aortoiliac disease represents a more diffuse atherosclerotic progression that involves predominately the abdominal aorta with disease extension into the CIA. This disease pattern affects approximately 25% of patients with aortoiliac occlusive disease. Type III aortoiliac occlusive disease, which affects approximately 65% of patients with aortoiliac occlusive disease, is widespread disease that is seen above and below the inguinal ligament (Fig. 12). Patients with "multilevel" disease are older, more commonly male (with a male-to-female ratio of 6:1), and much more likely to have diabetes, hypertension, and associated atherosclerotic disease involving cerebral, coronary, and visceral arteries. Progression of the occlusive process is more likely in these patients than in those with localized aortoiliac disease. For these reasons, most patients with a type III pattern tend to present with symptoms of advanced ischemia and require revascularization for limb salvage rather than for claudication. These patients have a decreased 10-year life expectancy when compared to patients with localized aortoiliac disease.

Fig. 12. Type III aortoiliac occlusive disease is a multilevel disease pattern that affects the aortoiliac segment as well as infrainguinal femoropopliteal vessels. Most patients with this disease pattern tend to present with symptoms of advanced ischemia and require revascularization for limb salvage rather than for claudication.

The most commonly used classification system of iliac lesions has been set forth by the TASC II group with recommended treatment options. This lesion classification categorizes the extent of atherosclerosis and has suggested a therapeutic approach based on this classification (Table 3 and Fig. 13). According to this consensus document, endovascular therapy is the

treatment of choice for type A lesions, and surgery is the treatment of choice for type D lesions. Endovascular treatment is the preferred treatment for type B lesions, and surgery is the preferred treatment for good-risk patients with type C lesions. In comparison to the 2000 TASC II document, the commission has not only made allowances for treatment of more extensive lesions, but also took into account the continuing evolution of endovascular technology and the skills of individual interventionalists when stating that the patient's comorbidities, fully informed patient preference, and the local operator's long-term success rates must be considered when making treatment decisions for type B and type C lesions

Table 3. TASC II Classification of Aortoiliac Occlusive Lesions

Type A lesions
• Unilateral or bilateral stenoses of CIA
• Unilateral or bilateral single short (≤ 3 cm) stenosis of EIA
Type B lesions
• Short (≤ 3 cm) stenosis of infrarenal aorta
• Unilateral CIA occlusion
• Single or multiple stenosis totaling 3–10 cm involving the EIA not extending into the CFA
• Unilateral EIA occlusion not involving the origins of internal iliac or CFA
Type C lesions
• Bilateral CIA occlusions
• Bilateral EIA stenoses 3–10 cm long not extending into the CFA
• Unilateral EIA stenosis extending into the CFA
• Unilateral EIA occlusion that involves the origins of internal iliac and/or CFA
• Heavily calcified unilateral EIA occlusion with or without involvement of origins of internal iliac and/or CFA
Type D lesions
• Infrarenal aortoiliac occlusion
• Diffuse disease involving the aorta and both iliac arteries requiring treatment
• Diffuse multiple stenoses involving the unilateral CIA, EIA, and CFA
• Unilateral occlusions of both CIA and EIA
• Bilateral occlusions of EIA
• Iliac stenoses in patients with AAA requiring treatment and not amenable to endograft placement or other lesions requiring open aortic or iliac surgery

AAA = abdominal aortic aneurysm; CFA = common femoral artery; CIA = common iliac artery; EIA = external iliac artery; TASC II = Trans-Atlantic Inter-Society Consensus.

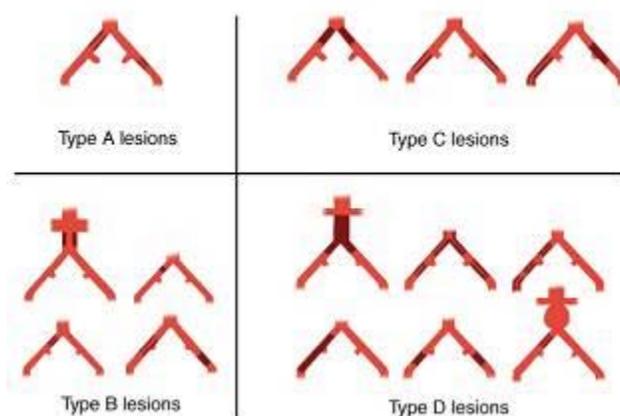

Fig. 13. Schematic depiction of Trans-Atlantic Inter-Society Consensus classification of aortoiliac occlusive lesions

General Treatment Considerations

There is no effective medical therapy for the management of aortoiliac disease, but control of risk factors may help slow progression of atherosclerosis. Patients should have hypertension, hyperlipidemia, and diabetes mellitus controlled. They should be advised to stop smoking. Most patients are empirically placed on antiplatelet therapy. A graduated exercise program may improve walking efficiency, endothelial function, and metabolic adaptations in skeletal muscle, but, there is usually minimal improvement in patients with aortoiliac disease who are treated with these measures. Failure to respond to exercise and/or drug therapy should prompt consideration for limb revascularization. Patients with buttock claudication and reduced or absent femoral pulses who fail to respond to exercise and drug therapy should be considered for revascularization because they are less likely than patients with more distal lesions to improve without concomitant surgical or endovascular intervention.

Surgical Reconstruction of Aortoiliac Occlusive Disease

Aortobifemoral Bypass

Surgical options for treatment of aortoiliac occlusive diseases consist of various configurations of aortobifemoral bypass (ABF) grafting, various types of extra-anatomic bypass grafts, and aortoiliac endarterectomy. The procedure performed is determined by several factors, including anatomic distribution of the disease, clinical condition of the patient, and personal preference of the surgeon.

In most cases, ABF is performed because patients usually have disease in both iliac systems. Although one side may be more severely affected than the other, progression does occur, and bilateral bypass does not complicate the procedure or add to the physiologic stress of the operation. ABF reliably relieves symptoms, has excellent long-term patency (approximately 70 to 75% at 10 years), and can be completed with a tolerable perioperative mortality (2 to 3%).

Technical Considerations for Aortobifemoral Bypass

Both femoral arteries are initially exposed to ensure that they are adequate for the distal

anastomoses. The abdomen is then opened in the midline, the small intestine is retracted to the right, and the posterior peritoneum overlying the aorta is incised. A retroperitoneal approach may be selected as an alternative in certain situations. This approach involves making a left flank incision and displacing the peritoneum and its contents to the right. Such an approach is contraindicated if the right renal artery is acutely occluded, because visualization from the left flank is very poor. Tunneling of a graft to the right femoral artery also is more difficult from a retroperitoneal approach, but can be achieved. The retroperitoneal approach has been reputed to be better tolerated than midline laparotomy for patients with multiple previous abdominal operations and with severe pulmonary disease. Further proposed advantages of the retroperitoneal approach include less GI disturbance, decreased third-space fluid losses, and ease with which the pararenal aorta can be accessed. There are randomized reports, however, that support and refute the superiority of this approach. A collagen-impregnated, knitted Dacron graft is used to perform the proximal aortic anastomosis, which can then be made in either an end-to-end or end-to-side fashion using 3-0 polypropylene suture. The proximal anastomosis should be made as close as possible to the renal arteries to decrease the incidence of restenosis from progression of the atherosclerotic occlusive process in the future.

An end-to-end proximal aortic anastomosis is necessary in those patients with an aortic aneurysm or complete aortic occlusion extending up to the renal arteries (Fig. 14). Although in theory, the end-to-end configuration allows for less turbulence and less chance of competitive flow with still patent host iliac vessels, there have not been consistent results to substantiate differences in patency between end-to-end and end-to-side grafts. Relative indications for an end-to-side proximal aortic anastomosis include the presence of large aberrant renal arteries, an unusually large IMA with poor back-bleeding, suggesting inadequate collateralization, and/or occlusive disease involving bilateral external iliac arteries. Under such circumstances, end-to-end bypass from the proximal aorta to the femoral level devascularizes the pelvic region because there is no antegrade or retrograde flow in the occluded external iliac arteries to supply the hypogastric arteries. As a result of the pelvic devascularization, there is an increased incidence of impotence, postoperative colon ischemia, buttock ischemia, and paraplegia secondary to spinal cord ischemia, despite the presence of excellent femoral and distal pulses.

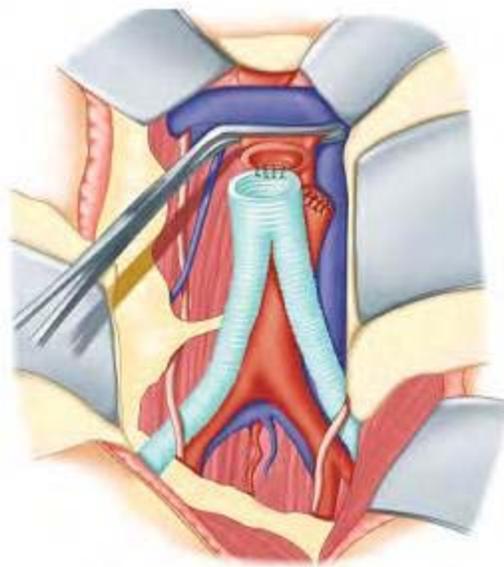

Fig. 14. In an end-to-end proximal aortic anastomosis, the aorta is divided in half. The proximal end of the aorta is anastomosed to the end of a prosthetic graft while the distal divided aortic stump is oversewn.

An end-to-side proximal aortic anastomosis can be associated with certain disadvantages, which include the potential for distal embolization when applying a partially occlusive aortic clamp (Fig. 15). Furthermore, the distal aorta often proceeds to total occlusion after an end-to-side anastomosis. There may also be a higher incidence of aortoenteric fistula following construction of end-to-side proximal anastomoses because the anterior projection makes subsequent tissue coverage and reperitonealization of the graft more difficult. The limbs of the graft are tunneled through the retroperitoneum to the groin, where an end-to-side anastomosis is fashioned between the graft and the bifurcation of the CFA using 5-0 polypropylene suture. Endarterectomy or patch angioplasty of the profunda femoris may be required concurrently. Once the anastomoses have been fashioned and the graft thoroughly flushed, the clamps are removed and the surgeon carefully controls the degree of aortic occlusion until full flow is re-established. During this period the patient must be carefully monitored for hypotension. Declamping hypotension is a complication of sudden restoration of aortic flow, particularly following prolonged occlusion. Once flow has been re-established, the peritoneum is carefully reapproximated over the prosthesis to prevent fistulization into the intestine.

Fig. 15. In an end-to-side aortic anastomosis, the end of a prosthetic graft is connected to the side of an aortic incision

Despite the presence of multilevel disease in most patients, a properly performed aortobifemoral operation can provide arterial inflow and alleviate claudication symptoms in 70 to 80% of patients; however, 10 to 15% of patients will require simultaneous outflow reconstruction to address distal ischemia and facilitate limb salvage. The advantage of concomitant distal revascularization is avoidance of reoperation in a scarred groin. As a rule, if the profunda femoris can accept a 4-mm probe and if a No. 3 Fogarty embolectomy catheter can be passed distally for 20 cm or more, the PFA will be sufficient for outflow and concomitant distal revascularization is not necessary.

Aortic Endarterectomy

Aortoiliac endarterectomy is rarely performed, as it is associated with greater blood loss, greater sexual dysfunction, and is more difficult to perform. Long-term patency is comparable with aortobifemoral grafting, and thus it remains a reasonable option in cases in which the risk of infection of a graft is excessive, because it involves no prosthetic tissue. Aortoiliac endarterectomy was useful when disease was localized to either the aorta or CIAs; however, at present, aortoiliac PTA, stents, and other catheter-based therapies have become first-line treatments in this scenario. Endarterectomy should not be performed if the aorta is aneurysmal because of continued aneurysmal degeneration of the endarterectomized segment. If there is total occlusion of the aorta to the level of the renal arteries, aortic transection several centimeters below the renal arteries with thrombectomy of the aortic cuff followed by graft insertion is easier and more expeditious when compared to endarterectomy. Involvement of the EIA makes aortic endarterectomy more difficult to complete because of decreased vessel

diameter, increased length, and exposure issues. The ability to establish an appropriate endarterectomy plane is compromised due to the muscular and inherently adherent nature of the media in this location. There is a higher incidence of early thrombosis and late failure with extended aortoiliofemoral endarterectomy when compared to bypass grafting as a result of recurrent stenosis.

Axillofemoral Bypass

An axillofemoral bypass is an extra-anatomic reconstruction that derives arterial inflow from the axillary artery to the femoral artery. This is a treatment option for those patients with medical comorbidities that prohibit an abdominal vascular reconstruction. It may be performed under local anesthesia and is used for limb salvage. Extra-anatomic bypasses have lower patency when compared to aortobifemoral, and therefore, are seldom recommended for claudication. Before performing this operation, the surgeon should check pulses and BP in both arms to ensure that there is no obvious disease affecting flow through the axillary system. Angiography of the axillosubclavian vasculature is not necessary, but can be helpful if performed at the time of aortography. The axillary artery is exposed below the clavicle, and a 6- to 8-mm externally reinforced PTFE graft is tunneled subcutaneously down the lateral chest wall and lateral abdomen to the groin. It is anastomosed to the ipsilateral distal at the CFA bifurcation into the superficial femoral and profunda femoris arteries. A femorofemoral crossover graft using a 6- to 8-mm externally reinforced PTFE graft is then used to revascularize the opposite extremity if necessary. Reported patency rates over 5 years vary from 30 to 80%. Paradoxically, although it is a less complex procedure than aortofemoral grafting, the mortality rate is higher (10%), reflecting the compromised medical status of these patients.

Iliofemoral Bypass

One option for patients with unilateral occlusion of the distal common iliac or external iliac arteries is iliofemoral grafting (Fig. 16). Long-term patency is comparable to aortounifemoral bypass and because the procedure can be performed using a retroperitoneal approach without clamping the aorta, the perioperative mortality is less.

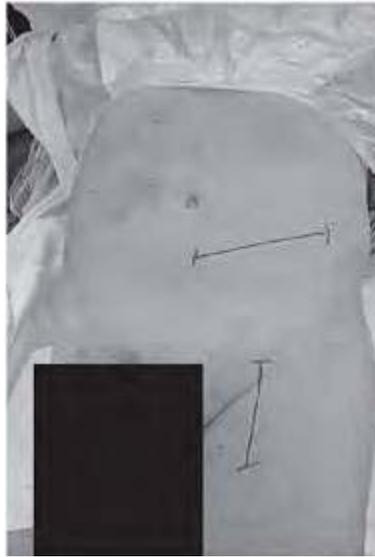

Fig. 16 A. Skin markings showing the incisions of an iliofemoral bypass

Fig. 16 B. A prosthetic bypass graft is used for an iliofemoral artery bypass in which the proximal anastomosis is connected to the common iliac artery (*long arrow*) while the distal anastomosis is connected to the common femoral artery (*short arrow*).

Femorofemoral Bypass

A femorofemoral bypass is another option for patients with unilateral stenosis or occlusion of the common or EIA who have rest pain, tissue loss, or intractable claudication. The primary (assisted) patency at 5 years is reported to be 60 to 70%, and, although this is inferior when compared to aortofemoral bypass, there are physiologic benefits, especially for

patients with multiple comorbidities, because it is not necessary to cross-clamp the aorta. There are no studies supporting the superiority of unsupported or externally supported PTFE over Dacron for choice of conduit. The fear of the recipient extremity stealing blood from the extremity ipsilateral to the donor limb is not realized unless the donor iliac artery and donor outflow arteries are diseased. Depending on the skills of the interventionalist/surgeon, many iliac lesions classified as TASC II B, C, or D can now be addressed using an endovascular approach, thus obviating the need to perform a femorofemoral bypass. Additionally, femorofemoral bypass can be used as an adjuvant procedure after iliac inflow has been optimized with endovascular methods.

Obturator Bypass

An obturator bypass is used to reconstruct arterial anatomy in patients with groin sepsis resulting from prior prosthetic grafting, intra-arterial drug abuse, groin neoplasm, or damage from prior groin irradiation. This bypass can originate from the CIA, EIA, or uninvolved limb of an ABF. A conduit of Dacron, PTFE, or autologous vein is tunneled through the anteromedial portion of the obturator membrane to the distal superficial femoral or popliteal artery. The obturator membrane must be divided sharply so as to avoid injury to adjacent structures, and care must be taken to identify the obturator artery and nerve that pass posterolaterally. After the bypass is completed and the wounds isolated, the infected area is entered, the involved arteries are débrided to healthy tissue, and vascularized muscle flaps are mobilized to cover the ligated ends. There have been varied results in terms of patency and limb salvage for obturator bypass. Some authors have reported 57% 5-year patency and 77% 5-year limb salvage rates, whereas others have shown a high rate of reinfection and low patency requiring reintervention.

Thoracofemoral Bypass

The indications for thoracofemoral bypass are (a) multiple prior surgeries with a failed infrarenal aortic reconstruction and (b) infected aortic prosthesis. This procedure is more physiologically demanding than other extra-anatomic reconstructions because the patient must not only tolerate clamping the descending thoracic aorta but also performance of a left thoracotomy. The graft is tunneled to the left CFA from the left thorax posterior to the left kidney in the anterior axillary line using a small incision in the periphery of the diaphragm and

an incision in the left inguinal ligament to gain access to the extraperitoneal space from below. The right limb is tunneled in the space of Retzius in an attempt to decrease kinking that is more likely to occur with subcutaneous, suprapubic tunneling. Thoracofemoral bypass has long-term patency comparable to aortofemoral bypass.

Complications of Surgical Aortoiliac Reconstruction

With current surgical techniques and conduits, early postoperative hemorrhage is unusual and occurs in 1 to 2% of cases. It is usually the result of technical oversight or coagulation abnormality. Acute limb ischemia (ALI) occurring after aortoiliac surgery may be the result of acute thrombosis or distal thromboembolism. The surgeon can prevent thromboembolic events by (a) avoiding excessive manipulation of the aorta, (b) ensuring adequate systemic heparinization, (c) judicious placement of vascular clamps, and (d) thorough flushing before restoring blood flow. Acute thrombosis of an aortofemoral graft limb in the early perioperative period occurs in 1 to 3% of patients.¹¹² Thrombectomy of the graft limb is performed through a transverse opening in the hood of the graft at the femoral anastomosis. With this approach, it is possible to inspect the interior of the anastomosis and pass embolectomy catheters distally to clear the superficial femoral and profunda arteries. Various complications may be encountered following aortoiliac or aortobifemoral reconstruction (Table 4).

Table 4. Perioperative Complications of Aortobifemoral Bypass Grafting

Medical complications
• Perioperative myocardial infarction
• Respiratory failure
• Ischemia-induced renal failure
• Bleeding from IV heparinization
• Stroke
Procedure-related complications
Early
• Declamping shock
• Graft thrombosis
• Retroperitoneal bleeding
• Groin hematoma
• Bowel ischemia/infarction
• Peripheral embolization
• Erectile dysfunction
• Lymphatic leak
• Chylous ascites
• Paraplegia
Late
• Graft infection
• Anastomotic pseudoaneurysm
• Aortoenteric fistula
• Aortourinary fistula
• Graft thrombosis

Intestinal ischemia following aortic reconstruction occurs in approximately 2% of cases; however, with colonoscopy, mucosal ischemia, which is a milder form, is seen more frequently. The surgeon can identify patients who require concomitant revascularization of the IMA, hypogastric arteries, or mesenteric arteries by examining the preoperative arteriogram for the presence of associated occlusive lesions in the celiac axis, the superior mesenteric arteries, or both. Likewise patients with patent and enlarged IMA or a history of prior colonic resections will benefit from IMA reimplantation.

In a comprehensive review of 747 patients who had aortoiliac operations for occlusive disease, secondary operations for late complications such as reocclusion, pseudoaneurysms, and infection were necessary in 21% of cases over a 22-year period. The most frequent late complication is graft thrombosis. Limb occlusion occurs in 5 to 10% of patients within 5 years of the index operation and in 15 to 30% of patients 10 years or more after the index operation. Anastomotic pseudoaneurysms occur in 1 to 5% of femoral anastomoses in patients with aortofemoral grafts. Predisposing factors to pseudoaneurysm formation include progression of degenerative changes within the host artery, excessive tension at the anastomosis, and infection. Due to the associated risks of thrombosis, distal embolization, infection, and rupture, anastomotic aneurysms should be repaired expeditiously.

Infection following aortoiliac reconstruction is a devastating complication that occurs in 1% of cases. Femoral anastomoses of aortofemoral reconstructions and axillofemoral bypasses are prone to infection. Use of prophylactic antibiotics and meticulous surgical technique are vital in preventing contamination of the graft at the time of implantation. If infection appears to be localized to a single groin, one may consider the treatment strategies of graft preservation, aggressive local wound débridement, antibiotic solution irrigation, and soft tissue coverage with rotational muscle flaps. This nonexcisional treatment approach may be useful in selective cases of localized femoral graft infection. Most patients with infected aortoiliofemoral reconstructions usually require graft excision and revascularization via remote uncontaminated routes or the use of in situ replacement to clear the infective process and maintain limb viability. Aortoenteric fistula and associated GI hemorrhage are devastating complications, with a 50% incidence of death or limb loss. The incidence of aortoenteric fistula formation appears to be higher after an end-to-side proximal anastomosis, because it is more difficult to cover the prosthesis with viable tissue and avoid contact with the GI tract with this configuration. Treatment of aortoenteric fistula requires resection of all prosthetic material, closure of the infrarenal abdominal aorta, repair of the GI tract, and revascularization by means of an extra-anatomic graft.

LOWER EXTREMITY ARTERIAL OCCLUSIVE DISEASE

The symptoms of LE occlusive disease are classified into two large categories: ALI and chronic limb ischemia (CLI). Ninety percent (90%) of acute ischemias are either thrombotic or embolic. Frequently, sudden onset of limb-threatening ischemia may be the result of acute exacerbation of the pre-existing atherosclerotic disease. Chronic ischemia is largely due to atherosclerotic changes of the LE that manifest from asymptomatic to limb-threatening gangrene. As the population ages, the prevalence of chronic occlusive disease of the LE is increasing and it significantly influences lifestyle, morbidity, and mortality. In addition, multiple comorbid conditions increase risks of surgical procedures. Endovascular interventions become an important alternative in treating LE occlusive disease. However, despite rapid evolving endovascular technology, LE endovascular intervention continues to be one of the most controversial areas of endovascular therapy.

Epidemiology

In a detailed review of the literature, McDaniel and Cronenwett concluded that claudication occurred in 1.8% of patients under 60 years of age, 3.7% of patients between 60 and 70 years of age, and 5.2% of patients over 70 years of age. Leng and his colleagues scanned 784 subjects using ultrasound in a random sample of men and women ages 56 to 77 years. Of the subjects that were scanned, 64% demonstrated atherosclerotic plaque. However, a large number of patients had occlusive disease without significant symptoms. In a study by Schroll and Munck, only 19% of the patients with peripheral vascular disease were symptomatic. Using ankle-brachial indices (ABIs), Stoffers and colleagues scanned 3171 individuals between the ages of 45 and 75 and identified 6.9 % of patients who had ABIs <0.95 , only 22% of whom had symptoms. In addition, they demonstrate that the concomitant cardiovascular and cerebrovascular diseases were three to four times higher among the group with asymptomatic peripheral vascular diseases than those without peripheral vascular disease. Furthermore, they confirm that 68% of all peripheral arterial obstructive diseases were unknown to the primary care physician and this group mainly represented less advanced cases of atherosclerosis. However, among patients with an ABI ratio <0.75 , 42% were unknown to the primary physicians.

Diagnostic Evaluation

The diagnosis of LE occlusive disease often is made based upon a focused history and physical examination, and confirmed by the imaging studies. A well-performed physical examination often reveals the site of lesions by detecting changes in pulses, temperature, and appearances. The bedside ABIs using BP cuff also aid in diagnosis. Various clinical signs and symptoms are useful to differentiate conditions of viable, threatened, and irreversible limb ischemia caused by arterial insufficiency.

Noninvasive studies are important in documenting the severity of occlusive disease objectively. Ultrasound Dopplers measuring ABIs and segmental pressures are widely used in North America and Europe. Normal ABI is >1.0 . In patients with claudication, ABIs decrease to 0.5 to 0.9 and to even lower levels in patients with rest pain or tissue loss. Segmental pressures are helpful in identifying the level of involvement. Decrease in segmental pressure between two segments indicates significant disease. Ultrasound duplex scans are used to identify the site of lesion by revealing flow disturbance and velocity changes. A meta-analysis of 71 studies by Koelemay and associates confirmed that duplex scanning is accurate for assessing arterial occlusive disease in patients suffering from claudication or critical ischemia,

with an accumulative sensitivity of 80% and specificity of over 95%. Adding an ultrasound contrast agent further increases sensitivity and specificity to ultrasound technology. Other noninvasive imaging technologies such as MRA and CTA are rapidly evolving and gaining popularity in the diagnosis of LE occlusive disease (Figs. 17 and 18).

Fig. 17. A high-resolution computed tomography angiography of a patient with normal right lower extremity arterial circulation. Distal occlusive disease is noted in the left tibial arteries (*arrow*).

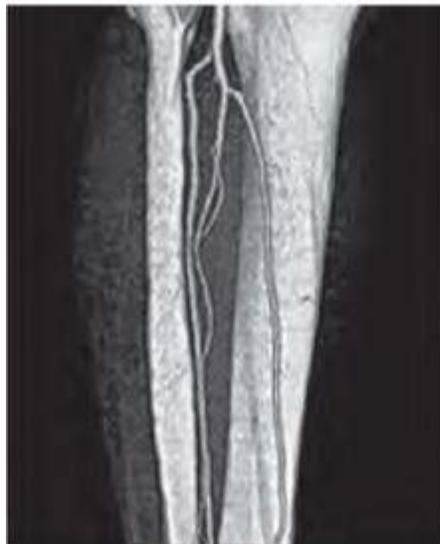

Fig 18 A. A multidetector computed tomographic angiography of a patient with an infrapopliteal arterial circulation

Fig 18 B. Pedal arterial circulation. The high spatial resolution and image quality of these images show three patent infrapopliteal runoff vessels and patent pedal vessels at the foot level

Contrast angiography remains the gold standard in imaging study. Using contrast angiography, interventionists can locate and size the anatomic significant lesions and measure the pressure gradient across the lesion, as well as plan for potential intervention. Angiography is, however, semi-invasive and should be confined to patients for whom surgical or percutaneous intervention is contemplated. Patients with borderline renal function may need to have alternate contrast agents such as gadolinium or carbon dioxide to avoid contrast-induced nephrotoxicity.

Differential Diagnosis

Arterial insufficiency frequently leads to muscle ischemic pain involving the LE muscularly, particularly during exercise. Intermittent claudication is pain affecting the calf, and, less commonly, the thigh and buttock, which is induced by exercise and relieved by rest. Symptom severity varies from mild to severe. Intermittent claudication occurs as a result of muscle ischemia during exercise caused by obstruction to arterial flow. For differential diagnosis of intermittent claudication, there are a variety of neurologic, musculoskeletal, and venous conditions that may produce symptoms of calf pain (Table 5). Additionally, various non-atherosclerotic conditions also can cause symptoms consistent with intermittent LE claudication (Table 6). Nocturnal calf muscle spasms or night cramps are not indicative of arterial disease. They are common but are difficult to diagnose with certainty. Foot ulceration is

not always the result of arterial insufficiency. Ischemic ulcers occur on the toes or lateral side of the foot and are painful. By comparison, venous ulcers, which also are common, occur above the medial malleolus. These venous stasis ulcers are typically surrounded by a peripheral area of darkened skin discoloration that is also known as *lipodermatosclerosis*. Neuropathic ulcers usually are found on weight-bearing surfaces, have thick calluses, and are pain free. Ulcers may be the result of more than one etiology. Rest pain must be distinguished from peripheral neuropathy, which is prevalent in diabetic patients. Patients with diabetic neuropathy tend to have decreased vibration and position sense and decreased reflexes. Spinal stenosis causes pain that is exacerbated with standing and back extension.

Table 5 Differential Diagnosis of Intermittent Claudication

Condition	Location of Pain or Discomfort	Characteristic Discomfort	Onset Relative to Exercise	Effect of Rest	Effect of Body Position	Other Characteristics
Intermittent claudication (calf)	Calf muscles	Cramping pain	After same degree of exercise	Quickly relieved	None	Reproducible
Chronic compartment syndrome	Calf muscles	Tight, bursting pain	After much exercise (e.g., jogging)	Subsides very slowly	Relief speeded by elevation	Typically heavy-muscled athletes
Venous claudication	Entire leg, but usually worse in thigh and groin	Tight, bursting pain	After walking	Subsides slowly	Relief speeded by elevation	History of iliofemoral deep venous thrombosis, signs of venous congestion, edema
Nerve root compression (e.g., herniated disk)	Radiates down leg, usually posteriorly	Sharp lancinating pain	Soon, if not immediately after onset	Not quickly relieved (also often present at rest)	Relief may be aided by adjusting back position	History of back problems
Symptomatic Baker's cyst	Behind knee, down calf	Swelling, soreness, tenderness	With exercise	Present at rest	None	Not intermittent
Intermittent claudication (hip, thigh, buttock)	Hip, thigh, buttocks	Aching discomfort, weakness	After same degree of exercise	Quickly relieved	None	Reproducible
Hip arthritis	Hip, thigh, buttocks	Aching discomfort	After variable degree of exercise	Not quickly relieved (and may be present at rest)	More comfortable sitting, weight taken off legs	Variable, may relate to activity level, weather changes
Spinal cord compression	Hip, thigh, buttocks (follows dermatome)	Weakness more than pain	After walking or standing for same length of time	Relieved by stopping only if position changed	Relief by lumbar spine flexion (sitting or stooping forward) pressure	Frequent history of back problems, provoked by increased intra-abdominal pressure
Intermittent claudication (foot)	Foot, arch	Severe deep pain and numbness	After same degree of exercise	Quickly relieved	None	Reproducible
Arthritic, inflammatory process	Foot, arch	Aching pain	After variable degree of exercise	Not quickly relieved (and may be present at rest)	May be relieved by not bearing weight	Variable, may relate to activity level

Table 6. Non-Atherosclerotic Causes of Intermittent Claudication

• Aortic coarctation
• Arterial fibrodysplasia
• Iliac syndrome of the cyclist
• Peripheral emboli
• Persistent sciatic artery
• Popliteal aneurysm
• Popliteal cyst
• Popliteal entrapment
• Primary vascular tumors
• Pseudoxanthoma elasticum
• Remote trauma or radiation injury
• Takayasu's disease
• Thromboangiitis obliterans

Lower Extremity Occlusive Disease Classification

LE occlusive disease may range from exhibiting no symptoms to limb-threatening gangrene. There are two major classifications based on the clinical presentations.

The Fontaine classification uses four stages: Fontaine I is the stage when patients are asymptomatic; Fontaine II is when they have mild (IIa) or severe (IIb) claudication; Fontaine III is when they have ischemic rest pain; and Fontaine IV is when patients suffer tissue loss such as ulceration or gangrene (Table 7).

Table 7 Classification of Peripheral Arterial Disease Based on the Fontaine and Rutherford Classifications

Fontaine Classification		Rutherford Classification		
Stage	Clinical	Grade	Category	Clinical
I	Asymptomatic	0	0	Asymptomatic
IIa	Mild claudication	I	1	Mild claudication
IIb	Moderate to severe claudication	I	2	Moderate claudication
			3	Severe claudication
III	Ischemic rest pain	II	4	Ischemic rest pain
IV	Ulceration or gangrene	III	5	Minor tissue loss
			6	Major tissue loss

The Rutherford classification has four grades (0–III) and seven categories (0–6). Asymptomatic patients are classified into category 0; claudicants are stratified into grade I and divided into three categories based on the severity of the symptoms; patients with rest pain belong to grade II and category 4; patients with tissue loss are classified into grade III and categories 5 and 6, based on the significance of the tissue loss. These clinical classifications help to establish uniform standards in evaluating and reporting the results of diagnostic

measurements and therapeutic interventions (see Table 7).

The most clinically useful classification of LE atherosclerotic disease should be based on morphologic characters of the lesions. The TASC II task force published a guideline separating LE arterial diseases into femoropopliteal and infrapopliteal lesions (Table 8). This guideline is particularly useful in determining intervention strategies based on the disease classifications. Based on the guideline, femoropopliteal lesions are divided into four types: A, B, C, and D. Type A lesions are single focal lesions <3 cm in length that did not involve the origins of the superficial femoral artery (SFA) or the distal popliteal artery; Type B lesions are single lesions 3 to 5 cm in length not involving the distal popliteal artery or multiple or heavily calcified lesions <3 cm in length; Type C lesions are multiple stenoses or occlusions >15 cm in length, or recurrent stenoses or occlusions that need treatment after two endovascular interventions. Type D lesions were those with complete occlusion of CFA, SFA, or popliteal artery.

Table 8. TASC II Classification of Femoral Popliteal Occlusive Lesions

Type A lesions
• Single stenosis ≤10 cm in length
• Single occlusion ≤5 cm in length
Type B lesions
• Multiple lesions (stenoses or occlusions), each ≤5 cm
• Single stenosis or occlusion ≤15 cm not involving the infra geniculate popliteal artery
• Single or multiple lesions in the absence of continuous tibial vessels to improve inflow for a distal bypass
• Heavily calcified occlusion ≤5 cm in length
• Single popliteal stenosis
Type C lesions
• Multiple stenoses or occlusions totaling >15 cm with or without heavy calcification
• Recurrent stenoses or occlusions that need treatment after two endovascular interventions
Type D lesions
• Chronic total occlusions of CFA or SFA (>20 cm, involving the popliteal artery)
• Chronic total occlusion of popliteal artery and proximal trifurcation vessels

CFA = common femoral artery; SFA = superficial femoral artery; TASC II = Trans-Atlantic Inter-Society Consensus.

In a similar fashion, infrapopliteal arterial diseases are classified into four types based on TASC II guideline (Fig. 19). Type A lesions are single lesions <1 cm in length not involving the trifurcation; Type B lesions are multiple lesions <1 cm in length or single lesions shorter than 1 cm involving the trifurcation; Type C lesions are those lesions extensively involving trifurcation or those that are 1- to 4-cm stenotic or 1- to 2-cm occlusive lesions; Type D lesions are occlusions longer than 2 cm or diffuse diseases.

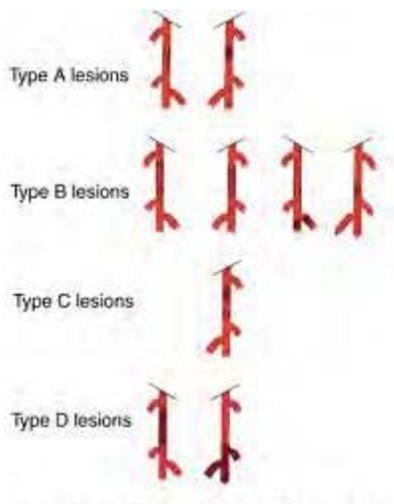

Fig. 19. Schematic depiction of Trans-Atlantic Inter-Society Consensus classification of femoral popliteal occlusive lesions

Clinical Manifestations of Chronic Limb Ischemia

The term *chronic limb ischemia* is reserved for patients with objectively proven arterial occlusive disease and symptoms lasting for more than 2 weeks. Symptoms include rest pain and tissue loss such as ulceration or gangrene (Table 9). The diagnosis should be corroborated with noninvasive diagnostic tests such as the ABI, toe pressures, and transcutaneous oxygen measurements. Ischemic rest pain most commonly occurs below an ankle pressure of 50 mmHg or a toe pressure <30 mmHg.² Ulcers are not always of an ischemic etiology (Table 10). In many instances, there are other etiologic factors (traumatic, venous, or neuropathic) that are contributory, but it is underlying peripheral arterial disease (PAD) that may be responsible for delayed or absent healing (Fig. 20). Healing of ulcers requires an inflammatory response and greater perfusion than is required to support intact skin and underlying tissues. As a result, the ankle and toe pressure levels needed for healing are higher than the pressures seen with ischemic rest pain. For patients with ulcers or gangrene, the presence of CLI is suggested by an ankle pressure <70 mmHg or a toe systolic pressure <50 mmHg.² It is important to understand that there is no definite consensus regarding the vascular hemodynamic parameters required to make the diagnosis of CLI.

Table 9. Clinical Categories of Chronic Limb Ischemia

Grade	Category	Clinical Description	Objective Criteria
0	0	Asymptomatic—no hemodynamically significant occlusive disease	Normal treadmill or reactive hyperemia test
	1	Mild claudication	Able to complete treadmill exercise ^a ; AP after exercise >50 mmHg but at least 20 mmHg lower than resting value
1	2	Moderate claudication	Between categories 1 and 3
	3	Severe claudication	Cannot complete standard treadmill exercise ^a and AP after exercise <50 mmHg
II ^b	4	Ischemic rest pain	Resting AP <40 mmHg, flat or barely pulsatile ankle or metatarsal PVR; TP <30 mmHg
III ^b	5	Minor tissue loss—nonhealing ulcer, focal gangrene with diffuse pedal ischemia	Resting AP <60 mmHg, ankle or metatarsal PVR flat or barely pulsatile; TP <40 mmHg
	6	Major tissue loss—extending above TM level, functional foot no longer salvageable	Same as category 5

Table 10. Symptoms and Signs of Neuropathic Ulcer versus Ischemic Ulcer

Neuropathic Ulcer	Ischemic Ulcer
Painless	Painful
Normal pulses	Absent pulses
Regular margins, typically punched-out appearance	Irregular margin
Often located on plantar surface of foot	Commonly located on toes, glabrous margins
Presence of calluses	Calluses absent or infrequent
Loss of sensation, reflexes, and vibration	Variable sensory findings
Increased in blood flow (atrioventricular shunting)	Decreased in blood flow
	Collapsed veins
Dilated veins	Cold foot
Dry, warm foot	No bony deformities
Bony deformities	Pale and cyanotic in appearance
Red or hyperemic in appearance	

Fig. 20 A A neuropathic ulcer is characterized by a punched-out appearance with loss of sensation in the surrounding skin. The foot may be warm to touch, and pulses may be present in the distal pedal arteries

Fig. 20 B An ischemic ulcer is characterized by a gangrenous skin change in the foot or toes. The foot is usually cold to touch with absent pedal pulses. The foot is painful to touch with decreased distal capillary refills.

One of the most common sites for occlusive disease is in the distal SFA as it passes deep through the adductor canal. It may be that the entrapment by the adductor hiatus prevents the compensatory dilation that occurs in atherosclerotic vessels. Stenoses, which develop here, progress to occlusion of the distal third of the SFA (Fig. 21). When distal SFA occlusion develops slowly, it may be totally asymptomatic because of development of collaterals from the proximal SFA or the profunda femoris artery (PFA) can bypass the occlusion and reconstitute the popliteal artery. Symptom development is a function of the extent of occlusion, adequacy of collaterals, and also the activity level of the patients.

Fig. 21. Computed tomography angiogram of a patient with an occluded left superficial femoral artery (*single long arrow*) with reconstituted superficial femoral artery at the level of midthigh. Diffuse arterial calcifications (*double small arrows*) are noted in the mid and distal left superficial femoral arteries.

Presenting symptoms of femoropopliteal occlusive disease are broadly classified into two types: limb-threatening and non-limb-threatening ischemia. Claudication is non-limb-threatening, while rest pain, ulceration, and gangrene are limb-threatening and warrant urgent intervention. Occlusive disease of the femoral artery may be isolated or occur in conjunction with multilevel disease that involves both the aortoiliac segment and the tibial vessels. Symptoms in patients with multilevel disease are more severe than in those with single-level disease. Pain from isolated SFA and popliteal occlusion typically manifests as calf claudication. Cramping pain develops in the calf on ambulation, occurs at a reproducible distance, and is relieved by rest. Activities such as climbing stairs or going uphill also exacerbate the pain. Many patients report worsening symptoms during cold weather. It is important to evaluate whether the symptoms are progressive or static. In >70% of patients, the disease is stable, particularly with risk factor modification.

Progression of the underlying atherosclerotic process is more likely to occur in patients with diabetes, those who continue to smoke, and those who fail to modify their atherosclerotic risk factors. In comparison, rest pain is constant, and usually occurs in the forefoot across the metatarsophalangeal joint. It is worse at night and requires placing the foot in a dependent position to improve symptoms. Patients may report that they either sleep in a chair or hang the

foot off the side of the bed. The pain is severe and relentless, even with narcotics. Ischemic ulceration most commonly involves the toes. Any toe can be affected. Occasionally, ulcers develop on the dorsum of the foot. Ulceration can occur in atypical positions in an ischemic foot from trauma such as friction from poorly fitting shoes. Injury to a foot with borderline ischemia can convert an otherwise stable situation into one that is limb-threatening. The initial development of gangrene commonly involves the digits. As with all vascular patients, it is important to evaluate their risk factors, intercurrent cardiac diseases, and any prior vascular interventions.

Treatment Considerations for Chronic Limb Ischemia

Patients with vascular diseases frequently have complicated medical comorbidities. Careful patient evaluation and selection should be performed for any peripheral arterial vascular procedure. The fundamental principle is to assess not only the surgical risk from the peripheral arterial system but also the global nature of the atherosclerotic process. Full cardiac evaluations are often necessary due to the high incidence of concomitant atherosclerotic coronary arteries disease, resulting in a high risk for ischemic events. Hertzner and associates reviewed coronary angiographies on 1000 patients undergoing elective vascular procedures and identified 25% of concomitant correctable CAD, including 21% in patients undergoing elective peripheral vascular intervention. Conte and associates analyzed their 20-year experience in a tertiary practice setting in 1642 open LE reconstructive surgeries and concluded that patients requiring LE reconstruction presented an increasingly complex medical and surgical challenge compared with the previous decade. With aging of the population, there are a growing number of vascular patients who have prohibitive medical comorbidities that are deemed high-risk for open surgical repair. Endovascular intervention provides an attractive alternative.

As for open surgical repair, the clinical indications for endovascular intervention of LE PADs include lifestyle-limiting claudication, ischemic rest pain, and tissue loss or gangrene. Importantly, endovascular procedures should be performed by a competent vascular interventionist who understands the vascular disease process and is familiar with a variety of endovascular techniques. In addition, certain lesions such as long segment occlusion, heavily calcified lesion, orifice lesion, or lesions that can be not be traversed by a guidewire may not be amendable to endovascular treatment or may be associated with poor outcomes. A proper selection of patients and techniques is critical in achieving a good long-term outcome.

Endovascular intervention for LE occlusive disease is continuously evolving. Success

and patency rates of endovascular intervention are closely related to the anatomic and morphologic characters of the treated lesions. The TASC II work group made recommendations on the intervention strategies of LE arterial diseases based on the morphologic characters. Based on the TASC II guidelines, endovascular treatment is recommended for type A lesions, open surgery is recommended for Type D lesions, and no recommendations were made for Types B and C lesions. However, with rapid advancement in endovascular technologies, there are increased numbers of lesions amenable to endovascular interventions.

There is less literature support on infrapopliteal endovascular intervention due to higher complication and lower success rates. The treatment is restricted to patients with limb-threatening ischemia who lack surgical alternatives. However, with further advancement of endovascular technology and the development of new devices, endovascular intervention will become an integral part of treatment (Table 11). By itself or combined with open technique, percutaneous intervention plays an important role in therapeutic options for LE occlusive disease. As described by the TASC II guidelines, four criteria should be measured to evaluate the clinical success of the treatment: improvement in walking distance, symptomatic improvement, quality of life, and overall graft patency. These criteria should all be carefully weighed and evaluated for each individual before endovascular therapy.

Table 11. Summary of Endovascular Treatment Strategies Using Device-Based Infrapopliteal Intervention

Intervention	Advantages	Disadvantages
Angioplasty	<ul style="list-style-type: none"> • Easy to use • Broad range of applications 	<ul style="list-style-type: none"> • Failure in long lesions, calcified lesions, and disease at multiple levels
Balloon-expandable stent	<ul style="list-style-type: none"> • Overcomes arterial recoil from angioplasty • Useful in treatment of flow-limiting dissection 	<ul style="list-style-type: none"> • Crushability can lead to restenosis • Poor distal runoff can result in stent thrombosis; limited data
Self-expanding stent	<ul style="list-style-type: none"> • Vessel conformability and wall apposition prevents kinking and crushing of stent 	<ul style="list-style-type: none"> • Limited sizes; limited data; multicenter trials under way
Bioabsorbable stent	<ul style="list-style-type: none"> • Overcomes arterial recoil from angioplasty • Absorbed long-term to prevent risk of stent thrombosis 	<ul style="list-style-type: none"> • Limited data; multicenter trials under way
Cryoplasty	<ul style="list-style-type: none"> • Reduces the risk of flow-limiting dissection, therefore reducing the need for stent implantation 	<ul style="list-style-type: none"> • Short-term results of a multicenter trial are promising; however, long-term data are limited
Cutting balloon	<ul style="list-style-type: none"> • Useful in anastomotic segments of bypass grafts and in-stent restenosis where "watermelon seeding" can prevent adequate expansion of plaque 	<ul style="list-style-type: none"> • Limited data
Mechanical atherectomy	<ul style="list-style-type: none"> • Allows for debulking of plaque without the need for stent implantation in most cases • Allows for removal of plaque for histologic analysis 	<ul style="list-style-type: none"> • Limited use in areas of heavy calcification • No large, randomized, prospective trial comparing this technique to angioplasty and stenting
Laser	<ul style="list-style-type: none"> • Useful in acute thrombotic and chronic total occlusions 	<ul style="list-style-type: none"> • Minimal data in infrapopliteal arteries • Need adjunctive treatment with angioplasty, stenting, or atherectomy

Endovascular Treatment

Technical Considerations

A sterile field is required in either an OR or an angiography suite with image capability. The most common and safest access site is the CFA via either a retrograde or antegrade approach. For diagnostic angiography, arterial access should be contralateral to the symptomatic sides. For therapeutic procedures, location of the lesion and the anatomic structures of the arterial tree determine the puncture site. To avoid puncturing the iliac artery or SFA, the femoral head is located under the fluoroscopy and used as the guide for the level of needle entry. In addition, there are several useful techniques in helping access a pulseless CFA, including puncturing guided by ultrasound, using a micropuncture kit, and targeting calcification in a calcified vessel. An antegrade approach may be challenging, particularly in obese patients. Meticulous technique is crucial in preventing complications, and a bony landmark can be used as guidance to ensure CFA puncture.

Traversing the lesion with a wire is the most critical part of the procedure. Typically, 0.035-in guidewires are used for femoropopliteal lesions and 0.014- or 0.018-in guidewires are used for infrapopliteal access. Hydrophilic-coated wires, such as Glide wires, are useful in navigating through tight stenosis or occlusion. An angled-tip wire with a torque device may be helpful in crossing an eccentric lesion, and a shaped selective catheter is frequently used in helping manipulate the wire across the lesion. The soft and floppy end of the wire is carefully advanced, crossing the lesion under fluoroscopy, and gentle force is applied while manipulating the wire. Once the lesion has been traversed, one needs to pay particular attention to the tip of the wire to ensure a secure wire access and avoid vessel wall perforation or dissection.

Once the access to the diseased vessel is secured and the wire has successfully traversed the lesion, several treatment modalities can be used either used alone or in conjunction with others, including angioplasty, stent or stent graft placement, and atherectomy. The available angioplasty techniques are balloon angioplasty, cryoplasty, subintimal angioplasty (SA), and cutting balloon. The most commonly used atherectomy techniques include percutaneous atherectomy catheter and laser atherectomy device.

Systemic anticoagulation should be maintained routinely during LE arterial interventions to minimize the risk of pericatheter thrombosis. Unfractionated heparin is the most commonly used agent, given on a weight-based formula. It is a common clinical practice to use a 80 to 100 mg/kg initial bolus for a therapeutic procedure to achieve the activated clotting time above 250

seconds on the catheter insertion and subsequently 1000 units for each additional hour of the procedure. Newer agents such as low molecular weight heparin, platelet IIb/IIIa inhibitor, direct thrombin inhibitor, or recombinant hirudin have been available and can be used either alone or in conjunction with heparin, particularly in patients sensitive to unfractionated heparin. After procedures, all patients are placed on antiplatelet therapy such as aspirin. Additional antiplatelet agents such as clopidogrel (Plavix) are given to selected patients with stent placement for at least 6 weeks after LE interventions, unless otherwise contraindicated.

Percutaneous Transluminal Balloon Angioplasty

After the lesion is crossed with a wire, an appropriate balloon angioplasty catheter is selected and tracked along the wire to traverse the lesion. The length of the selected catheter should be slightly longer than the lesion and the diameter should be equal to the adjacent normal vessel. The balloon tends to be approximately 10 to 20% oversized. The radiopaque markers of the balloon catheter are placed so that they will straddle the lesion. Then, the balloon is inflated with saline and contrast mixture to allow visualization of the insufflation process under the fluoroscopy (Fig. 22). The patient may experience mild pain, which is not uncommon. However, severe pain can be indicative of vessel rupture, dissection, or other complications. An angiography is crucial in confirming the intraluminal location of the catheter and absence of contrast extravasation. The inflation is continued until the waist of the atherosclerotic lesion disappears and the balloon is at full profile. Frequently, several inflations are required to achieve full profile of the balloon (Fig. 23). Occasionally, a lower profile balloon is needed to predilate the tight stenosis so that the selected balloon catheter can cross the lesion.

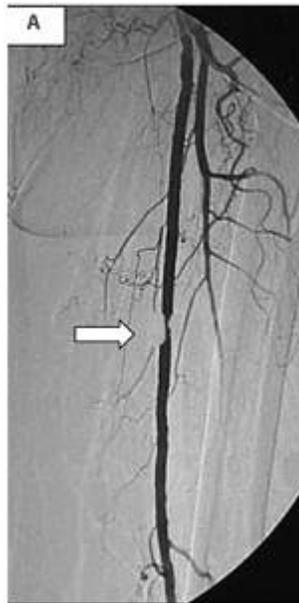

Fig. 22 A. Angiogram demonstrating a focal stenosis in the superficial femoral artery (*arrow*).

Fig. 22 B. This lesion was treated with a balloon angioplasty catheter that inflated a dilating balloon and expanded the flow lumen

Fig. 22 C. Completion angiogram demonstrating satisfactory radiographic result.

Fig. 23 A. Angiogram demonstrating a segmental occlusion in the distal superficial femoral artery (*single arrow*).

Fig. 23 B. This lesion was treated with cryoplasty, which lowered the balloon catheter temperature to a temporary freezing state during the balloon angioplasty procedure (*double arrows*)

Fig.23 C. Completion angiogram demonstrated satisfactory result with no evidence of vessel dissection.

Besides length and diameter, the operators need to be familiar with several balloon characters. Noncompliant and low-compliant balloons tend to be inflated to their preset diameter and offer greater dilating force at the site of stenosis. Low-compliant balloons are the

mainstay for peripheral intervention. A balloon with a low profile is used to minimize complication at the entry site and for crossing the tight lesions. Upon inflation, most balloons do not rewrap to their preinflation diameter and assume a larger profile. Furthermore, trackability, pushability, and crossability of the balloon should be considered when choosing a particular type. Lastly, shoulder length is an important characteristic when performing PTA to avoid injury to the adjacent arterial segments. After PTA, a completion angiogram is performed while the wire is still in place. Leaving the wire in place provides access for repeating the procedure if the result is unsatisfactory.

PTA is an established and effective therapy for select patients with LE occlusive diseases. Studies have shown that PTA of the femoropopliteal segment achieved over a 90% technical success rate and a 38 to 58% 5-year primary patency rate. However, efficacy of PTA is highly dependent upon anatomic selection and patient condition. PTA of lesions longer than 7 to 10 cm offer limited patency, while PTA of shorter lesions, such as those that are <3 cm, have fairly good results. Lofberg and associates performed 127 femoropopliteal PTA procedures and reported a primary 5-year success rate of 12% in limbs with an occlusion longer than 5 cm vs. 32% in limbs with an occlusion <5 cm in length.¹⁵¹ Occlusive lesions have much worse initial technical success rates than stenotic lesions. Concentric lesions respond better to PTA than eccentric lesions, and heavy calcifications have a negative impact on success rates. A meta-analysis by Hunink and associates showed that adjusted 5-year primary patencies after angioplasty of femoropopliteal lesions varied from 12 to 68%, the best results being for patients with claudication and stenotic lesions. Distal runoff is another powerful predictor of long-term success. Johnston analyzed 254 consecutive patients who underwent femoral and popliteal PTA and reported that 5-year patency rates of 53% for stenotic lesions and 36% for occlusive lesions in patients with good runoffs vs. a 5-year patency of 31% for stenotic lesions and 16% for occlusive lesions in patients with poor runoff. Literature reviews showed that 5-year patency rates varied from 27 to 67% based on the runoff statuses.

Due to limited success with infrapopliteal PTA, the indication for infrapopliteal artery PTA is stringent, reserved for limb salvage. Current patency rates from infrapopliteal PTA can be improved further by proper patient selection, ensuring straight-line flow to the foot in at least one tibial vessel, and close patient surveillance for early reintervention. Possible future advances including the use of drug-eluting stents (DES), cutting balloons, and atherectomy devices are being investigated to improve clinical outcomes following endovascular interventions on the tibial arteries. Varty and associates reported a 1-year limb salvage rate of

77% in patients with critical ischemia who underwent infrapopliteal PTA. In patients with favorable anatomies, a 2-year limb salvage rate after infrapopliteal artery PTA is expected to exceed 80 %.

Subintimal Angioplasty

The technique of SA was first described in 1987 when successful establishment of flow was made by accidental creation of a subintimal channel during treatment of a long popliteal artery occlusion. SA is recommended for chronic occlusion, long segments of lesion, and heavily calcified lesions. In addition, this technique is applicable for vessels with diffuse diseases and for vessels that had previously failed an intraluminal approach because it is difficult to negotiate the wire across the entire diseased segment without dissection.

The principle of this technique is to bypass the occlusion by deliberately creating a subintimal dissection plan commencing proximal to the lesion and continuing in the subintimal space before breaking back into the true lumen distal to the lesion. The occluded lumen is recanalized through the subintimal plan. SA can be performed through either ipsilateral antegrade or contralateral retrograde using the CFA approach. If selecting contralateral CFA puncture, a long guiding sheath is placed across the aortic bifurcation to provide access for the femoropopliteal and infrapopliteal vessels. The subintimal dissection is initiated at the origin of an occlusion by directing the tip of an angled guidewire, usually an angled hydrophilic wire such as Glidewire. A supporting catheter is used to guide the tip of the guidewire away from the important collaterals. When the wire is advanced, a loop is naturally formed at the tip of the guidewire. Once the subintimal plan is entered, the wire tends to move freely in the dissection space. Subintimal location of the wire and the catheter can be confirmed by injecting a small amount of diluted contrast. At this point, the wire and the catheter are then advanced along the subintimal plan until the occlusion segment is passed. A loss of resistance is often encountered as the guidewire re-enters the true lumen distal to the occlusion. Recanalization is confirmed by advancing the catheter over the guidewire beyond the point of re-entry and obtaining an angiogram. This is followed by a balloon angioplasty. To confirm the patency following balloon dilatation, a completion angiogram is performed before withdrawing the catheter and wire. If flow is impaired, repeat balloon dilatation may be necessary. Frequently, a stent is required to maintain a patent lumen and treat residual stenosis if more than a 30% luminal reduction is confirmed on completion angiogram.

Multiple studies have demonstrated the efficacy of SA. Bolia and his colleagues and

London and his colleagues reported their extensive experiences on SA for treating long segment occlusions of infrainguinal vessels. They achieved a technical success rate of over 80% for both femoropopliteal and tibial arteries. One-year patency rates varied from 53% for infrapopliteal vessels to 71% for femoropopliteal segments. Limb salvage rates reached over 80% at 12 months. They also reported that the factors influencing patency are smoking, number of runoff vessels, and occlusion length. Studies by other groups showed similar results. Treiman and colleagues treated 25 patients with 6- to 18-cm femoropopliteal occlusion and achieved a technical success rate of 92% and a 12-month primary patency rate of 92%, while Lipsitz and associates reported a technical success rate of 87% in treating 39 patients and achieved a 12-month cumulative patency rate of 74%. Additionally, Ingle and associates reported a technical success rate of 87% on 67 patients with femoropopliteal lesions and a 36-month limb salvage rate of 94%. As demonstrated herein, although technical success rates are similar in most series, the patency rates vary widely in different studies. Patient selection, anatomic character, and lesion locations may account for the wide range of outcomes.

Stent Placement

Although suggested by Dotter during the late 1960s, the use of an endoluminal stent was not pursued until the limitations of PTA were widely recognized. There are several situations where stent placement is appealing. The primary indication is the potential salvage of an unacceptable angioplasty result. Stent placement is typically used when residual stenosis after PTA is 30% or greater. An endoluminal stent is also used for dissection, perforation, and other PTA complications. Primary stent placement has become a viable alternative for treating ulcerative lesions that may potentially be the source for embolization. Primary stent is also used to treat occlusive lesions that have a tendency of reocclusion and distal embolization after PTA. In addition, an endoluminal stent is potentially beneficial for early restenosis post-PTA. DESs are currently under investigation in the United States and may be promising in decreasing restenotic rates.

Even though technical success rates are high, a published series on femoropopliteal artery stents show that patency rates are comparable to PTA alone with primary patency rates varying from 18 to 72% at 3 years. Gray and associates stented 58 limbs after suboptimal PTA for long SFA lesions and demonstrated a 1-year primary patency rate of 22%. However, Mewissen treated 137 limbs using self-expanding SMART nitinol stents in patients with TASC II A, B, and C femoropopliteal lesions and reported a 1-year primary patency rate of 76% and a

24-month primary patency rate of 60%. Appropriate patient selection and the anatomic characteristics of the lesions are crucial in the success of treatment outcomes. Additionally, stent characteristics may contribute to the patency rate.

Several clinical studies have demonstrated the significant improvements of the new generation of nitinol stents for the SFA lesions: the German Multicenter Experience, the Mewissen trial, the BLASTER Trial, and the SIROCCO trials.¹⁶¹ The German Multicenter Experience was a retrospective review of 111 SFA stenting procedures and found the 6-month patency rates for Smart stents and Wall stents were 82% and 37%, respectively. The BLASTER (Bilateral Lower Arterial Stenting Employing Reopro) Trial evaluated the feasibility of using nitinol stents with and without IV abciximab for the treatment of femoral artery disease. Preliminary results showed a 1-year clinical patency rate of 83%.

Furthermore, DESs, which proved effective at decreasing restenosis in coronary intervention, may offer another promising alternative in LE diseases. The drug, released over a period of time, interferes with smooth muscle cell proliferation, the main cellular element and source of extracellular-matrix-producing restenosis. The first DES clinical trial used Cordis Cypher SMART stents coated with sirolimus (SIROCCO trial). The SIROCCO results showed binary inlesion restenosis rates of 0% in the sirolimus-eluting group vs. 23.5% in the noneluting group at 6-month follow-up angiography.

Stent Graft

The concept of endobypass using stent graft in treating atherosclerotic SFA disease has been entertained. A stent graft is placed percutaneously across a long segment or multiple segments of lesions and is used to create a femoropopliteal bypass. Theoretically, endobypass has the potential of being as successful as surgical bypass graft by relining the vessel wall in its anatomical position without the negative impact of anastomosis. Stent grafts can be divided into two categories: unsupported and fully supported. The unsupported grafts consist of segments of bypass graft, such as PTFE, with an expandable stent at one or both ends. The unsupported grafts are flexible with a low profile, but prone to external compression. The supported stent grafts consist of a metallic skeleton covered with graft fabric. The presence of a dense metal skeleton promotes an extensive inflammatory response and increases the risk of thrombosis. There is no FDA-approved stent graft for peripheral intervention. However, Viabahn (WL Gore, Calif) is the most commonly used device in the United States, composed of an ultrathin PTFE graft externally supported by a self-expanding nitinol meshwork. The

Viabahn device has a specific delivery mechanism—pulling back the attached string—which results in a proximal-to-distal delivery of the endoprosthesis.

Although it is an intriguing concept, data on endobypass results are limited and the graft thrombosis rate is high. Additionally, covering major collateral vessels can potentially jeopardize the viability of the limb if stent graft occlusion occurs. Bauermeister treated 35 patients with Hemobahn and reported a 28.6% occlusion rate on an average 7-month follow-up. Kedora and colleagues recently conducted a prospective, randomized study comparing covered PTFE/nitinol self-expanding stent grafts with prosthetic above-the-knee femoropopliteal bypass. Fifty limbs were randomized into each group. Primary patency at 1-year was approximately 74% for both cohorts, with a mean follow-up of 18 months. The covered nitinol PTFE stent graft in the SFA had a 1-year patency rate comparable to surgical bypass, with a significantly shorter hospital stay (0.9 vs. 3.1 days).

Atherectomy

The basic principle of atherectomy is to remove the atheroma from obstructed arterial vessels. There are currently five atherectomy devices approved by the FDA: Simpson AtheroCath (DVI, Redwood City, Calif), Transluminal Extraction Catheter (Interventional Technologies, San Diego, Calif), Theratec recanalization arterial catheter (Trac-Wright), Auth Rotablator (Heart Technologies, Redmond, Wash), and SilverHawk system (FoxHollow Technologies, Redwood City, Calif). These devices either cut and remove or pulverize the atheroma plaques.

The Simpson AtheroCath has a directional cutting element that is exposed to one third of the circumference of the arterial wall. The atheroma protruding into the window is excised and pushed into the collection chamber. The Transluminal Extraction Catheter has an over-the-wire, nondirectional cutter mounted on the distal end of a torque tube. The excised atheroma is simultaneously removed by aspiration through the torque tube. The Theratec recanalization arterial catheter is a nondirectional, noncoaxial, atheroablative device. The rotating cam tip pulverizes the atheromatous lesion into minute particles. The Auth Rotablator is a nondirectional, coaxial, atheroablative device with a metal burr embedded with fine diamond chips. Lastly, the SilverHawk device, approved by the FDA for peripheral use in 2003, is a monorail catheter designed to overcome the drawback of direction atherectomy catheter, such as the Simpson AtheroCath. The working end consists of a hinged housing unit containing a carbide cutting blade. The blade is activated from the motor drive unit and the

catheter is then advanced through the length of the lesion. Once each pass is completed, the cutter then packs the tissue into the distal end of the nosecone to maximize collection capacity. The SilverHawk can then either be removed or torqued to treat a different quadrant in the same lesion or other lesions.

Despite the promising early technical and clinical success, the mid- and long-term results have been disappointing due to a high incidence of restenosis. However, a multicenter clinical registry of plaque atherectomy in patients with femoropopliteal occlusive disease showed potential clinical efficacy of this technology as the 6- and 12-month rates of survival free of target lesion revascularization were 90 and 80%, respectively. Importantly, nearly three fourths (73%) of patients treated with plaque excision modality did not require adjunctive endovascular therapy as infrainguinal stenting was necessary in only 6.3% of lesions. Results from the TALON registry support the role of plaque excision in selective patients with LE arterial disease.

Laser Atherectomy

Since laser atherectomy was reported in the 1960s, a variety of innovative approaches have been developed in an effort to overcome the limitation of laser angioplasty. Recent developments in excimer laser technology have led to increased optimism regarding the ability to safely deliver laser energy. Excimer laser atherectomy approved by the FDA for peripheral artery intervention uses precision laser energy control (shallow tissue penetration) and safer wavelengths (ultraviolet as opposed to the infrared spectra in older laser technology), which decreases perforation and thermal injury to the treated vessels.

A laser atherectomy catheter, with diameters varying from 0.9 mm to 2.5 mm, is tracked over the guidewire to the desired target. Once activated, the excimer laser uses ultraviolet energy to ablate the lesion and create a nonthrombogenic arterial lumen. This lumen is further dilated by an angioplasty balloon. Because the excimer laser can potentially reduce the rate of distal embolization by evaporating the lesion, it may be used as an adjunct tool for ostial lesions and lesions that can be traversed by a wire but not an angioplasty balloon catheter.

Several studies regarding the use of excimer laser atherectomy combined with balloon angioplasty on LE occlusive disease have shown promising clinical outcomes. Peripheral excimer laser angioplasty trials involved 318 patients with chronic SFA occlusion. They achieved a technical success rate of 83.2%, a 1-year primary patency rate of 33.6%, and an assisted primary patency rate of 65%.¹⁶⁸ Steinkamp and his colleagues treated 127 patients

with long-segment of popliteal artery occlusion using laser atherectomy followed by balloon angioplasty and reported a 3-year primary patency rate of 22%. The multicenter clinical trial evaluating the use of laser angioplasty for critical limb ischemia supports the efficacy of this treatment modality in selective patients as the 6-month primary patency rate and clinical improvement were 33 and 89%, respectively.

Complications of Endovascular Interventions

Angioplasty-Related Complications

Complications related to PTA vary widely, including dissection, rupture, embolization, pseudoaneurysms, restenosis, hematoma, and acute occlusion secondary to thrombosis, vasospasm, or intimal injury. Clark and associates analyzed the data from 205 patients in the SCVIR Transluminal Angioplasty and Revascularization registry and reported a complication rate of 7.3% for patients undergoing femoropopliteal angioplasty. Minor complications accounted for 75% of the cases, including distal emboli (41.7%), puncture site hematomas (41.7%), contained vessel rupture (8.3%), and vagal reactions (8.3%). In another study, Axisa and colleagues reported an overall rate of significant complications for patients undergoing PTA of the lower extremities as 4.2%, including retroperitoneal bleeding (0.2%), false aneurysm (0.2%), ALI (1.5%), and vessel perforation (1.7%).

Complications limiting the application of SA are parallel to those of PTA. A study investigating the use of SA in 65 patients with SFA occlusion found that complications developed in 15% of patients. These complications included significant stenosis (44%), SFA rupture (6%), distal embolization (3%), retroperitoneal hemorrhage (1.5%), and pseudoaneurysm (1.5%). Additional complications reported consist of perforation, thrombosis, dissection, and extensions beyond the planned re-entry site. Importantly, damage to significant collateral vessels may occur in 1 to 1.5% of patient who undergo SA. If a successful channel is not achieved in this situation, the patient may have a compromised distal circulation that necessitates distal bypass. Cryoplasty is a modified form of angioplasty, and long-term results on LE intervention are not yet available. Fava and associates treated 15 patients with femoropopliteal disease and had a 13% complication rate involving guidewire dissection and PTA-induced dissection of a tandem lesion remote to the cryoplasty zone.

Endoluminal Stent and Stent Graft–Related Complications

In addition to the aforementioned complications with angioplasty, endoluminal stents are associated with the risk of stent fracture and deformity. The adductor canal has nonlaminar flow dynamics, especially with walking. The forces exerted on the SFA include torsion, compression, extension, and flexion. These forces exert significant stress on the SFA and stents. In addition, the LE is subject to external trauma, which further increases the risk of stent deformity and fracture (Fig. 24). The SIROCCO study showed that stent fracture, although not associated with clinical symptoms, occurs in 18.2% of the procedures involving both the DES and control stent.

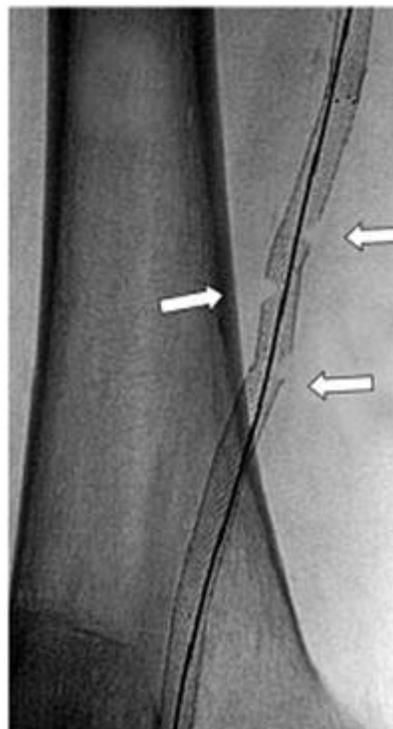

Fig. 24. Due to various geometric forces, including torsion, compression, extension, and flexion, which exert on the superficial femoral artery, stent fracture (*arrows*) is a known complication following superficial femoral artery stent placement.

Stent grafts may present an additional complication of covering important collaterals, which results in compromised distal circulation. A prospective study evaluating Hemobahn stent grafts in the treatment of femoropopliteal arterial occlusions demonstrated a 23% immediate complication rate, including distal embolization (7.7%), groin hematoma (13.5%), and arteriovenous fistula (1.9%).¹⁷⁵

Atherectomy-Related Complications

Overall complication rates associated with atherectomy range from 15.4 to 42.8% and include spasm, thrombosis, dissection, perforation, distal emboli, no reflow, and hematoma. Jahnke and associates conducted a prospective study evaluating high-speed, rotational atherectomy in 15 patients with infrapopliteal occlusive disease. They yielded a 94% technical success rate, which was complicated by vessel rupture (5%), distal embolization (5%), and arterial spasm (5%). Although the excimer laser atherectomy reduces embolic events by evaporating the lesion, embolization still remains a problematic complication. Studies show that distal embolic events occur in 3 to 4% of procedures, and perforation in 2.2 to 4.3% of cases. Other complications compromising laser atherectomy therapy include acute reocclusion, vasospasm, direct vessel injury, and dissection.

SURGICAL TREATMENT FOR CHRONIC LIMB ISCHEMIA DUE TO FEMOROPOPLITEAL DISEASE

Endarterectomy

Endarterectomy has a limited, albeit important, role in LE occlusive disease. It is most frequently used when there is disease in the CFA or involving the PFA. In this procedure, the surgeon opens the diseased segment longitudinally and develops a cleavage plane within the media that is developed proximally and distally. This permits the inner layer containing the atheroma to be excised. Great care must be taken at the distal end of the endarterectomy to ensure either a smooth transition or to tack down the distal endpoint to prevent the flow from elevating a potentially occlusive atheromatous flap. Currently, there is essentially no role for long open endarterectomy in the treatment of SFA stenoses or occlusions. The high incidence of restenosis is what limits use of endarterectomy in this location. Short-segment stenoses are more appropriately treated with balloon angioplasty. Endarterectomy using a catheter-based approach (e.g., Moll endarterectomy device) supplemented with stent grafting or stenting across the endpoint of the endarterectomy is currently being re-evaluated; however, no long-term data are available.

Bypass grafting

Bypass grafting remains the primary intervention for LE occlusive disease. The type of bypass and conduit are important variables to consider. Patients with occlusive disease limited

to the SFA, who have at least 4 cm (ideally 10 cm) of normal popliteal artery reconstituted above the knee joint and at least one continuous vessel to the foot, can be treated with an above-knee (AK) femoropopliteal bypass graft. Despite the fact that in this above-knee location, the differential patencies between prosthetic (PTFE) and vein graft are comparable; undoubtedly, it remains ideal to use a saphenous vein as the bypass conduit, if possible. Saving the vein for future coronary artery bypass or distal leg bypass grafting has been shown to be a flawed argument. One must also take into consideration that the consequences to the vascular outflow after a thrombosed prosthetic are worse than after a thrombosed vein graft.

When the disease extends to involve the popliteal artery or the tibial vessels, the surgeon must select an appropriate outflow vessel to perform a bypass. Suitable outflow vessels are defined as uninterrupted flow channels beyond the anastomosis into the foot. In order of descending preference, they are: AK popliteal artery, below-knee (BK) popliteal artery, posterior tibial artery, anterior tibial artery, and peroneal artery. In patients with diabetes, it is frequently the peroneal artery that is spared. Although the peroneal artery has no direct flow into the foot, collateralization to the posterior tibial and anterior tibial arteries makes it an appropriate outflow vessel. There is no objective evidence to preferentially select tibial over peroneal arteries if they are vessels of equal caliber and quality. The dorsalis pedis, which is the continuation of the anterior tibial in the foot, is frequently spared from atherosclerotic disease and can be used as a target for distal bypasses. Patency is affected by the length of the bypass (longer bypasses have reduced patency), quality of the recipient artery, extent of runoff to the foot, and quality of the conduit (saphenous vein/graft). Five-year assisted patency rates for infrapopliteal venous bypasses are 60%. Venous conduits also have been shown to be suitable for bypasses to plantar arteries. In this location, venous conduits have a 3-year limb salvage of 84% and a 3-year secondary patency of 74%. A meta-analysis suggests unsatisfactory results when PTFE-coated grafts are used to bypass to infrapopliteal arteries. In this location, prosthetic grafts have a 5-year primary patency rate of 30.5%. Additionally, due to distal embolization and compromise of outflow vessels, prosthetic graft occlusion may have more severe consequences than vein graft occlusion.

Two techniques are used for distal bypass grafting: reversed saphenous vein grafting and in situ saphenous vein grafting. There is no difference in outcomes (patency or limb salvage) between these techniques. In the former, the vein is excised in its entirety from the leg using open or endoscopic vein harvest, reversed to render the valves nonfunctional, and tunneled from the CFA inflow to the distal target vessels. End-to-side anastomoses are then created.

Several adjunctive techniques have been tried to improve the patency of bypass grafts to

tibial arteries. Creation of an arteriovenous fistula at the distal anastomosis is one option, but it has not been shown to improve patency. Another method involves creating various configurations of vein cuffs or patches at the distal anastomosis in an attempt to streamline the flow and to reduce the likelihood of neointimal hyperplasia. Results with this approach are more promising, especially when done to improve patency of a below-the-knee prosthetic; however, there are no definitive comparative trials that support the superiority of one configuration over another.

Amputation

Primary amputation is defined as an amputation that is performed without a prior attempt at surgical or endovascular revascularization. It is rarely necessary in patients who, as a result of neglect, present with class III ALI. Primary amputation may play a role in patients with critical limb ischemia who are deemed nonambulatory because of knee contractures, debilitating strokes, or dementia.

COMPLICATIONS OF SURGICAL RECONSTRUCTION

Vein Graft Stenoses

Fifteen percent of vein grafts will develop intrinsic stenoses within the first 18 months following implantation. Consequently, patients with a vein graft were entered into duplex surveillance protocols (scans every 3 months) to detect elevated (>300 cm/s) or abnormally low (<45 cm/s) graft velocities early. Stenoses greater than 50%, especially if associated with changes in ABI, should be repaired to prevent graft thrombosis. Repair usually entails patch angioplasty or short-segment venous interposition, but PTA/stenting is an option for short, focal lesions. Grafts with stenoses that are identified and repaired before thrombosis have assisted primary patency identical to primary patency, whereas a thrombosed autogenous bypass has limited longevity, resulting from ischemic injury to the vein wall. Secondary patency is markedly inferior to primary assisted patency. The recommendation for routine duplex ultrasound surveillance of autogenous infrainguinal bypasses was recently brought into question by a randomized, controlled trial that demonstrated no cost benefit or quality-of-life improvement after 18 months in patients with femoropopliteal venous bypasses. Many surgeons continue with programs of vein graft surveillance, as has been suggested in older

trials, awaiting further confirmation of the findings from the more recent study. When intervening on a failing infrainguinal bypass, the original indication for surgery is an important consideration. Limb salvage rates for occluded grafts are better if the indication for the original bypass was claudication rather than rest pain or tissue loss. An acutely occluded infrainguinal graft (≤ 30 postoperative days) has a 25% limb salvage rate.

Limb Swelling

Limb swelling is common following revascularization and usually returns to baseline within 2 to 3 months. The etiology is multifactorial, with lymphatic interruption, interstitial edema, and disruption of venous drainage all contributing. Limb swelling tends to worsen with repeat revascularization.

Wound Infection

Because the most common inflow vessel for distal bypass is the CFA, groin infection is common and occurs in 7% of cases. When an autogenous conduit such as a saphenous vein is used, most infection can be managed with local wound care because it involves the subcutaneous tissue or skin rather than infection of the actual vein. When a prosthetic graft has been used, management of graft infection is a major undertaking. Infection of a LE prosthetic bypass graft is associated with a significant amputation rate because of the tendency for graft thrombosis and anastomotic disruption. Prosthetic graft infections cannot be eradicated with antibiotics, and they mandate graft excision and complex revascularization using a vein, if available.

Choice of Conduit for Infrainguinal Bypass Grafting

Autogenous Vein

Autogenous vein is superior to prosthetic conduits for all infrainguinal bypasses, even in the AK position. This preference is applicable not only for the initial bypass but also for reoperative cases. For long bypasses, ipsilateral great saphenous vein (GSV), contralateral GSV, small saphenous vein, arm vein, and spliced vein are used, in decreasing order of preference. If only a short segment of vein is missing, the SFA can be endarterectomized and

the proximal anastomosis performed distally to decrease the length of the conduit and to avoid harvesting and splicing additional vein. When GSV is not available and a relatively short bypass is necessary, arm vein or small saphenous vein is effective. Small saphenous vein is of particular use when a posterior approach is used. If a longer bypass with vein is necessary, arm vein is preferable because it is less awkward to harvest. Another conduit alternative is to harvest the upper arm basilic, median cubital, and cephalic veins in continuity, while incising valves in the basilic segment and using the cephalic segment in reversed configuration to provide a relatively long, unspliced autogenous conduit.

Cryopreserved Grafts

Cryopreserved grafts are usually cadaveric arteries or veins that have been subjected to rate-controlled freezing with dimethyl sulfoxide and other cryopreservants. Cryopreserved vein grafts are more expensive than prosthetic grafts and are more prone to failure. The endothelial lining is lost as part of the freezing process, making these grafts prone to early thrombosis. Cryopreserved grafts also are prone to aneurysmal degeneration. Despite the fact that these grafts have not performed as well as prosthetic bypasses and autogenous vein in clinical practice, they can still play a role when revascularization is required following removal of infected prosthetic bypass grafts, especially when autogenous vein is unavailable to create a new bypass through clean tissue planes.

Human Umbilical Vein

Human umbilical vein (HUV) is less commonly used than PTFE, because it is thicker and more cumbersome to handle and because of concerns about aneurysmal degeneration. HUV allografts are stabilized with glutaraldehyde and do not have viable cells or antigenic reactivity. These grafts have poor handling characteristics and require extra care when suturing because of an outer Dacron mesh wrapping, which is used to decrease aneurysmal degeneration. Dardik and colleagues have reported favorable results after using HUV and an adjunctive distal arteriovenous fistula. One trial comparing HUV with PTFE and saphenous vein showed that HUV was better than PTFE but worse than saphenous vein in terms of 5-year patency in the AK location. In a systematic review, HUV appears to perform better than cryopreserved veins.

Prosthetic Conduits and Adjunctive Modifications

If vein is truly unavailable, PTFE or Dacron is the best option for AK bypass. The addition of rings to PTFE did not confer benefit in a single prospective, randomized clinical trial. For infrageniculate prosthetic bypasses, use of a vein patch, cuff, or other venous anastomotic modification can improve patency (52% patency at 2 years for PTFE with vein cuff vs. 29% for PTFE with no cuff) and also improve limb salvage (84% vs. 62%).

Although prosthetic grafts are readily available, easy to handle, and do not require extensive dissection to harvest, their propensity to undergo thrombosis and develop neointimal hyperplasia makes them a less favorable alternative when compared to vein. In a recent review of vein and prosthetic AK femoropopliteal bypasses, the 5-year primary patency rates were reported to be 74 and 39%, respectively. Outcomes were even worse for BK prosthetic bypasses. Unfortunately, the use of autologous venous conduits is not possible in as many as 30% of patients. The GSV may be unsuitable because of small size and poor quality or unavailable due to prior harvest.

Methods to improve prosthetic graft performance have consisted of altering the geometry at the distal anastomosis to get the benefit obtained with vein cuffs (Distaflo, Bard Peripheral Vascular, Tempe, Ariz) and covalently bonding agents onto the luminal surface with anticoagulant, anti-inflammatory and antiproliferative characteristics (Propaten, Gore, Flagstaff, Ariz). One randomized trial that compared precuffed PTFE and PTFE with a vein cuff enrolled 104 patients at 10 centers. Eighty-nine patients were randomized to 47 precuffed PTFE bypasses and 44 bypasses with a vein cuff. At 1 and 2 years, primary patency rates were 52 and 49% for the precuffed group and 62 and 44% for the vein cuffed group, respectively. At 1 year and 2 years, the limb salvage rate was 72 and 65% for the precuffed group and 75 and 62% in the vein cuffed group, respectively. Although numbers are small and follow-up short, the midterm analysis revealed that Distaflo precuffed grafts and PTFE grafts with vein cuff had similar results. The authors concluded that a precuffed graft was a reasonable alternative for infragenicular reconstruction in the absence of saphenous vein. Other authors have been less optimistic and question if there is any benefit derived from geometrically altering prosthetic conduits.

Another approach for improving outcomes when using prosthetic for bypass grafts involves bonding anticoagulants to the conduit. The Gore Propaten graft has heparin bonded onto the luminal surface of the PTFE graft using Carmeda BioActive Surface technology, which immobilizes the heparin molecule with a single covalent bond that does not alter its

anticoagulant properties. The heparin binding does not alter the microstructure and handling characteristics of the PTFE. A prospective, randomized trial by Devine and associates suggested that heparin-bonded Dacron or PTFE was superior to plain PTFE for AK popliteal bypasses. The 3-year primary patency for the heparin-bonded grafts was 55% compared with 42% for PTFE ($P < .044$). Both of these patency rates are inferior to GSV; however, if the improved results with heparin bonding continue to be substantiated, then heparin-bonded prosthetic grafts will become the preferred conduit for AK bypass in the absence of suitable vein. A recent review of available studies with this graft showed an 80% 1-year patency for BK bypasses.¹⁹⁵ Randomized, controlled clinical trials with more patients and longer follow-up are necessary to validate whether the PROPATEN vascular graft is superior to other prosthetics, and if, indeed, it is comparable to autogenous vein for BK interventions.

Clinical Results of Surgical and Endovascular Interventions for Femoropopliteal Occlusive Disease

Balloon angioplasty of the femoropopliteal vessels has not enjoyed the degree of success seen with iliac angioplasty. Patency in this region is dependent upon whether the patient presents with claudication vs. limb-threatening ischemia, the status of the distal runoff vessels, and lesion morphology. Initial technical success for femoropopliteal angioplasty is seen in 80 to 90% of cases, with failures to cross a lesion occurring in 7% of stenoses and 18% of occlusive lesions. Studies have shown that PTA of the femoropopliteal segment achieved greater than a 90% technical success rate and had a 59% primary patency rate at 5-years. PTA of lesions longer than 7 to 10 cm results in compromised patency, while PTA of shorter lesions (<3 cm) gives fairly good results. Lofberg and associates performed 127 femoropopliteal PTA procedures and reported a primary patency rate at 5-year follow-up of 12% in limbs with occlusion longer than 5 cm vs. 32% in limbs with occlusion <5 cm in length. Occlusive lesions have much worse initial technical success rates than stenotic lesions. Concentric lesions respond better to PTA than eccentric lesions, and heavy calcifications have a negative impact on success rates. Distal runoff is another powerful predictor of long-term success.

Johnston and associates analyzed 254 consecutive patients who underwent femoropopliteal PTA and reported a 5-year patency rate of 53% for stenotic lesions and 36% for occlusive lesions in patients with good runoff vs. 5-year patency of 31% for stenotic lesions and 16% for occlusive lesions in patients with poor runoff. A meta-analysis by Hunink and colleagues showed that adjusted 5-year primary patencies after angioplasty of femoropopliteal

lesions varied from 12 to 68%, the best results occurring in patients with claudication and stenotic lesions. Although the initial technical success is better for stenoses than occlusions, long-term patency rates for stenoses and short occlusions have been variable and there have been conflicting results regarding the efficacy of stent use. Early published series that examined efficacy of femoropopliteal artery stents showed patency rates that were comparable to stand-alone PTA with primary patency rates varying from 18 to 72% at 3 years. Patient selection and the anatomic character of the lesions may play important roles in the outcomes. Additionally, stent characteristics may contribute to the patency rate. Several clinical studies have demonstrated significant improvements in patency when the newer generations of nitinol stents are used to treat SFA lesions.

Mewissen treated 137 lower limbs in 122 patients with CLI, secondary to TASC II A ($n = 12$) or TASC II B or C ($n = 125$) lesions in the SFA. Patients were treated with Cordis SMART self-expanding nitinol stents. Binary restenosis ($>50\%$) was measured by standard duplex velocity criteria at various postintervention intervals. Primary stent patency, defined as absence of binary restenosis in this study, was calculated by life table methods from the time of intervention. The mean lesion length was 12.2 cm (range, 4 to 28 cm). The technical success was 98%. Mean follow-up was 302 days. The primary stent patency rates were 92%, 76%, 66%, and 60% at 6, 12, 18, and 24-months, respectively. Ferreira and associates treated 59 patients who had 74 femoropopliteal lesions (60% TASC II D) with Zilver nitinol self-expanding stents (COOK, Bloomington, Ind). Mean recanalization length was 19 cm (range 3 to 53 cm). Mean follow-up time was 2.4 years (range 3 days to 4.8 years). Kaplan-Meier estimates for primary patency rates were 90%, 78%, 74%, 69%, and 69% at 1, 2, 3, 4, and 4.8 years, respectively.

There is general agreement that for suboptimal PTA of an SFA lesion, stent placement is indicated, but a recent randomized trial by Schillinger and associates suggests that primary stenting results in lower restenosis rates than PTA and selective stenting. Restenosis rates at 2 years were 45.7% vs. 69.2% in favor of primary stenting compared with PTA and optional secondary stenting using an intention-to-treat analysis ($P = .031$). Consistently, stenting, both primary and selective, was superior to stand-alone PTA with respect to the occurrence of restenosis (49.2% vs. 74.3%; $P = .028$) by a treatment-received analysis.

Nitinol bare metal stents that are designed specifically for BK interventions are showing very encouraging results. Bosiers and colleagues reported their 12-month results using the commercially available non-drug-eluting Xpert (Abbott Vascular, Santa Clara, Calif) nitinol stent system in BK arterial interventions. They had a 12-month primary patency rate of 76.3%,

and a limb salvage rate of 95.9%. They followed patients to 12 months and performed angiography with quantitative vessel analysis on the 73% of patients available. Angiography revealed a binary restenosis rate (>50%) of only 20.5%, which is comparable to well-accepted coronary DES study outcomes. The authors attributed this optimal performance to the maintenance of flow dynamics because the stent was specifically designed for use in small vessels. Kickuth and colleagues also have obtained good results using the Xpert stent. After stent placement, the primary cumulative patency rate at 6 months for the study group of 35 patients was 82%. The sustained clinical improvement rate as evidenced by improved ABI was 80%, and freedom from major amputation was 100% at the 6-month follow-up. The rate of major complications was 17%.

Wolf and associates published a multicenter, prospective randomized trial comparing PTA with bypass in 263 men who had iliac, femoral, or popliteal artery obstruction. In 56 patients, cumulative 1-year primary patency after PTA was 43% and, after bypass surgery, was 82%, demonstrating that for long SFA stenoses or occlusions, surgery is better than PTA. Another recent randomized study (BASIL trial) of 452 patients with CLI demonstrated no difference in amputation-free survival at 6 months between surgery and PTA/stenting. The authors commented that surgery was somewhat more expensive and recommended that endovascular intervention should be used as first-line therapy, especially in medically unfit patients. They did conclude that at 2-year follow-up, healthy patients without medical comorbidities derived greater benefit from surgery because it was associated with decreased need for reintervention and had a decreased hazard ratio in terms of all-cause mortality. Using the 2000 TASC II definitions and a Markov state transition model decision analysis, Nolan and colleagues showed that PTA/stenting surpasses bypass efficacy for TASC II C lesions if PTA/stenting primary patency is greater than 32% at 5 years, patient age is >80 years, and/or GSV bypass operative mortality is greater than 6%.

MESENTERIC ARTERY DISEASE

Vascular occlusive disease of the mesenteric vessels is a relatively uncommon but potentially devastating condition that generally presents in patients more than 60 years of age, is three times more frequent in women, and has been recognized as an entity since 1936. The incidence of such a disease is low and represents 2% of the revascularization operations for atheromatous lesions. The most common cause of mesenteric ischemia is atherosclerotic vascular disease. Autopsy studies have demonstrated splanchnic atherosclerosis in 35 to 70%

of cases. Other etiologies exist and include FMD, panarteritis nodosa, arteritis, and celiac artery (CA) compression from a median arcuate ligament, but they are unusual and have an incidence of one in nine compared to that of atherosclerosis.

Chronic mesenteric ischemia is related to a lack of blood supply in the splanchnic region and is caused by disease in one or more visceral arteries: the celiac trunk, the SMA, and the IMA. Mesenteric ischemia is thought to occur when two of the three visceral vessels are affected with severe stenosis or occlusion; however, in as many as 9% of cases, only a single vessel is involved [superior mesenteric artery (SMA) in 5% and celiac trunk in 4% of cases].⁷³ This disease process may evolve in a chronic fashion, as in the case of progressive luminal obliteration due to atherosclerosis. On the other hand, mesenteric ischemia can occur suddenly, as in the case of thromboembolism. Despite recent progress in perioperative management and better understanding in pathophysiology, mesenteric ischemia is considered one of the most catastrophic vascular disorders, with mortality rates ranging from 50 to 75%. Delay in diagnosis and treatment are the main contributing factors in its high mortality. It is estimated that mesenteric ischemia accounts for one in every 1000 hospital admissions in this country. The prevalence is rising due in part to the increased awareness of this disease, the advanced age of the population, and the significant comorbidity of these elderly patients. Early recognition and prompt treatment before the onset of irreversible intestinal ischemia are essential to improve the outcome.

Anatomy and Pathophysiology

Mesenteric arterial circulation is remarkable for its rich collateral network. Three main mesenteric arteries provide the arterial perfusion to the GI system: the CA, SMA, and IMA. In general, the CA provides arterial circulation to the foregut (distal esophagus to duodenum), hepatobiliary system, and spleen; the SMA supplies the midgut (jejunum to midcolon); and the IMA supplies the hindgut (midcolon to rectum). The CA and SMA arise from the ventral surface of the infradiaphragmatic suprarenal abdominal aorta, while the IMA originates from the left lateral portion of the infrarenal aorta. These anatomic origins in relation to the aorta are important when a mesenteric angiogram is performed to determine the luminal patency. To fully visualize the origins of the CA and SMA, it is necessary to perform both an anteroposterior and a lateral projection of the aorta because most arterial occlusive lesions occur in the proximal segments of these mesenteric trunks.

Because of the abundant collateral flow between these mesenteric arteries, progressive

diminution of flow in one or even two of the main mesenteric trunks is usually tolerated, provided that uninvolved mesenteric branches can enlarge over time to provide sufficient compensatory collateral flow. In contrast, acute occlusion of a main mesenteric trunk may result in profound ischemia due to lack of sufficient collateral flow. Collateral network between the CA and the SMA exist primarily through the superior and inferior pancreaticoduodenal arteries. The IMA may provide collateral arterial flow to the SMA through the marginal artery of Drummond, the arc of Riolan, and other unnamed retroperitoneal collateral vessels termed *meandering mesenteric arteries* (Fig. 25). Lastly, collateral visceral vessels may provide important arterial flow to the IMA and the hindgut through the hypogastric arteries and the hemorrhoidal arterial network.

Fig. 25. An aortogram showing a prominent collateral vessel that is the arc of Riolan (*arrow*) in a patient with an inferior mesenteric artery occlusion. This vessel network provides collateral flow between the superior mesenteric artery and inferior mesenteric artery

Regulation of mesenteric blood flow is largely modulated by both hormonal and neural stimuli, which characteristically regulate systemic blood flow. In addition, the mesenteric

circulation responds to the GI contents. Hormonal regulation is mediated by splanchnic vasodilators such as nitric oxide, glucagon, and vasoactive intestinal peptide. Certain intrinsic vasoconstrictors such as vasopressin can diminish the mesenteric blood flow. On the other hand, neural regulation is provided by the extensive visceral autonomic innervation.

Clinical manifestation of mesenteric ischemia is predominantly postprandial abdominal pain, which signifies that the increased oxygen demand of digestion is not met by the GI collateral circulation. The postprandial pain frequently occurs in the midabdomen, suggesting that the diversion of blood flow from the SMA to supply the stomach impairs perfusion to the small bowel. This leads to transient anaerobic metabolism and acidosis. Persistent or profound mesenteric ischemia will lead to mucosal compromise with release of intracellular contents and by-products of anaerobic metabolism to the splanchnic and systemic circulation. Injured bowel mucosa allows unimpeded influx of toxic substances from the bowel lumen with systemic consequences. If full-thickness necrosis occurs in the bowel wall, intestinal perforation ensues, which will lead to peritonitis. Concomitant atherosclerotic disease in cardiac or systemic circulation frequently compounds the diagnostic and therapeutic complexity of mesenteric ischemia.

Types of Mesenteric Artery Occlusive Disease

There are three major mechanisms of visceral ischemia involving the mesenteric arteries, which include: (a) acute mesenteric ischemia, which can be either embolic or thrombotic in origin; (b) chronic mesenteric ischemia; and (c) nonocclusive mesenteric ischemia. Despite the variability of these syndromes, a common anatomic pathology is involved in these processes. The SMA is the most commonly involved vessel in acute mesenteric ischemia. Acute thrombosis occurs in patients with underlying mesenteric atherosclerosis, which typically involves the origin of the mesenteric arteries while sparing the collateral branches. In acute embolic mesenteric ischemia, the emboli typically originate from a cardiac source and frequently occur in patients with atrial fibrillation or following myocardial infarction (Figs. 26 and 27). Nonocclusive mesenteric ischemia is characterized by a low flow state in otherwise normal mesenteric arteries, and most frequently occurs in critically ill patients on vasopressors. Finally, chronic mesenteric ischemia is a functional consequence of a long-standing atherosclerotic process that typically involves at least two of the three main mesenteric vessels. The gradual development of the occlusive process allows the development of collateral vessels that prevent the manifestations of acute ischemia, but are not sufficient to meet the high

postprandial intestinal oxygen requirements, giving rise to the classical symptoms of postprandial abdominal pain and the resultant food fear.

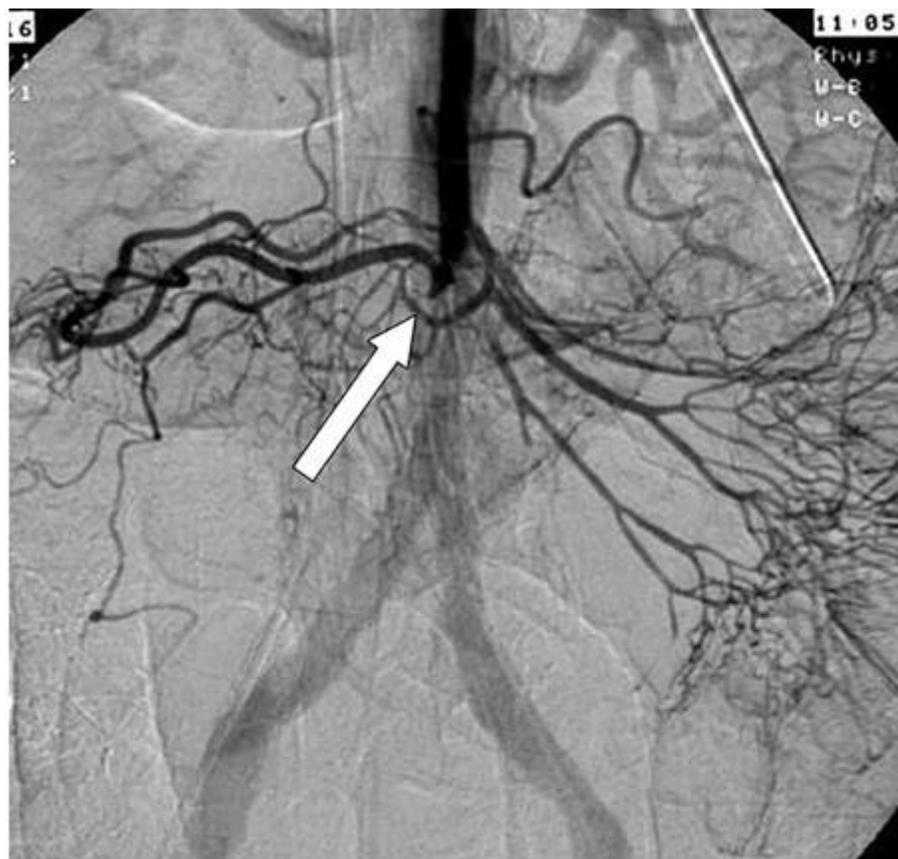

Fig.26. An anteroposterior view of a selective superior mesenteric artery angiogram showed an abrupt cutoff of the middle colic artery, which was caused by emboli (*arrow*) due to atrial fibrillation

Fig. 27. A lateral mesenteric angiogram showing an abrupt cutoff of the proximal superior mesenteric artery, which is consistent with superior mesenteric artery embolism (*arrow*).

Mesenteric arteriography also can play a therapeutic role. Once the diagnosis of nonocclusive mesenteric ischemia is made on the arteriogram, an infusion catheter can be placed at the SMA orifice and vasodilating agents such as papaverine can be administered intra-arterially. The papaverine infusion may be continued postoperatively to treat persistent vasospasm, a common occurrence following mesenteric reperfusion. Transcatheter thrombolytic therapy has little role in the management of thrombotic mesenteric occlusion. Although thrombolytic agents may transiently recannulate the occluded vessels, the underlying occlusive lesions require definitive treatment. Furthermore, thrombolytic therapy typically requires a prolonged period of time to restore perfusion, during which the intestinal viability will be difficult to assess.

A word of caution would be appropriate here regarding patients with typical history of chronic intestinal angina who present with an acute abdomen and classical findings of peritoneal irritation. Arteriography is the gold standard for the diagnosis of mesenteric occlusive disease; however, it can be a time-consuming diagnostic modality. In this group of patients, immediate exploration for assessment of intestinal viability and vascular reconstruction is the best choice.

Surgical Repair

Acute Embolic Mesenteric Ischemia

Initial management of patients with acute mesenteric ischemia includes fluid resuscitation and systemic anticoagulation with heparin to prevent further thrombus propagation. Significant metabolic acidosis not responding to fluid resuscitation should be corrected with sodium bicarbonate. A central venous catheter, peripheral arterial catheter, and a Foley catheter should be placed for hemodynamic status monitoring. Appropriate antibiotics are given before surgical exploration. The operative management of acute mesenteric ischemia is dictated by the cause of the occlusion. It is helpful to obtain a preoperative mesenteric arteriogram to confirm the diagnosis and to plan appropriate treatment options. However, the diagnosis of mesenteric ischemia frequently cannot be established before surgical exploration; and therefore, patients in a moribund condition with acute abdominal symptoms should undergo immediate surgical exploration, avoiding the delay required to perform an arteriogram.

The primary goal of surgical treatment in embolic mesenteric ischemia is to restore arterial perfusion with removal of the embolus from the vessel. The abdomen is explored through a midline incision, which often reveals variable degrees of intestinal ischemia from the midjejunum to the ascending or transverse colon. The transverse colon is lifted superiorly, and the small intestine is reflected toward the right upper quadrant. The SMA is approached at the root of the small bowel mesentery, usually as it emerges from beneath the pancreas to cross over the junction of the third and fourth portions of the duodenum. Alternatively, the SMA can be approached by incising the retroperitoneum lateral to the fourth portion of the duodenum, which is rotated medially to expose the SMA. Once the proximal SMA is identified and controlled with vascular clamps, a transverse arteriotomy is made to extract the embolus, using standard balloon embolectomy catheters. In the event the embolus has lodged more distally, exposure of the distal SMA may be obtained in the root of the small bowel mesentery by isolating individual jejunal and ileal branches to allow a more comprehensive thromboembolectomy. Following the restoration of SMA flow, an assessment of intestinal viability must be made, and nonviable bowel must be resected. Several methods have been described to evaluate the viability of the intestine, which include intraoperative IV fluorescein injection and inspection with a Wood's lamp, and Doppler assessment of antimesenteric intestinal arterial pulsations. A second-look procedure should be considered in many patients,

and is performed 24 to 48 hours following embolectomy. The goal of the procedure is reassessment of the extent of bowel viability, which may not be obvious immediately following the initial embolectomy. If nonviable intestine is evident in the second-look procedure, additional bowel resections should be performed at that time.

Acute Thrombotic Mesenteric Ischemia

Thrombotic mesenteric ischemia usually involves a severely atherosclerotic vessel, typically the proximal CA and SMA. Therefore, these patients require a reconstructive procedure to the SMA to bypass the proximal occlusive lesion and restore adequate mesenteric flow. The saphenous vein is the graft material of choice, and prosthetic materials should be avoided in patients with nonviable bowel, due to the risk of bacterial contamination if resection of necrotic intestine is performed. The bypass graft may originate from either the aorta or iliac artery. Advantages from using the supraceliac infradiaphragmatic aorta as opposed to the infrarenal aorta as the inflow vessel include a more smooth graft configuration with less chance of kinking, and the absence of atherosclerotic disease in the supraceliac aortic segment. Exposure of the supraceliac aorta is technically more challenging and time consuming than that of the iliac artery, which, unless calcified, is an appropriate inflow. Patency rates are similar regardless of inflow vessel choice.

Chronic Mesenteric Ischemia

The therapeutic goal in patients with chronic mesenteric ischemia is to revascularize mesenteric circulation and prevent the development of bowel infarction. Mesenteric occlusive disease can be treated successfully by either transaortic endarterectomy or mesenteric artery bypass. Transaortic endarterectomy is indicated for ostial lesions of patent CA and SMA. A left medial rotation is performed, and the aorta and the mesenteric branches are exposed. A lateral aortotomy is performed, encompassing both the CA and SMA orifices. The visceral arteries must be adequately mobilized so that the termination site of endarterectomy can be visualized. Otherwise, an intimal flap may develop, which can lead to early thrombosis or distal embolization.

For occlusive lesions located 1 to 2 cm distal to the mesenteric origin, mesenteric artery bypass should be performed. Multiple mesenteric arteries are typically involved in chronic mesenteric ischemia, and both the CA and SMA should be revascularized whenever possible.

In general, bypass grafting may be performed either antegrade from the supraceliac aorta or retrograde from either the infrarenal aorta or iliac artery. Both autogenous saphenous vein grafts and prosthetic grafts have been used with satisfactory and equivalent success. An antegrade bypass also can be performed using a small-caliber bifurcated graft from the supraceliac aorta to both the CA and SMA, which yields an excellent long-term result.

Celiac Artery Compression Syndrome

The decision to intervene in patients with CA compression syndrome should be based on both an appropriate symptom complex and the finding of CA compression in the absence of other findings to explain the symptoms. The treatment goal is to release the ligamentous structure that compresses the proximal CA and to correct any persistent stricture by bypass grafting. The patient should be cautioned that relief of the celiac compression cannot be guaranteed to relieve the symptoms. In a number of reports on endovascular management of chronic mesenteric ischemia, the presence of CA compression syndrome has been identified as a major factor of technical failure and recurrence. Therefore, angioplasty and stenting should not be undertaken if extrinsic compression of the CA by the median arcuate ligament is suspected based on preoperative imaging studies. Open surgical treatment should be performed instead.

Endovascular Treatment

Chronic Mesenteric Ischemia

Endovascular treatment of mesenteric artery stenosis or short segment occlusion by balloon dilatation or stent placement represents a less invasive therapeutic alternative to open surgical intervention, particularly in patients whose medical comorbidities place them in a high operative risk category. Endovascular therapy is also suited to patients with recurrent disease or anastomotic stenosis following previous open mesenteric revascularization. Prophylactic mesenteric revascularization is rarely performed in the asymptomatic patient undergoing an aortic procedure for other indications. However, the natural history of untreated chronic mesenteric ischemia may justify revascularization in some minimally symptomatic or asymptomatic patients if the operative risks are acceptable, because the first clinical presentation may be acute intestinal ischemia in as many as 50% of the patients, with a

mortality rate that ranges from 15 to 70%. This is particularly true when the SMA is involved. Mesenteric angioplasty and stenting is particularly suitable for this patient subgroup given its low morbidity and mortality. Because of the limited experience with stent use in mesenteric vessels, appropriate indications for primary stent placement have not been clearly defined. Guidelines generally include calcified ostial stenoses, high-grade eccentric stenoses, chronic occlusions, and significant residual stenosis greater than 30% or the presence of dissection after angioplasty. Restenosis after PTA is also an indication for stent placement.

Acute Mesenteric Ischemia

Catheter-directed thrombolytic therapy is a potentially useful treatment modality for acute mesenteric ischemia, which can be initiated with intra-arterial delivery of thrombolytic agent into the mesenteric thrombus at the time of diagnostic angiography. Various thrombolytic medications, including urokinase (Abbokinase, Abbott Laboratory, North Chicago, Ill) or recombinant tissue plasminogen activator (Activase, Genentech, South San Francisco, Calif), have been reported to be successful in a small series of case reports. Catheter-directed thrombolytic therapy has a higher probability of restoring mesenteric blood flow success when performed within 12 hours of symptom onset. Successful resolution of a mesenteric thrombus will facilitate the identification of the underlying mesenteric occlusive disease process. As a result, subsequent operative mesenteric revascularization or mesenteric balloon angioplasty and stenting may be performed electively to correct the mesenteric stenosis. There are two main drawbacks with regard to thrombolytic therapy in mesenteric ischemia. Percutaneous, catheter-directed thrombolysis (CDT) does not allow the possibility to inspect the potentially ischemic intestine following restoration of the mesenteric flow. Additionally, a prolonged period of time may be necessary to achieve successful CDT, due in part to serial angiographic surveillance to document thrombus resolution. An incomplete or unsuccessful thrombolysis may lead to delayed operative revascularization, which may further necessitate bowel resection for irreversible intestinal necrosis. Therefore, catheter-directed thrombolytic therapy for acute mesenteric ischemia should only be considered in selected patients under a closely scrutinized clinical protocol.

Nonocclusive Mesenteric Ischemia

The treatment of nonocclusive mesenteric ischemia is primarily pharmacologic with

selective mesenteric arterial catheterization followed by infusion of vasodilatory agents such as tolazoline or papaverine. Once the diagnosis is made on the mesenteric arteriography, intra-arterial papaverine is given at a dose of 30 to 60 mg/h. This must be coupled with the cessation of other vasoconstricting agents. Concomitant IV heparin should be administered to prevent thrombosis in the cannulated vessels. Treatment strategy thereafter is dependent on the patient's clinical response to the vasodilator therapy. If abdominal symptoms improve, mesenteric arteriography should be repeated to document the resolution of vasospasm. The patient's hemodynamic status must be carefully monitored during papaverine infusion, as significant hypotension can develop in the event that the infusion catheter migrates into the aorta, which can lead to systemic circulation of papaverine. Surgical exploration is indicated if the patient develops signs of continued bowel ischemia or infarction as evidenced by rebound tenderness or involuntary guarding. In these circumstances, papaverine infusion should be continued intraoperatively and postoperatively. The OR should be kept as warm as possible, and warm irrigation fluid and laparotomy pads should be used to prevent further intestinal vasoconstriction during exploration.

Techniques of Endovascular Interventions

To perform endovascular mesenteric revascularization, intraluminal access is performed via a femoral or brachial artery approach. Once an introducer sheath is placed in the femoral artery, an anteroposterior and lateral aortogram just below the level of the diaphragm is obtained with a pigtail catheter to identify the origin of the CA and SMA. Initial catheterization of the mesenteric artery can be performed using a variety of selective angled catheters, which include the RDC, Cobra-2, Simmons I (Boston Scientific/Meditech, Natick, Mass), or SOS Omni catheter (AngioDynamics, Queensbury, NY). Once the mesenteric artery is cannulated, systemic heparin (5000 IU) is administered IV. A selective mesenteric angiogram is then performed to identify the diseased segment, which is followed by the placement of a 0.035-in or less traumatic 0.014- to 0.018-in guidewire to cross the stenotic lesion. Once the guidewire is placed across the stenosis, the catheter is carefully advanced over the guidewire across the lesion. In the event that the mesenteric artery is severely angulated as it arises from the aorta, a second stiffer guidewire (Amplatz or Rosen Guidewire, Boston Scientific) may be exchanged through the catheter to facilitate the placement of a 6F guiding sheath (Pinnacle, Boston Scientific).

With the image intensifier angled in a lateral position to fully visualize the proximal

mesenteric segment, a balloon angioplasty is advanced over the guidewire through the guiding sheath and positioned across the stenosis. The balloon diameter should be chosen based on the vessel size of the adjacent normal mesenteric vessel. Once balloon angioplasty is completed, a postangioplasty angiogram is necessary to document the procedural result. Radiographic evidence of either residual stenosis or mesenteric artery dissection constitutes suboptimal angioplasty results that warrant mesenteric stent placement. Moreover, atherosclerotic involvement of the proximal mesenteric artery or vessel orifice should be treated with a balloon-expandable stent placement. These stents can be placed over a low profile 0.014- or 0.018-in guidewire system. It is preferable to deliver the balloon-mounted stent through a guiding sheath, which is positioned just proximal to the mesenteric orifice while the balloon-mounted stent is advanced across the stenosis. The stent is next deployed by expanding the angioplasty balloon to its designated inflation pressure. The balloon is then deflated and carefully withdrawn through the guiding sheath.

Completion angiogram is performed by hand injecting a small volume of contrast through the guiding sheath. It is critical to maintain the guidewire access until a satisfactory completion angiogram is obtained. If the completion angiogram reveals suboptimal radiographic results, such as residual stenosis or dissection, additional catheter-based intervention can be performed through the same guidewire. These interventions may include repeat balloon angioplasty for residual stenosis or additional stent placement for mesenteric artery dissection. During the procedure, intra-arterial infusion of papaverine or nitroglycerine can be used to decrease vasospasm. Administration of antiplatelet agents is also recommended, for at least 6 months or even indefinitely if other risk factors of cardiovascular disease are present.

Complications of Endovascular Treatment

Complications are not common and rarely become life threatening. These include access site thrombosis, hematomas, and infection. Dissection can occur during PTA and is managed with placement of a stent. Balloon-mounted stents are preferred over the self-expanding ones because of the higher radial force and the more precise placement. Distal embolization has also been reported but it never resulted in acute intestinal ischemia, likely due to the rich network of collaterals already developed.

TOPIC 9. ARTERIAL TROMBOSIS AND EMBOLISM

ACUTE UPPER EXTREMITY ISCHEMIA

Acute ischemia in the upper extremity constitutes 10–15% of all acute extremity ischemia. The etiology is emboli in 90% of the patients. The reason for this higher rate compared with the leg is that atherosclerosis is less common in arm arteries. Emboli have the same origins as in the lower extremity and usually end up obstructing the brachial artery. Sometimes plaques or an aneurysm in the subclavian or axillary arteries is the primary source of emboli. Embolization to the right arm is more common than to the left due to the vascular anatomy. For the 10% of patients with atherosclerosis and acute thrombosis as the main cause for their arm ischemia, the primary lesions are located in the brachiocephalic trunk or in the subclavian artery. Such pathologies are usually asymptomatic due to well-developed collaterals around the shoulder joint until thrombosis occurs, and they cause either micro- or macroembolization. Other less frequent causes of acute upper extremity ischemia are listed in Table 1

Table 1. Less common causes of acute upper extremity ischemia

Cause	Characteristics
Arteritis	Lesions in distal and proximal arteries
Buerger's disease	Digital ischemia in young heavy smokers
Coagulation disorders	Generalized or distal thrombosis
Raynaud's disease	Digital ischemia

Subclavian artery thrombosis is a condition in which the blood flow through the vessel is obstructed. The condition usually occurs secondary to some form of antecedent injury to the vessel, hypercoagulable state, or atherosclerotic changes. The condition is common in young athletic individuals who exert a significant amount of upper body activity. Sudden occlusion

from emboli followed by thrombosis of the artery is common in the population with signs of significant atherosclerotic disease.

The patient presenting with acute subclavian artery occlusion usually has a history of repetitive use and/or stress injury to the upper extremity on the affected side. A history of upper extremity claudication is common.

In situations in which the occlusion is secondary to atherosclerosis, acute thromboses of the artery are generally asymptomatic. In fact, in 9% of autopsy series, the left subclavian artery was either stenotic or occluded. If symptoms are present, upper extremity claudication on the affected side is most common. The patient may also present with dizziness, vertigo, imbalance, visual disturbances, or hemisensory dysfunction indicative of a subclavian steal syndrome. However, note that subclavian steal is observed on 2% of cerebral angiograms and causes no symptoms.

EMBOLISM

Embolism is considered the most common cause of acute arm ischemia (74%). The emboli are attributed to a variety of sources. Cardiac embolism is the most frequently reported cause of acute arm ischemia (58% to 93%) and atrial fibrillation is the usual etiology. Over the years the incidence of atrial fibrillation has remained fairly constant although the cause of fibrillation has changed from valvular heart disease as a result of rheumatic fever to ischemic heart disease and myocardial infarction. Rare causes include endocarditis, atrial myxoma, ventricular aneurysm, cardiac failure, and paradoxical embolism.

Non-cardiac embolism determines 1% to 32% of the acute arm emboli. Proximal upper limb stenosis caused by atherosclerotic plaque or external compression (cervical ribs) can result in thrombo-embolism or atheroembolism, which may cause large vessel occlusion or acute digital ischemia.

Other causes include atheroma in the aortic arch, primary subclavian aneurysm or aneurysm secondary to extrinsic compression from thoracic outlet syndrome, old fracture, and chronic trauma such as that from the use of crutches. Rarer sources are the proximal end of an occluded axillofemoral graft, arteritis, malignant emboli, and fibromuscular dysplasia. Despite a classic embolic presentation and operative findings, an embolic source may not be found in at least 12% of patients.

THROMBOSIS

Reports suggest that 5% of cases in population studies and 9% to 35% in surgical series are due to thrombosis. Jivegard et al. estimated that in patients who had embolectomy, the chance of thrombosis being the true cause was 5.5% in the arm. Most of the proximal arterial lesions that can cause emboli can also result in thrombosis, including atherosclerotic plaques, aneurysm, acute aortic dissection, and arteritis (Takayasu's disease).

Atherosclerosis in the upper extremity appears especially prominent in older men. The disease may be at the origin of the great vessels or distally in the axillary or brachial arteries. Aneurysms of the subclavian or axillary arteries may also result in upper extremity ischemia through two mechanisms. They may directly cause ischemic symptoms by thrombosis or by producing emboli that occlude the distal circulation (Raynaud's phenomenon).

Less common causes include arteritis from connective tissue disorders (scleroderma), radiation arteritis, hyperthrombotic conditions and thrombosis associated with malignancy or steroid use.

Clinical Presentation

Acute arm ischemia is usually apparent on the basis of the physical examination. The symptoms are often relatively discreet, especially early after onset. The explanation for this is the well developed collateral system circumventing the brachial artery around the elbow, which is the most common site for embolic obstruction. The “six Ps” – pain, pallor, paresthesia, paralysis, pulselessness, poikilothermia – are applicable also for acute arm ischemia, but coldness and color changes are more prominent than for the legs. Accordingly, the most common findings in the physical examination are a cold arm with diminished strength and disturbed hand and finger motor functions. Tingling and numbness are also frequent. The radial pulse is usually absent but is pounding in the upper arm proximal to the obstruction. Gangrene and rest pain appear only when the obstruction is distal to the elbow and affects both of the paired arteries in a finger or in the lower arm. Ischemic signs or symptoms suggesting acute digital artery occlusion in only one or two fingers, imply microembolization.

Diagnostics

Only the few patients with uncertain diagnosis, and those with a history and physical findings that indicates thrombosis, need additional work-up. Examples include patients with a history of chronic arm ischemia (arm fatigue, muscle atrophy, and microembolization) and

bruits over proximal arteries. Angiography should then be performed to reveal the site of the causing lesion. Duplex ultrasound is rarely needed to diagnose acute arm ischemia but may occasionally be helpful.

Management Before Treatment

Even though symptoms and examination findings may be so subtle that conservative treatment is tempting, surgical removal of the obstruction is almost always preferable. It has been suggested that in patients with a lower-arm blood pressure >60 mmHg embolectomy can be omitted, but such a strategy has not to our knowledge been evaluated systematically. In a patient series of nearly symptomless acute arm ischemia, which was left to resolve spontaneously or with anticoagulation as the only treatment, late symptoms developed in up to 45% of the cases. Surgical treatment is also fairly straightforward. It can be performed using local anesthesia and is associated with few complications. Very often an embolus is a manifestation of severe cardiac disease, so the patient's cardiopulmonary function should be assessed and optimized as soon as possible. Preoperative preparations include an electrocardiogram (ECG) and laboratory tests to guide anticoagulation treatment. Heparin treatment is started perioperatively and continued postoperatively in most patients.

Operation

Embolectomy

As mentioned previously, the most common site for embolic obstruction is the brachial artery.

The arm is placed on an arm table. We prefer to perform embolectomy using local anesthesia. Often a transverse incision placed over the palpable brachial pulse can be used. If proximal extension of the incision is required, this should be done in parallel with and dorsal to the dorsal aspect of the biceps muscle. It has to be kept in mind that 10–20% of patients may have a different brachial artery anatomy. The most common variation is a high bifurcation of the radial and ulnar arteries, and next in frequency is a doubled brachial artery.

An alternative location for embolectomy in the arm is to expose the brachial artery in the

bicipital groove. A longitudinal incision starting 10 cm above the elbow that is extended proximally is then used.

If it is hard to achieve a good inflow, a proximal lesion may cause the embolization or thrombosis. More complicated vascular procedures are then required to reestablish flow. The embolectomy attempt is then discontinued and the patient taken to the angiography suite for a complete examination. If practically feasible, an alternative is to obtain the angiogram in the operating room. Frequently, however, the preferred treatment is endovascular, and this is better done in the angiography suite. Occasionally the films will reveal a proximal obstruction that needs open repair. Examples of such are carotid-subclavian, subclavian-axillary, and axillary-brachial bypasses.

Embolectomy via the Brachial Artery

Brachial Artery in the Upper Arm

The incision is made along the posterior border of the biceps muscle; a length of 6–8 cm is usually enough.

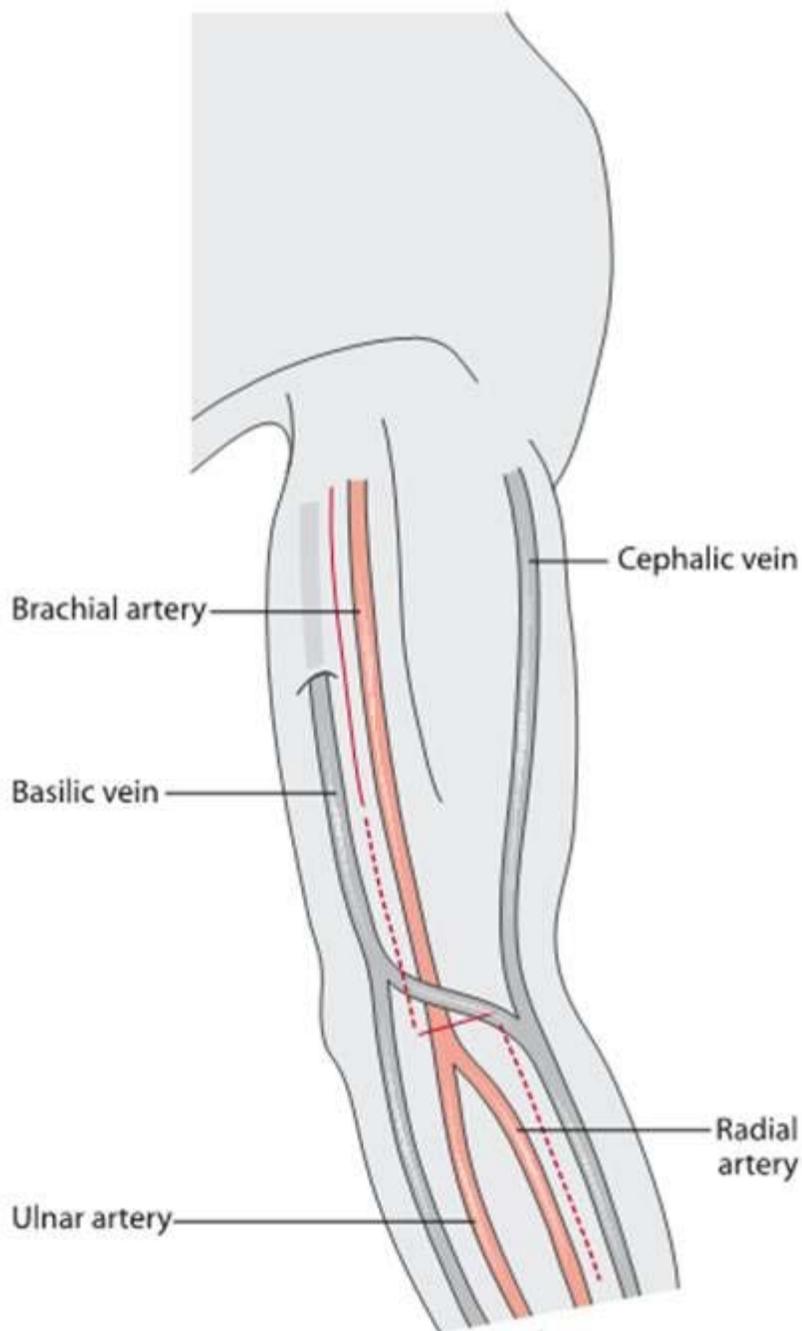

Fig. Transverse incision in the elbow for exposing the brachial artery and with possible elongations (dottedlines) when access to the ulnar and radial branches as well as to more proximal parts of the brachial artery is needed

The muscles are retracted medially and laterally, and the artery lies in the neurovascular bundle immediately below the muscles. The sheath is incised and the artery freed from the median nerve and the medial cutaneous nerve that surrounds it.

Brachial Artery at the Elbow

The incision is placed 2 cm below the elbow crease and should continue up on the medial side along the artery. If possible, veins transversing the wound should be preserved, but they can be divided if necessary for exposure. The medial insertion of the biceps tendon is divided entirely, and the artery lies immediately beneath it. By following the wound proximally, more of the artery can be exposed. If the origins of the radial and ulnar artery need to be assessed, the wound can be elongated distally on the ulnar side of the volar aspect of the arm. The median nerve lies close to the brachial artery, and it is important to avoid injuring it.

A transverse arteriotomy in the brachial artery is made as close as possible to the bifurcation of the ulnar and radial arteries. The embolectomy is performed in proximal and distal directions with #2 and #3 Fogarty catheters. Separate embolectomy in each branch should be done if technically simple. The Fogarty catheter otherwise slips down into the larger and straighter ulnar artery. The route of the catheter can be checked by palpation at the wrist level when the inflated balloon passes. On the other hand, restored flow in one of the arteries is usually enough for a result that is sufficient for adequate hand perfusion. The arteriotomy is closed with interrupted 6-0 sutures, and distal pulses and the perfusion in the hand are evaluated. If the result is inadequate – poor backflow after embolectomy, absence of pulse, a weak continuous-wave Doppler signal, and questionable hand perfusion – the arteriotomy should be reopened and intraoperative angiography performed.

Endovascular Treatment

Thrombolysis is as feasible for acute upper extremity ischemia as it is in the leg. The limited ischemia that often occurs after most embolic events because of the collateral network around the elbow also allows the time needed for planning and moving the patient to the angiosuite. The technique involves cannulation in the groin with a 7-French sheath. Long guide wires and catheters are required to reach the occluded site and makes identification of proximal lesions possible. A new arterial puncture in the brachial artery may be necessary for thrombolysis of distal occlusions. It can be argued that thrombolysis in spite of acceptable results, rarely is needed for treating this disease because open embolectomy can be performed under local anesthesia with good results and little surgical morbidity. The advantages with endovascular treatment are indeed limited. For patients in whom suspicion of thrombosis is

strong or when proximal lesions are likely, it should be attempted first. However, case series indicates that results of thrombolysis are inferior for forearm occlusions. In summary, thrombolysis is an alternative but has little to offer in reducing risk or improving outcome compared with embolectomy for most patients.

Management After Treatment

Patients usually regain full function of their hand immediately after the procedure, and postoperative regimens consist of anticoagulation and a search for the embolic source. The search for cardiac sources may advocate repeated ECGs, echocardiography, and duplex ultrasound of proximal arteries.

Results and Outcome

The number of salvaged arms after surgical intervention is very high, 90–95 %, and arm function is usually fully recovered. The remaining 5–10% represents patients with extensive thrombosis involving many vascular segments and most branches of the distal arteries. The postoperative mortality is around 10–40% in most patient series, reflecting that embolization often is a consequence of severe cardiac disease. Postoperative mortality is similar for thrombolysis to treat acute arm ischemia, while early technical success is slightly lower or similar. Less favorable results with thrombolysis are achieved when the distal arteries also are obstructed.

ACUTE LEG ISCHEMIA

Acute leg ischemia is associated with a great risk for amputation and death. The age of the patients is high, and to some extent acute leg ischemia can be considered an end-of-life disease. Patients' symptoms and the clinical signs of the afflicted leg vary. Sometimes grave ischemia immediately threatens limb viability, such as after a large embolization to a healthy vascular bed. Other times the symptoms are less dramatic, appearing as onset of rest pain in a patient with claudication. This is usually due to thrombosis of a previously stenosed artery.

Table 2. Incidence of acute leg ischemia

Country	Year	Surveyed population size	Population	Yearly incidence per 100,000 inhabitants
Sweden	1965-1983	1.5 million	All treated or amputated, >70 years old	125 (men) 150 (women)
USA	2000		All hospitalized	95
Sweden	1990-1994	2.0 million	All treated	60 (men) 77 (Women)
United Kingdom	1995	0.5 million	All diagnosed	14-16

It is the severity of ischemia that determines management and treatment. To minimize the risk for amputation or persistent dysfunction it is important to rapidly restore perfusion if an extremity is immediately threatened. When the leg shows signs of severe ischemia but is clearly viable, it is equally important to thoroughly evaluate and optimize the patient before any intervention is initiated. These basic management principles are generally applicable. Accordingly, we recommend “management by severity” rather than “management by etiology” (thrombosis versus embolus) but recognize that the latter can also be an effective strategy.

Embolism

Embolism is by far the most common cause of acute arm ischaemia, accounting for 74–100% of cases.

In the lower extremities, controversy exists regarding the ratio between arterial embolism and thrombosis, with different studies giving numbers ranging from 4:1 to 1:9.

The heart is invariably the most common origin of peripheral arterial emboli, and is responsible for 58–93% of cases. However, the pattern of the underlying heart disease has changed recently as the incidence of rheumatic valvular disease has decreased significantly

Cardiac Sources of Emboli

Nowadays, the most common sources of arterial emboli of cardiac origin are:

atrial fibrillation due to atherosclerotic heart disease, accounting for 32–75% of cases, followed by myocardial infarction with mural thrombi formation, which is responsible for 21–32% of peripheral emboli.

Less common cardiac sources of emboli are:

idiopathic dilated cardiomyopathy

prosthetic valves

rheumatic mitral valve disease

intracavitary cardiac tumours (mainly myxomas)

paradoxical embolization through an intracardiac defect, usually a patent foramen ovale

fungal or bacterial endocarditis.

Noncardiac Sources

Noncardiac sources of emboli are being identified with increasing frequency, at the expense of undetermined causes, the frequency of which has steadily decreased due to improvements in diagnostic methods. Noncardiac sources of emboli are nowadays found in 5–12% of patients, while in 9–12% the source of the emboli remains unknown.

Aneurysms are the most common noncardiac source of peripheral embolism, accounting for about 5% of distal emboli.

Ulcerated atherosclerotic plaques follow in order of frequency, carrying the risk of distal embolism from white thrombi adherent on their surface. Such emboli are usually sizeable, capable of obstructing major peripheral arteries.

A distinct variant of peripheral embolization due to an atherosclerotic plaque is atheroembolism, in which a portion of the plaque breaks off and undergoes embolization to peripheral arteries. Such emboli may evolve in three clinical forms:

1. The asymptomatic form, not diagnosed during the subject's lifetime and only recognized in autopsy studies.
2. A benign form such as blue toe syndrome or cutaneous livedo, with a spontaneous mild prognosis.
3. A diffuse multisystemic form with a very poor prognosis.

Cryptogenic Emboli

Despite complete diagnostic work-up, including complex investigations, the precise source of the emboli cannot be identified in 5–12% of cases. Such emboli are called cryptogenic and represent either the limited sensitivity of current diagnostic modalities or, in some cases, confusion with local thrombosis in situ.

Thrombosis

Thrombosis of an atherosclerotic artery or a vascular graft is another major cause of acute arterial occlusion of the extremities. As Virchow suggested in 1856, thrombus formation is the result of an interaction between an injured surface, stasis and the hypercoagulability of blood:

Arterial thrombosis most often develops at the points of severe stenosis. Since the course of atherosclerotic disease is chronic, a collateral network will have already developed and the clinical picture will be milder compared with arterial embolism. However, a thrombus can be formed in the absence of significant pre-existing stenosis, particularly when the surface of the plaque is ulcerated or after an intraplaque haemorrhage resulting in sudden arterial occlusion.

Low-flow conditions, such as congestive heart failure, hypovolaemia, hypotension of any cause or decreased blood flow due to a more proximal stenosis.

Hypercoagulable states, such as myeloproliferative disorders, hyperviscosity syndromes and coagulation disorders, may contribute to thrombosis of the diseased artery.

Other causes of arterial thrombosis include:

Arterial aneurysms, with the risk of thrombosis being higher the more peripherally the aneurysm is located.

Arterial by-pass graft thrombosis, which frequently induces acute limb-threatening ischaemia, as the graft has usually allowed collateral vessels to regress. Early graft failure, within the first postoperative month, is usually due to a technically suboptimal result, inappropriate indication or a transient episode of hypotension. Late graft failure, after 1 month, is secondary to intimal hyperplasia at the anastomotic sites or to progression of atherosclerotic disease.

Aortic dissection.

Fibromuscular dysplasia, occasionally involving the iliac arteries.

Cystic adventitial disease, usually affecting the popliteal artery and rarely the femoral.

Thromboangiitis obliterans, involving medium-sized muscular arteries.

Various arteritides, such as Takayasu's aortitis and giant cell arteritis.

Compartment syndrome.

Ehoracic outlet syndrome.

Popliteal entrapment syndrome.

Ergotism.

Magnitude of the Problem

It is difficult to find accurate incidence figures on acute leg ischemia. Data from some reports are given in Table 2. The numbers listed do not include conservatively treated patients or those whose legs were amputated as a primary procedure. The incidence increases with age and is seen with equal frequency in men and women. Regardless, the frequency indicates that it is a very common problem.

Pathogenesis

Acute leg ischemia is caused by a sudden deterioration of perfusion to the distal parts of the leg. While the abrupt inhibition of blood flow causes the ischemia, its consequences are variable because acute leg ischemia is multifactorial in origin. Hypercoagulable states, cardiac failure, and dehydration predispose the blood for thrombosis and make the tissue more vulnerable to decreased perfusion. Besides the fact that a healthy leg is more vulnerable than one accustomed to low perfusion, it is unknown what determines the viability of the tissue. The most important factor is probably the duration of ischemia. The type of tissue affected also influences viability. In the leg, the skin is more ischemia-tolerant than skeletal muscle.

Embolus and Thrombosis

The etiology of the occlusion is not what determines the management process. It is, however, of importance when choosing therapy. Embolus is usually best treated by embolectomy, whereas arterial thrombosis is preferably resolved by thrombolysis, percutaneous transluminal angioplasty (PTA), or a vascular reconstruction. The reason for this difference is that emboli often obstruct a relatively healthy vascular bed, whereas thrombosis occurs in an already diseased atherosclerotic artery. Consequently, emboli more often cause immediate threatening ischemia and require urgent restoration of blood flow. Thrombosis, on the other hand, occurs in a leg with previous arterial insufficiency with well-developed collaterals. In the latter case it is important not only to solve the acute thrombosis but also to get rid of the cause. It must be kept in mind that emboli can be lodged in atherosclerotic arteries as well, which then

makes embolectomy more difficult.

Table 3 summarizes typical findings in the medical history and physical examination that suggest thrombosis or embolism. Many risk factors, such as cardiac disease, are common for both embolization and thrombosis. Atrial fibrillation and a recent (less than 4 weeks) myocardial infarction with intramural thrombus are the two dominating sources for emboli (80–90%). Other possible origins are aneurysms and atherosclerotic plaques located proximal to the occluded vessel. The latter are often associated with microembolization (discussed later) but may also cause larger emboli.

Table 3. History and clinical findings differentiating the etiology of acute ischemia

Thrombosis	Embolism
Previous claudication	No previous symptoms of arterial insufficiency
No source of emboli	Obvious source of emboli (arterial fibrillation, myocardial infarction)
Long history (days to weeks)	Sudden onset (hours to days)
Less severe ischemia	Severe ischemia
Lack of pulses in the contralateral leg	Normal pulses in the contralateral leg
Positive signs of chronic ischemia	No signs of chronic ischemia

Plaque rupture, immobilization, and hypercoagulability are the main causes of acute thrombosis. Severe cardiac failure, dehydration, and bleeding are less common causes. Hypoperfusion due to such conditions can easily turn an extremity with longstanding slightly compromised perfusion into acute ischemia.

Location of embolic obstruction

Artery	%
Femoral	37–49
Iliac	20–27
Popliteal	12–16
Upper extremity:	15–18
Brachial	60
Axillary	25
Radial	8
Subclavian	7
Tibial	4–6
Aortic saddle	3–6

Clinical Presentation

Medical History

The typical patient with acute leg ischemia is old and has had a recent myocardial infarction. He or she describes a sudden onset of symptoms – a few hours of pain, coldness, loss of sensation, and poor mobility in the foot and calf. Accordingly, all signs of threatened leg viability are displayed. The event is most likely an embolization, and the patient needs urgent surgery. Unfortunately, such patients are unusual among those who are admitted for acute leg ischemia. The history is often variable, and sometimes it is difficult to decide even the time of onset of symptoms. It is important to obtain a detailed medical history to reveal any underlying conditions or lesions that may have caused the ischemia. Moreover, identifying and treating comorbidities may improve the outcome after surgery or thrombolysis.

Clinical Signs and Symptoms

The symptoms and signs of acute ischemia are often summarized as the “five Ps”: pain,

pallor, pulselessness, paresthesia, and paralysis. Besides being helpful for establishing diagnosis, careful evaluation of the five Ps is useful for assessing the severity of ischemia. Sometimes a sixth P's is used – poikilothermia, meaning a low skin temperature that does not vary with the environment.

Pain: For the typical patient, as the one described above, the pain is severe, continuous, and localized in the foot and toes. Its intensity is unrelated to the severity of ischemia. For instance, it is less pronounced when the ischemia is so severe that the nerve fibers transmitting the sensation of pain are damaged. Patients with diabetes often have neuropathy and a decreased sensation of pain.

Pallor: The ischemic leg is pale or white initially, but when ischemia aggravates the color turns to cyanotic blue. This cyanosis is caused by vessel dilatation and desaturation of hemoglobin in the skin and is induced by acidic metabolites in combination with stagnant blood flow. Consequently, cyanosis is a graver sign of ischemia than pallor.

Pulselessness: A palpable pulse in a peripheral artery means that the flow in the vessel is sufficient to give a pulse that is synchronous with vessel dilatation, which can be palpated with the fingers. In general, palpable pulses in the foot therefore exclude severe leg ischemia. When there is a fresh thrombus, pulses can be felt in spite of an occlusion, so this general principle must be applied with caution. Palpation of pulses can be used to identify the level of obstruction and is facilitated by comparing the presence of pulses at the same level in the contralateral leg.

When the examiner is not convinced that palpable pulses are present, distal blood pressures must be measured. It is prudent to always measure the ankle blood pressure. This is a simple way to verify ischemia and the measurement can be used to grade the severity and serve as a baseline for comparison with repeated examinations during the course of treatment. (This will be discussed further later.) The continuous-wave (CW) Doppler instrument does not give information about the magnitude of flow because it registers only flow velocities in the vessel. Therefore, an audible signal with a CW Doppler is not equivalent to a palpable pulse, and a severely ischemic leg can have audible Doppler signals.

Paresthesia: The thin nerve fibers conducting impulses from light touch are very sensitive to ischemia and are damaged soon after perfusion is interrupted. Pain fibers are less ischemia-sensitive. Accordingly, the most precise test of sensibility is to lightly touch the skin with the fingertips, alternating between the affected and the healthy leg. It is a common mistake to believe that the skin has been touched too gently when the patient actually has impaired

sensitivity. The examiner then may proceed to pinching and poking the skin with a needle. Such tests of pain fibers evaluate a much later stage of ischemic damage. The anatomic localization of impaired sensation is sometimes related to which nerves are involved. Frequently, however, it does not follow nerve distribution areas and is circumferential and most severe distally. Numbness and tingling are other symptoms of ischemic disturbance of nerve function.

Paralysis: Loss of motor function in the leg is initially caused by ischemic destruction of motor nerve fibers and at later stages the ischemia directly affects muscle tissue. When palpated, ischemic muscles are tender and have a spongy feeling. Accordingly, the entire leg can become paretic after proximal severe ischemia and misinterpreted as a consequence of stroke. Usually paralysis is more obscure, however, presenting as a decreased strength and mobility in the most distal parts of the leg where the ischemia is most severe. The most sensitive test of motor function is to ask the patient to try to move and spread the toes. This gives information about muscular function in the foot and calf. Bending the knee joint or lifting the whole leg is accomplished by large muscle groups in the thigh that remain intact for a long time after ischemic damage in the calf muscle and foot has become irreversible.

Evaluation of Severity of Ischemia

Classification

When a patient has been diagnosed to have acute leg ischemia, it is extremely important to evaluate its grade. Ischemic severity is the most important factor for selecting a management strategy, and it also affects treatment outcome. Classification according to severity must be done before the patient is moved to the floor or sent to the radiology department. We have found that the simple classification suggested by the Society for Vascular Surgery ad hoc committee (1997) is helpful for grading. It is displayed in Table 4.

Table 4. Categories of acute ischemia

		Sensibility	Motor function	Arterial Doppler signal	Venous Doppler signal
I	Viable	Normal	Normal	Audible (>30 mmHg)	Audible
IIa	Marginally threatened	Decreased or normal in the toes	Normal	Not audible	Audible
IIb	Immediately threatened	Decreased, not only in the toes	Mildly to moderately affected	Not audible	Audible
IV	Irreversibly damaged	Extensive anesthesia	Paralysis and rigor	Not audible	Not audible

Viable Leg

As indicated in Figure 2, a viable ischemic leg is not cyanotic, the toes can be moved voluntarily, and the ankle pressure is measurable. The rationale for choosing these parameters is that cyanosis and impaired motor function are of high prognostic value for outcome. The limit of 30mmHg for the ankle pressure is not important per se but is a practical limit useful to make sure that it is the arterial, and not a venous, pressure that has been measured. The dorsalis pedis, posterior tibial arteries, or branches from the peroneal artery can be insonated. The latter can be found just ventral to the lateral malleolus. If no audible signal is identified in any of these arteries or if there only is a weak signal that disappears immediately when the tourniquet is inflated, the ankle blood pressure should be recorded as zero. It is important to rely on the obtained results and not assume that there is a signal somewhere that is missed due to inexperience. Qualitative analysis of the Doppler signal is seldom useful when evaluating acute leg ischemia.

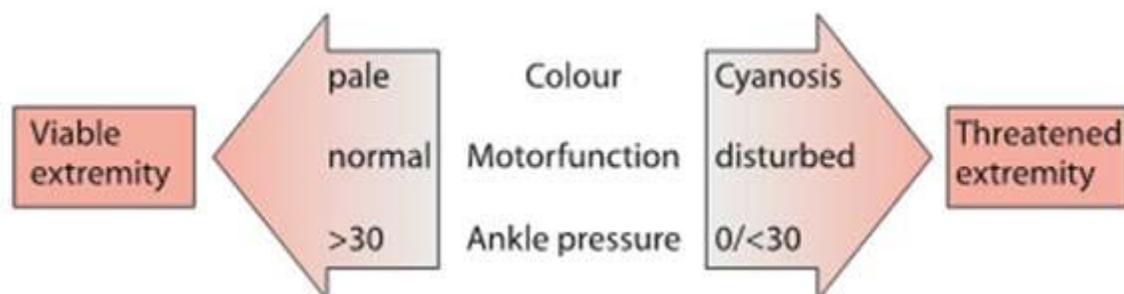

Fig. 2. Simplified algorithm to support the management of acute leg ischemia

Threatened Leg

As shown in Table 4, the threatened leg differs from the viable one in that the sensibility is impaired and there is no measurable ankle blood pressure. The threatened limb is further separated into marginally threatened and immediately threatened by the presence or absence of normal motor function. The threatened leg differs from the irreversibly damaged leg by the quality of the venous Doppler signal. In the irreversibly damaged leg, venous blood flow is stagnant and inaudible.

Management Strategy

A viable leg does not require immediate action and can be observed in the ward. A threatened leg needs urgent operation or thrombolysis. The latter is more time-consuming and recommended for the marginally threatened leg. The immediately threatened leg must be treated as soon as possible, usually with embolectomy or a vascular reconstruction. Irreversible ischemia is quite unusual but implies that the patient's leg cannot be saved. Figure 2 is intended to show a simplified algorithm to further support the management of acute leg ischemia.

Diagnostics

A well-conducted physical examination is enough to confirm the diagnosis of acute leg ischemia, determine the level of obstruction, and evaluate the severity of ischemia. When the leg is immediately threatened, further radiologic examinations or vascular laboratory tests should not under any circumstances delay surgical treatment. When the extremity is viable or marginally threatened, angiography should be performed. Duplex ultrasound is of limited value for evaluating acute leg ischemia and angiography is recommended for almost all patients in these two groups. If angiography is not available or if examination of the patient has verified that emboli is the cause and probably is best treated by embolectomy, angiography can be omitted. This situation is rare, however.

The arteriogram provides an anatomical map of the vascular bed and is very helpful in discriminating embolus and thrombosis. The former is essential for planning the surgical procedure, and the latter may be of importance for selecting the treatment strategy.

An arteriogram representing an embolus is shown in Fig. 3.

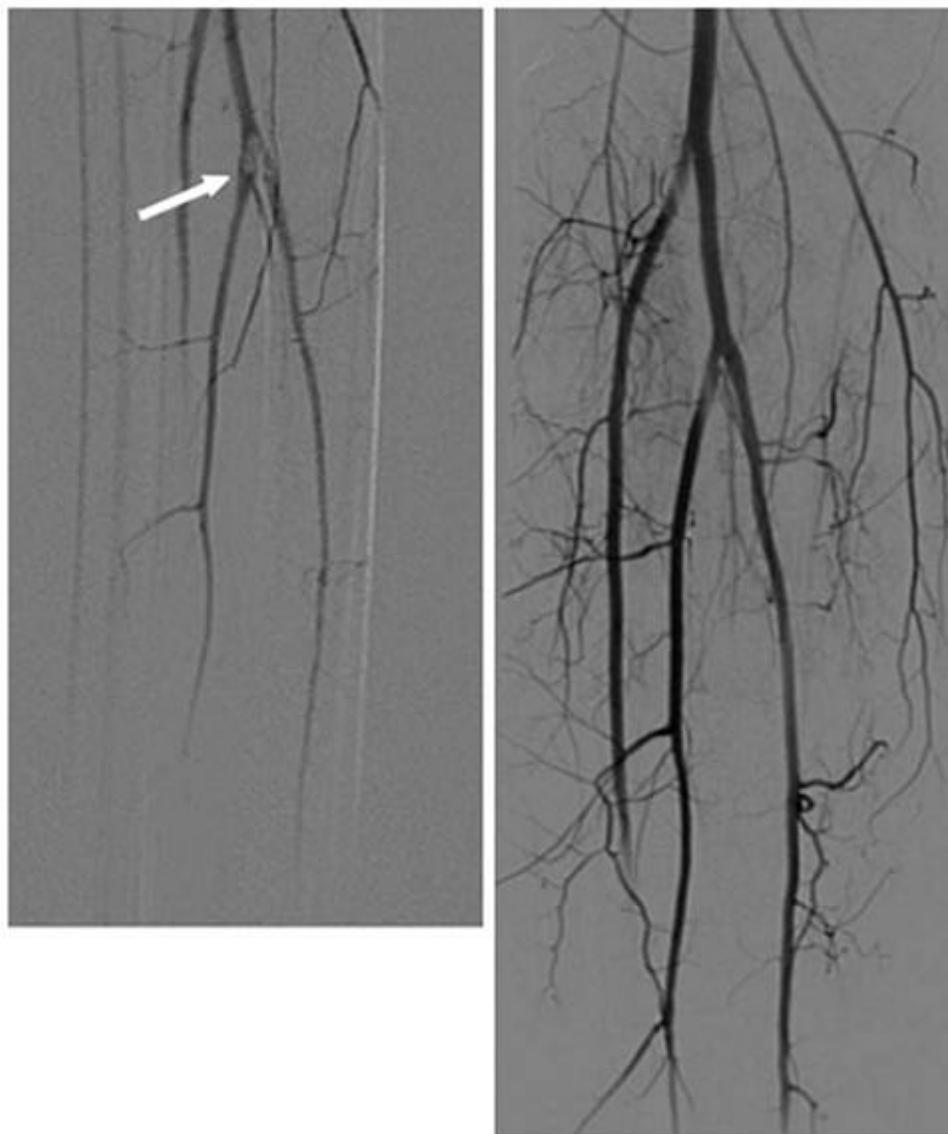

Fig. 3. Embolus lodged at the origins of the calf vessels (arrow).
Angiograms display ilms before and after thrombolysis

Angiographic signs of embolism are an abrupt, convex start of the occlusion and lack of collaterals. Thrombosis is likely when the arteriogram shows well-developed collaterals and

atherosclerotic changes in other vascular segments.

For most patients with viable and marginally threatened legs the diagnostic angiography is followed by therapeutic thrombolysis right away.

Angiography can be performed during daytime when qualified radiology staff is available. The patient should be optimized according to the recommendations given in the next section. Before angiography it is important to keep the patient well hydrated and to stop administration of metformin to reduce the risk of renal failure. Disturbances in coagulation parameters may interfere with arterial puncture and must also be checked before the investigation. The information is also important as baseline values in case of later thrombolysis.

The groin of the contralateral leg is the preferred puncture site for diagnostic angiography. A second antegrade puncture can be done in the ischemic extremity if thrombolysis is feasible.

Management and Treatment

Management Before Treatment

Viable Leg

If the leg is viable the patient is admitted for observation. A checklist of what needs to be done in the emergency department follows below:

1. Place an intravenous (IV) line.

2. Start infusion of fluids. Because dehydration is often a part of the pathogenic process, Ringer's acetate is usually preferred. Dextran is another option that also is beneficial for blood rheology.

3. Draw blood for hemoglobin and hematocrit, prothrombin time, partial thromboplastin time, complete blood count, creatinine, blood urea nitrogen, fibrinogen, and antithrombin. Consider the need to type and cross-match blood.

4. Order an electrocardiogram (ECG).

5. Administer analgesics according to pain intensity. Opiates are usually required (morphine 2.5–10mg IV).

6. Consider heparinization, especially if only Ringer's acetate is given. Heparin treatment should be postponed until after surgery if epidural anesthesia is likely.

Repeated assessments of the patient's clinical status are mandatory in the intensive care unit and when the patient has been moved to the ward. The time interval depends on the severity of ischemia and the medical history. This examination includes evaluating skin color, sensibility, and motor function as well as asking the patient about pain intensity.

Dextran is administered throughout the observation period. The risk for deterioration of heart failure due to dextran treatment is substantial and for patients at risk the volume load must be related to the treatment's expected possible benefits. For such patients it is wise to reduce the normal dose of 500ml in 12h to 250ml. Another option is to prolong the infusion time to 24h.

Heparin only or in combination with dextran is recommended when patients do have an embolic source or a coagulation disorder. There are two ways to administer heparin. The first is the standard method, consisting of a bolus dose of 5,000 units IV followed by infusion of heparin solution (100units/ml) with a drop counter. The dose at the start of infusion should be 500 units of heparin per kilogram of body weight per 24h. The dose is then adjusted according to activated partial thromboplastin time (APTT) values obtained every 4h. The APTT value should be 2–2.5 times the baseline value.

Low molecular weight heparin administered subcutaneously twice daily is the other option. A common dose is 10,000 units/day but it should be adjusted according to the patient's weight.

It is important to optimize cardiac and pulmonary function while monitoring the patient. Hypoxemia, anemia, arrhythmia, and hypotension worsen ischemia and should be abolished if possible. A cardiology consult is often needed.

The above-mentioned treatment regime of rehydration, anticoagulation, and optimization of cardiopulmonary function often improves the ischemic leg substantially. Frequently this is enough to sufficiently restore perfusion in the viable ischemic leg, and no other treatments are

needed. If no improvement occurs, angiography can be performed during the daytime, followed by thrombolysis, PTA, or vascular reconstruction.

Threatened Leg

If the leg is immediately threatened, the patient is prepared for operation right away. This includes the steps listed above for the viable leg, including contact with an anesthesiologist. When there is no cyanosis and motor function is normal – that is, the extremity is only marginally threatened – there is time for immediate angiography followed by thrombolysis or operation. An option is cautious monitoring and angiography as soon as possible.

Before starting the operation, the surgeon needs to consider the risk for having to perform a complete vascular reconstruction. It is probable that a bypass to the popliteal artery or a calf artery will be needed to restore circulation. If thrombosis is the likely cause and the obstruction is distal (a palpable pulse is felt in the groin but not distally), a bypass may also be required even when embolization is suspected.

Operation

Exposure of Different Vessel Segments in the Leg

Femoral Artery in the Groin, Fig. 4 A, B, C.

a A longitudinal skin incision starting 1–2 cm cranial to the inguinal skin fold and continued lateral to the artery is used to avoid the inguinal lymph nodes. A common mistake is to place the incision too far caudally, which usually means the dissection is taking place distal to the deep femoral.

b The dissection is continued sharply with the knife straight down to the fascia lateral to the lymph nodes and is then angulated 90° medially to reach the area over the artery. It should then be palpable. Lymph nodes should be avoided to minimize the risk for infection and development of seroma. The fascia is incised, and the anterior and lateral surfaces of the artery are approached.

c At this stage the anatomy is often unclear regarding the relation of branches to the

common femoral artery. Encircle the exposed artery with a vessel-loop, and gently lift the artery. Continue dissection until the bifurcation into superficial and deep femoral artery is identified. Its location varies from high up under the inguinal ligament up to 10 cm further down. At this stage, the surgeon must decide whether exposure and clamping of the common femoral are enough. This is usually the case for proximal control in trauma distally in the leg. In acute ischemia it is more common that the entire bifurcation needs to be exposed.

During the continued dissection, attention must be given to important branches that should be controlled and protected from iatrogenic injuries. These are, in particular, the circumflex iliac artery on the dorsal aspect of the common femoral artery and the deep femoral vein crossing over the anterior aspect of the deep femoral artery just after its bifurcation. To provide a safe and good exposure of the deep femoral to a level below its first bifurcation, this vein must be divided and suture-ligated. Partial division of the inguinal ligament is occasionally needed for satisfactory exposure.

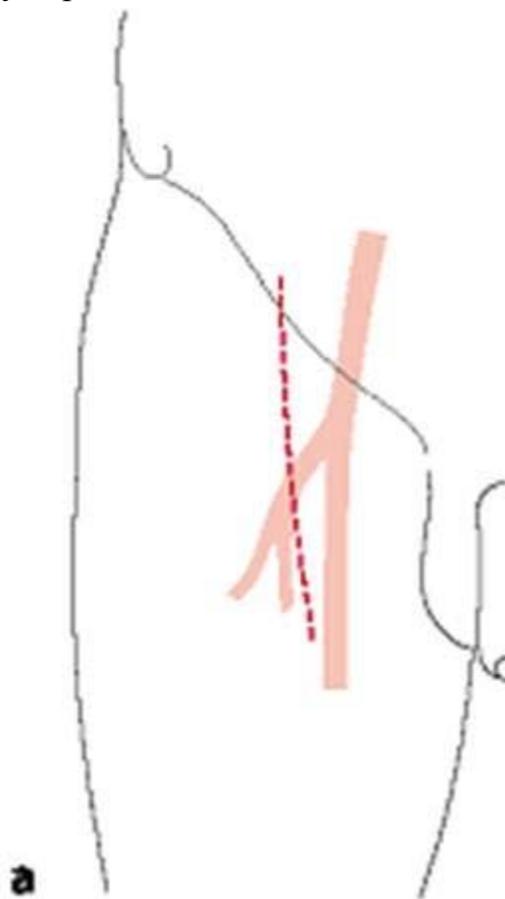

Fig. 4 A. Exposure of femoral artery in the groin

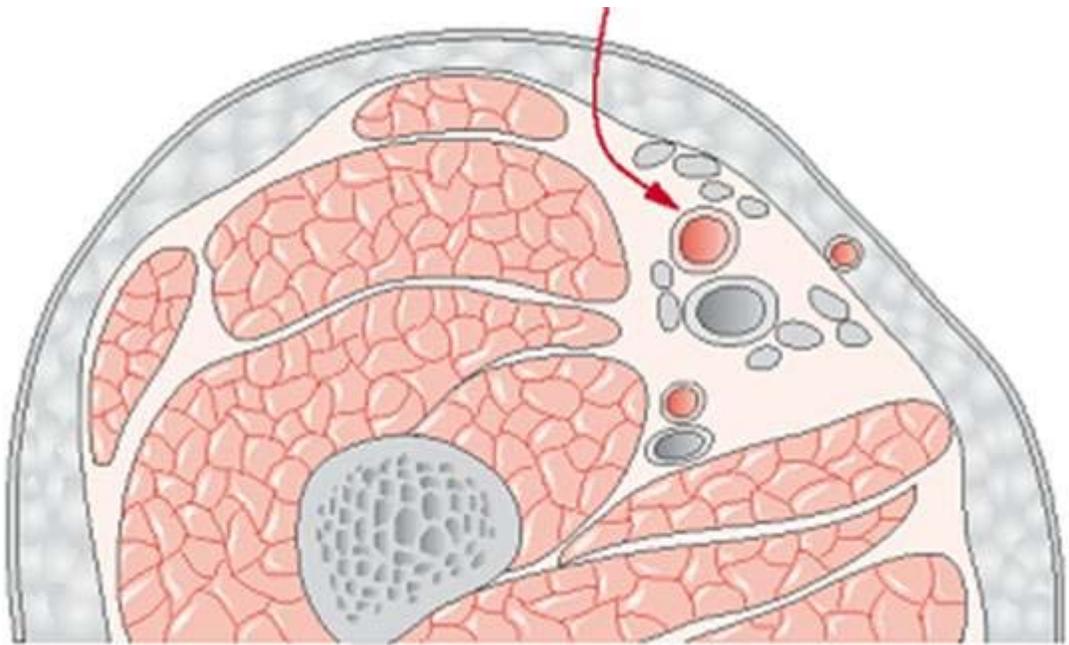

Fig. 4 B. Exposure of femoral artery in the groin

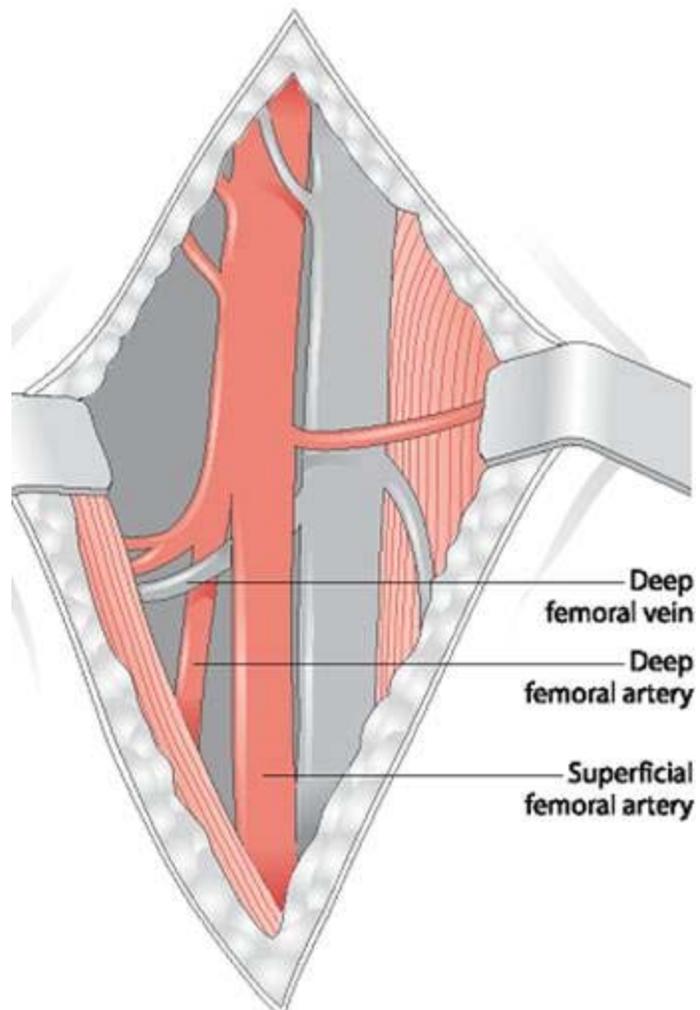

Fig. 4 C. Exposure of femoral artery in the groin

Superficial Femoral Artery, Fig. 5

A skin incision is made along the dorsal aspect of the sartorius muscle at a midhigh level. It is important to avoid injuries to the greater saphenous vein, which usually is located in the posterior flap of the incision. The incision can be elongated as needed. After the deep fascia is opened and the sartorius muscle is retracted anteriorly, the femoral artery is found and can be mobilized. Division of the adductor tendon is sometimes required for exposure.

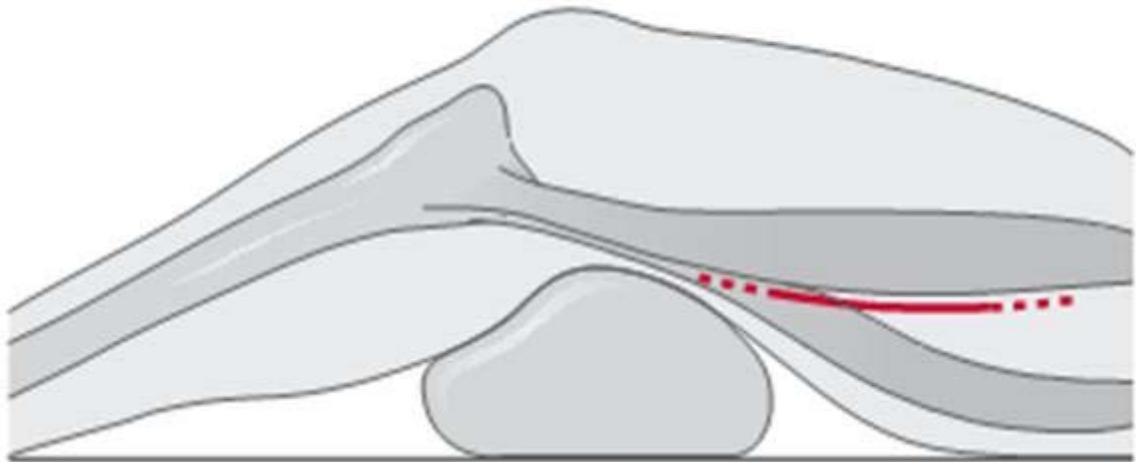

Fig. 5. Incision for exposure of the superficial femoral artery

Popliteal Artery Above the Knee, Fig. 6 A, B.

a The knee is supported on a sterile, draped pillow. The skin incision is started at the medial aspect of the femoral condyle and follows the anterior border of the sartorius muscle 10–15 cm in a proximal direction. Protect the greater saphenous vein and the saphenous nerve during dissection down to the fascia. After dividing the fascia longitudinally, continue the dissection in the groove between the sartorius and gracilis muscles, which leads to the fat in the popliteal fossa.

b The popliteal artery and adjacent veins and nerve are then, without further division of

muscles, easily found and separated in the anterior aspect of the fossa.

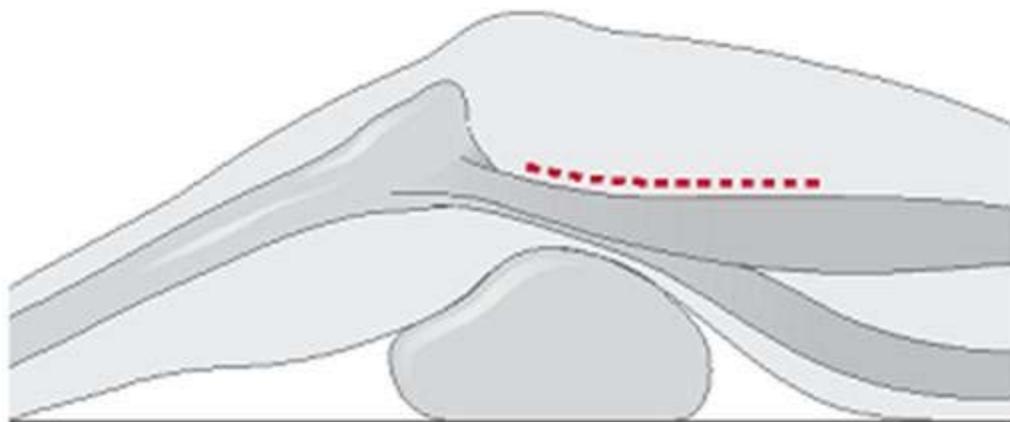

Fig. 6 A. Exposure of popliteal artery above the knee

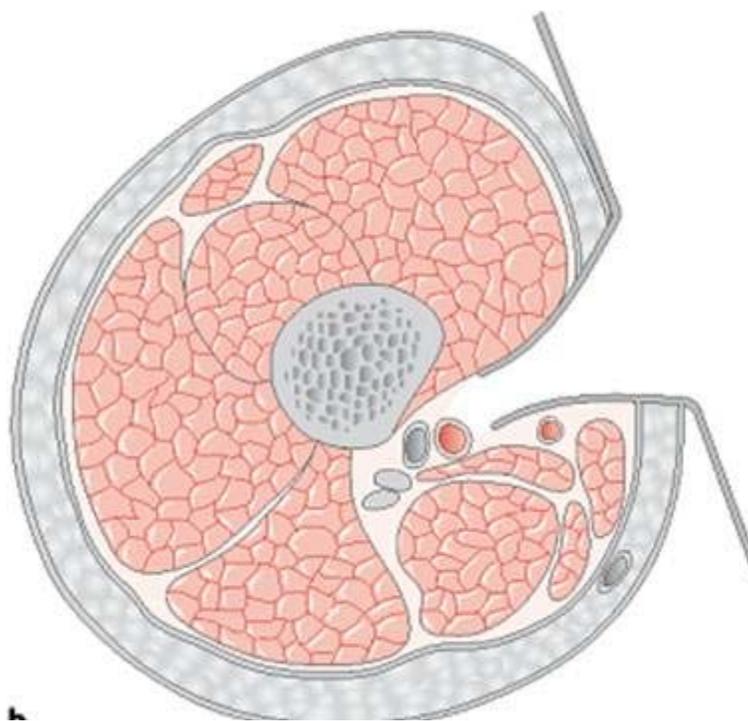

Fig. 6 B. Exposure of popliteal artery above the knee

Popliteal Artery Below the Knee, Fig. 7 A,B.

a A sterile pillow or pad is placed under the distal femur. The incision is placed 1 or 2 cm posterior to the medial border of the tibia, starting at the tibial tuberosity and extending 10–12 cm distally. Subcutaneous fat and fascia are sharply divided, with caution to the greater saphenous vein.

b The popliteal fossa is reached by retracting the gastrocnemius muscle dorsally. The deep fascia is divided and the artery usually easier to identify. Occasionally, pes anserinus must be divided for adequate exposure. The popliteal artery is often located just anterior to the nerve and in close contact with the popliteal vein and crossing branches from concomitant veins. If it is necessary to expose the more distal parts of the popliteal artery, the soleus muscle has to be divided and partly separated from the posterior border of the tibia.

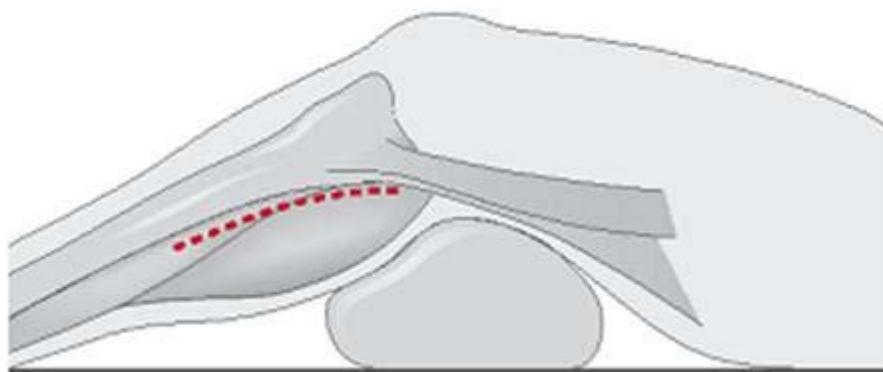

Fig. 7 A. Exposure of popliteal artery below the knee

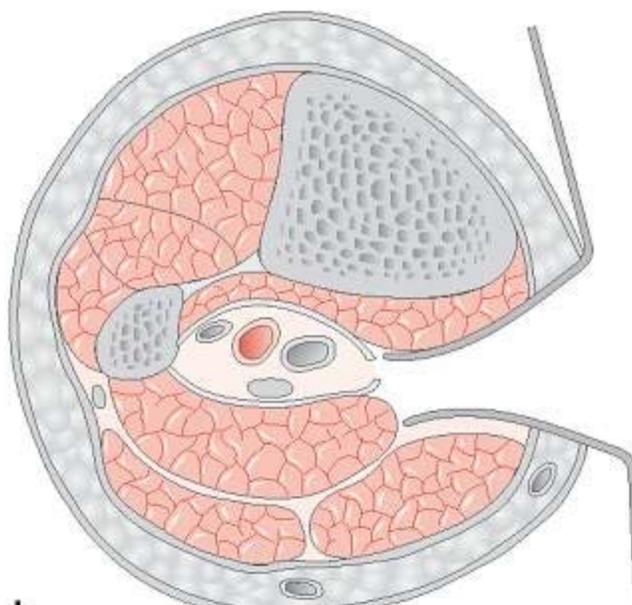

Fig. 7 B. Exposure of popliteal artery below the knee

Embolectomy

It is beyond the scope of this book to cover the technique for vascular reconstructions. But because embolectomy from the groin with balloon catheters (known as Fogarty catheters) is one of the most common emergency vascular operations in a general surgical clinic and may be performed by surgeons not so familiar with vascular surgery.

TECHNICAL TIPS

Embolectomy

Use an operating table that allows x-ray penetration. Local anesthesia is used if embolus is likely and the obstruction seems to be in the upper thigh or in pelvic vessels (no pulse in the groin). Make a longitudinal incision in the skin, and identify and expose the common, superficial, and deep femoral arteries. If the common femoral artery is soft-walled and free from arteriosclerosis – especially if a pounding pulse is felt proximal to the origin of the deep femoral artery – an embolus located in its bifurcation is likely. Make a short transverse arteriotomy including almost half the circumference. Place the arteriotomy only a few mm proximal to the origin of the profunda artery so it can be inspected and cannulated with ease. In most other cases, a longitudinal arteriotomy is preferable because it allows elongation and can be used as the site for the inflow anastomosis of a bypass. For proximal embolectomy, a #5 catheter is used.

Before the catheter is used the balloon should be checked by insufflation of a suitable volume of saline. Check the position of the lever of the syringe when the balloon is starting to fill, which gives a good idea of what is happening inside the artery. Wet the connection piece for the syringe to get a tight connection. It is smart to get external markers of the relationship between the catheter length and important anatomical structures; for example, the aortic bifurcation (located at the umbilicus level), the trifurcation level (located approximately 10 cm

below the knee joint), as well as the ankle level. The catheters have centimeter grading, which simplifies the orientation.

It is common for the embolus to already be protruding when the arteriotomy is done and a single pull with the catheter starting with the tip in the iliac artery is enough to ensure adequate inflow. This means that a strong pulse can be found above the arteriotomy, and a pulsatile heavy blood flow comes through the hole. For distal clot extraction, a #3 or #4 catheter is recommended. A slight bending of the catheter tip between the thumb and index finger might, in combination with rotation of the catheter, make it easier to pass down the different arterial branches (Fig. 8).

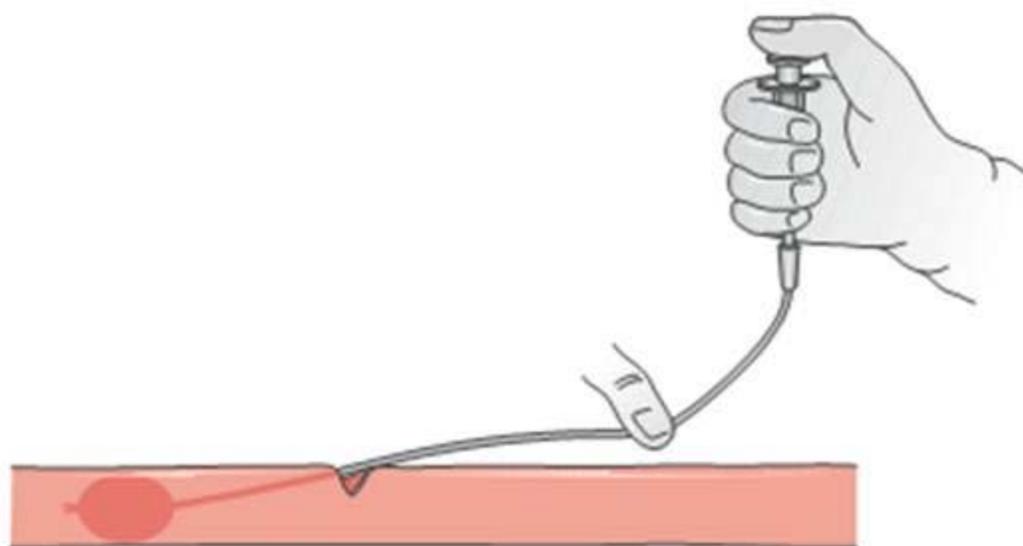

Fig. 8. Use of Fogarty catheter for embolectomy. Note that withdrawal is parallel to the artery

When the catheter is inserted into the artery and while the surgeon is working with it, hemostasis of the arteriotomy is achieved by a vessel-loop or by a thumb–index finger grip over the artery and the catheter. In a typical case, an embolus, including a possible secondary thrombus, can be passed relatively easily or with only slight resistance. If a major part of the catheter can be inserted the tip will be located in one of the calf arteries, most probably the posterior tibial artery or the peroneal artery. The balloon is insufflated simultaneously as the catheter is slowly withdrawn, which makes it easier to get a feeling for the dynamics and to not apply too much pressure against the vascular wall.

A feeling of “touch” is preferable, but a feeling of “pull” against the vascular wall

should be avoided.

To get the right feeling the same person needs to hold the catheter, pull it, and insufflate the balloon at the same time. To avoid damage in the arteriotomy, the direction of withdrawal should be parallel with the artery .

When the catheter is withdrawn it moves into larger segments of the artery and has to be successively insufflated until it reaches the arteriotomy. The reverse is, of course, valid when the embolectomy is done in a proximal direction. The thromboembolic masses can be suctioned or pulled out with forceps, and the arteriotomy should be inspected to be clean from remaining materials before the catheter is reinserted. The maneuver should be repeated until the catheter has been passed at least once without any exchange of thromboembolic materials and until there is an acceptable backflow from the distal vascular bed.

Depending on the degree of ischemia and collaterals, the backflow is, however, not always brisk.

If a catheter runs into early and hard resistance, this might be due to previously occluded segment that forced the catheter into a branch. It should then be withdrawn and reinserted, using great caution to avoid perforation. If the resistance cannot be passed and if acute ischemia is present, angiography should always be considered to examine the possibility of a vascular reconstruction.

Besides performing embolectomy in the superficial femoral, popliteal, and calf arteries, the deep femoral artery must be checked for an obstructing embolus or clot that needs to be extracted. Separate declamping of the superficial femoral and deep femoral arteries to check the backflow is the best way to do this. Remember the possibility that backflow from the distal vascular bed after embolectomy might emanate from collaterals located proximal to distally located clots. Back flow does not always assure that the peripheral vascular bed is free from further embolic masses. A basic rule is that every operation should be completed with intraoperative angiography to ensure good outflow and to rule out remaining emboli and secondary thrombus. To dissolve small amounts of remaining thrombus local infusion of 2–4 cc recombinant tissue plasminogen activator (rtPA) can be administered before the angiography catheter is pulled out.

Finally, the arteriotomy is closed. If necessary a patch of vein or synthetic material is used to avoid narrowing of the lumen. As mentioned before, the embolectomy procedure includes intraoperative angiography. If this examination indicates significant amounts of

emboli remaining in the embolectomized arteries or if the foot still appears as being inadequately perfused after the arteriotomy is closed, other measures need to be taken. If there are remaining emboli in the superficial femoral or popliteal arteries, another embolectomy attempt from the arteriotomy in the groin can be made. Clots, if seen in all the calf arteries, need to be removed through a second arteriotomy in the popliteal artery. This is done by a medial incision below the knee; note that local anesthesia is not sufficient for this. It is usually necessary to restore flow in two, or occasionally in only one, of the calf arteries.

Embolectomy at the popliteal level is the first treatment step when ischemia is limited to the distal calf and foot and when there is a palpable pulse in the groin or in the popliteal fossa.

Thrombosis

The preliminary diagnosis of embolus must be reconsidered if the exposed femoral artery in the groin is hard and calcified. In most situations, clot removal with Fogarty catheters will then fail. It is usually difficult or even impossible to pass the catheter distally, indicating the presence of stenoses or occlusions. Even if the embolectomy appears successful, early reocclusion is common. Such secondary thrombosis is usually more extensive and will aggravate the ischemia. Accordingly, angiography should be considered as the first step if the femoral artery is grossly arteriosclerotic and if it is hard to pass the catheter down to the calf level. It will confirm the etiology and reveal whether a bypass is required and feasible. Vascular reconstruction in acute leg ischemia is often rather difficult and experience in vascular surgery is required.

Intraoperative angiography

With the proximal clamp in position a 5 or 8 French baby-feeding catheter is inserted into the arteriotomy. The tip of the catheter is placed 5 cm into the superficial femoral artery and distal control around it is achieved with a vessel-loop. Contrast for intravascular use containing 140–300 mg iodine/ml is infused with a 20 cc syringe connected to a three-way valve. Heparinized Ringer's or saline (10 units/ml heparin) is flushed through the catheter before and after contrast injection to prevent thrombosis in the occluded vascular bed. If the patient is suspected to have renal failure, the amount of contrast used is kept at a minimum. Angled projections can be obtained without moving the C-arm by rotating the patient's foot.

The use of contrast in the Fogarty catheter balloon during fluoroscopy allows the calf vessel into which the catheter slides to be identified. The technique for intraoperative angiography is also a prerequisite for interoperative use of endovascular treatment options such as angioplasty (Fig. 9).

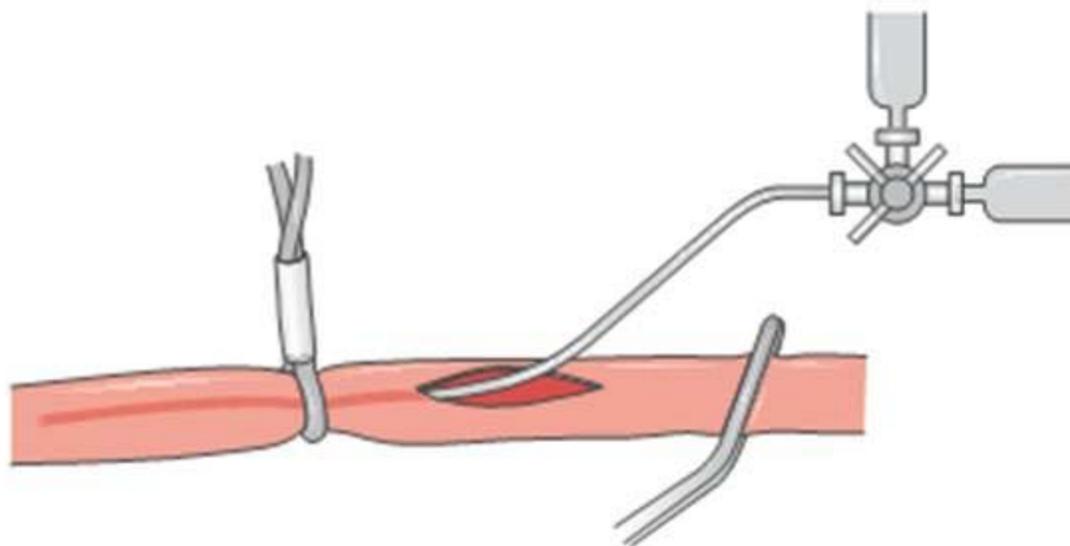

Fig. 9. Intraoperative angiography

Thrombolysis

Thrombolysis is performed in the angiosuite. A consultation with a specialist in coagulation disorders or a specialist in vascular medicine is sometimes needed to discuss possible problems related to coagulation before the procedure.

Treatment is usually directed toward resolving a fresh, thrombotic occlusion, but emboli and thrombi several weeks old can also be successfully lysed. The procedure starts with a diagnostic angiography via contralateral or antegrade ipsilateral arterial punctures. If thrombolytic treatment is decided the procedure continues right away, and the tip of a pulse-spray catheter is placed in the thrombus. The lytic agent is then forcefully injected directly into it to cause fragmentation. The primary choices for lytic agent are recombinant tissue plasminogen activator (rtPA) or urokinase. Because of the risk of allergic reactions, streptokinase should be avoided. Intermittent injections of 1 ml every 5–10 min to a total dose of 10–20 ml rtPA over 1–3 h is followed by angiographic control of the result. If the thrombus is completely lysed any underlying lesion is treated. If thrombus still remains, the rtPA infusion

is continued slowly over 6–12h with 1mg/h. If the initial thrombolysis fails, a variety of mechanical catheters can be used to try to further dissolve and aspirate the thrombus. Examples include the AngioJet and the Amplatz.

Because of the risk of bleeding and systemic complications, and also because the ischemic leg may deteriorate, careful monitoring during continued thrombolysis is necessary. This is best done in an intensive care or step-down unit. The patient should be kept supine in bed throughout the procedure. During this time the other measures suggested for optimizing coagulation and central circulation are continued. It is also necessary to check fibrinogen concentration to make sure the value does not decline to <1.0 mg/ml. Below this level surgical hemostasis is insufficient and the infusion should be stopped. Angiographic control of the result is performed afterwards, usually the following morning, and occasionally during the slow infusion to check the effect and allow repositioning of the catheter. The part of the thrombus surrounding the catheter is lysed first, which is why it often is beneficial to advance the catheter further into the thrombus after a few hours.

Finally, the lesion that caused the thrombosis is treated with angioplasty. To avoid unnecessary bleeding from the puncture site, the fibrinogen concentration is checked again before the sheath is withdrawn to ensure that the level exceeds 1.0 mg/ml.

Management After Treatment

Anticoagulation

Patients with embolic disease caused by cardiac arrhythmia or from other cardiac sources proven by ECG, medical history, or clinical signs should be anticoagulated postoperatively. Treatment regimens described previously are employed, followed by treatment with coumadin. Anticoagulation has no proven positive effect for the prognosis of the ischemic leg but is administered to reduce the risk of new emboli. The patient's abilities to comply with treatment and the risk for bleeding complications have to be weighed against the benefits. If the source of the emboli is not clear, it should be investigated. Findings of atrial fibrillation and heart thrombus can then be treated. If the ECG is normal, echocardiography is ordered to search for thrombus and valve deficiencies. If the left atrium is a likely embolic source, transesophageal echocardiography may be indicated.

When the etiology of leg ischemia is uncertain it is difficult to give general advice. There is no scientific evidence that long-term postoperative anticoagulation reduces the risk of

reocclusion or influences patient survival. Continued treatment with dextran or low molecular weight heparin is recommended at least during hospitalization.

If hypercoagulable states are suspected the patient needs to be worked up during the postoperative period to reduce the risk of reocclusion. Examples are patients with hyperhomocysteinemia, who may be treated with folates, and patients with antiphospholipid antibodies, who need coumadin and salicylic acid.

Reperfusion Syndrome

Patients treated for severe acute leg ischemia are at risk of developing reperfusion syndrome. This occurs when ischemic muscles are reperfused and metabolites from damaged and disintegrated muscle cells are spread systemically. A part of this process consists of leakage of myoglobin; it may be nephrotoxic and colors the urine red. The metabolites also affect central circulation and may cause arrhythmia and heart failure. The risk for reperfusion syndrome is higher when occlusions are proximal and the affected muscle mass is large. One example is saddle emboli located in the iliac bifurcation. The risk is also higher when the ischemia time is longer than 4–6 h.

The elevated mortality associated with severe acute leg ischemia may be due to reperfusion syndrome. Survival may therefore be improved by avoiding reperfusion and a lower mortality has been reported from hospitals where primary amputation is favored. It has also been suggested that thrombolysis saves lives by restoring perfusion gradually. For a threatened leg this is seldom an option because rapid restoration of perfusion is necessary to save it.

The best treatment for reperfusion syndrome is prevention by expeditious restoration of flow.

There are no clinically proven effective drugs but many have been successful in animal models, including heparin, mannitol, and prostaglandins.

Because heparin and mannitol also have other potential benefits and few side effects they are recommended during the postoperative period. Obviously, acidosis and hyperkalemia must be corrected, and the patient needs to be well hydrated and have good urine output. For patients with suspected reperfusion syn-

drome – urine acidosis and high serum myoglobin levels – alkalinization of the urine is often recommended in order to avoid renal failure despite weak support in the literature. If the urine is red, the urine pH <7.0, and serum myoglobin >10,000 mg/ml, 100 ml sodium bicarbonate is given IV. The dose is repeated until the pH is normalized.

Compartment Syndrome

The acute inflammation in the muscle after reestablishing perfusion leads to swelling and a risk for compartment syndrome. The available space for the muscles is limited in the leg and when the increased pressure in the compartments reduces capillary perfusion below the level necessary for tissue viability, nerve injury and muscle necrosis occur.

The essential clinical feature of compartment syndrome is pain – often very strong and “out of proportion,” which is accentuated by passive extension. The muscle is hard and tender when palpated. Unfortunately, nerves within the compartments are also affected, causing disturbance of sensibility and motor function. This makes diagnosis more difficult. Moreover, the patient is often not fully awake or disoriented, but early diagnosis is still important to save the muscle tissue. For that reason measurement of intracompartmental pressure is performed for diagnosis in some hospitals.

There are no precise limits that advocate fasciotomy, but 30mmHg has been proposed. The specificity for a correct diagnosis using this limit is high, but the sensitivity is much lower.

To notice signs of compartment syndrome after operation or thrombolysis for acute ischemia, frequent physical examinations are vital. Fasciotomy should be performed immediately following the procedure if any suspicion of compartment syndrome exists. Common advice is to always perform fasciotomy right after the vascular procedure when the ischemia is severe and has lasted over 4–6 h. To open all four compartments, we recommend using two long incisions, one placed laterally and one medially in the calf.

Results and Outcome

The outlook for patients with acute leg ischemia has generally been poor. The 30-day mortality when an embolus is the etiology varies between 10% and 40%. Survival is better when arterial thrombosis is the cause, around 90%. When considering the amputation rate after surgical treatment the figures are reversed – lower for embolic disease, at 10–30%, than for thrombosis, which of ten has an early amputation rate of around 40%.

A substantial number of the patients die or require amputation after 30 days. This is due to a combined effect of the patients’ advanced age and comorbidities. In studies not differentiating between etiologies, only 30–40% of the patients were alive 5 years after surgery,

and among those, 40–50% had had amputations.

Because the gradual release of ischemia is thought to reduce the risk for reperfusion syndrome and thereby the negative effects on the heart and kidneys mortality after thrombolysis is thought to be lower. It is difficult, however, to find data on thrombolytic therapy comparable to surgical results. A majority of patients will undergo surgery when thrombolysis is not technically possible, leaving a selected group to follow up. In the few randomized controlled trials that compare surgery and thrombolysis the short-term and long-term amputation rates are alike. Survival is also similar, but in one study it was lower after thrombolytic therapy at 1 year, 80%, compared with surgically treated patients, of whom only 60% were alive at that time.

Conditions Associated with Acute Leg Ischemia

Chronic Ischemia of the Lower Extremity

It is sometimes difficult to differentiate between acute leg ischemia, deterioration of chronic leg ischemia, and just severe end-stage chronic disease in general. Periods of pain escalation bring patients with chronic ischemia to the emergency department. Accentuated pain in these patients has a wide range of origins. Decreased foot perfusion can be due to dehydration or lowered systemic pressure as a consequence of heart failure or a change in medication. Ulcers are frequently painful, especially when complicated by infection or when dressings are changed. History and examination of vital functions and the leg usually disclose such conditions and can also sufficiently rule out acute leg ischemia that needs urgent treatment.

Patients with chronic ischemia benefit from careful planning of their treatment and should not – with few exceptions – be expeditiously treated. Elective therapy includes weighing risk factors against the outcome of the proposed treatment and all the work-up that is needed to get this information. (It is beyond this book's purpose to describe the management of chronic ischemia.) In the emergency department it is sensible to identify and directly treat the patients with true acute leg ischemia and schedule treatment of patients with chronic disease for later. Examples of findings in medical history and physical examination are listed in Table 5.

Table 5. Medical history and physical examination

findings suggesting chronic leg ischemia

History	Examination
Coronary artery disease and stroke	Lack of palpable pulses in both legs
Smoking	Ankle pressure 15–50 mmHg
Claudication, rest pain, and ischemic ulcers	Ulcers
Previous vascular surgery or amputation	Hyperemic foot skin while dependent
Lack of sudden onset of pain	

Acute Ischemia After Previous Vascular Reconstruction

A substantial number of patients have chronic leg ischemia and have undergone vascular reconstructions, so there is a high likelihood that emergency department physicians will have to take care of problems with postoperative acute leg ischemia in the operated leg. The clinical presentation of graft failure or occlusion is variable. An abrupt change in leg function and skin temperature accompanied by the onset of pain can occur any time after surgery, but especially within the first 6 months. Several years after the reconstruction it is slightly more common for progressive deterioration to occur and an eventual graft occlusion to pass unnoticed.

As discussed previously in this chapter the management principles are roughly the same as for primary acute leg ischemia. It is the status of the leg and the severity of ischemia that lead workup and management. Most patients will undergo angiography to establish diagnosis and to provide information about possibilities to restore blood flow. Thrombolysis is often the best treatment option because it exposes the underlying lesions that may have caused the occlusion. As for patients with acute ischemia, those with an immediately threatened leg after a reconstruction should be taken to the operating room and treated as fast as possible.

Blue Toe Syndrome

A toe that suddenly becomes cool, painful, and cyanotic, while pulses can be palpated in the foot, characterizes the classic presentation of blue toe syndrome. This has occasionally led to the assumption that the discoloration of the toe is not of vascular origin, and patients have been sent home without proper vascular assessment. Although coagulation disorders or vasculitis may contribute, such an assumption is dangerous. Atheroembolism is the main cause for blue toe syndrome and atheromatous plaques in the iliac or femoral arteries or thrombi in abdominal or popliteal aneurysms are the main sources. Blue toe syndrome can also present without palpable foot pulses. The presentation may then be less dramatic.

It is common that the patient does not notice the initial insult and wait to seek medical care until after several weeks. Ischemic ulceration at the tip of the toe may then be found in the examination. During the foot examination more signs of microembolization are usually found, including blue spots or patchy discoloration of the sole and heel. When both feet are affected it suggests an embolic source above the aortic bifurcation. The clinical examination should include assessing the aorta and all peripheral arteries, including pulses and auscultation for bruits. When pulses in the foot are not palpable, ankle blood pressure needs to be measured. In the search for aneurysms and stenoses patients need to be investigated with duplex ultrasound to verify examination findings. To prevent future embolization episodes lesions or aneurysms found should be treated as soon as possible.

Occasionally the pain is transient and the blue color will disappear within a few weeks. More common, however, is an extremely intense pain in the toe that is continuous and difficult to treat. Unfortunately, the pain often lasts several months until the toe is either amputated or healed.

The pain is best treated with oral opiates, and quite high doses are often required to ease the pain. A tricyclic antidepressant drug may be added to the regimen if analgesics are not enough.

While waiting for diagnostic studies and final treatment of the lesions, the patient is put on aspirin therapy. There is no scientific evidence for using other medications such as coumadin, steroids, or dipyridole. Still, if suspicion for a popliteal aneurysm is high we recommend anticoagulation with low molecular weight heparin until the aneurysm is corrected.

Popliteal Aneurysms

A common reason for acute leg ischemia is thrombosis of a popliteal aneurysm. Such

aneurysms are also one of the main sources for embolization to the digits in the foot and blue toe syndrome. Besides the clinical signs of acute ischemia discussed previously, a prominent wide popliteal pulse or a mass in the popliteal fossa is often palpated when popliteal aneurysm is the reason for the obstruction.

Popliteal aneurysms are frequent in men but rare in women. They are often bilateral – more than 50% – and associated with the presence of other aneurysms. For instance, 40% of patients with popliteal aneurysms also have an aneurysm in the abdominal aorta. Most popliteal aneurysms are identified during angiography performed as part of the management process for acute leg ischemia. When an aneurysm is suspected during angiography or examination, duplex ultrasound is performed to verify the finding and estimate the aneurysm's diameter.

If the severity of ischemia corresponds to the “immediately threatened” stage described earlier, the patient needs urgent surgery. The revascularization procedure is then often quite difficult. Exposure of the popliteal artery below the knee, including the origins of the calf arteries, should be followed by intraoperative angiography and an attempt to remove the thrombus. It is hoped that angiography can identify a spared calf artery distally. The calf arteries are sometimes slightly dilated in this patient group and can serve as a good distal landing site for a bypass excluding the aneurysm. Often, however, it is impossible to open up the distal vascular bed due to old embolic occlusions and the prognosis for the leg is poor. In such situations every possible alternative solution should be considered, including local thrombolysis, systemic prostaglandin infusion, and profundaplasty.

If the ischemia is less severe, thrombolysis may be considered following the angiography before surgical exclusion of the aneurysm. While thrombolysis previously has been considered questionable because of the risk for further fragmentation of thrombus within the popliteal aneurysm, this strategy may prove very favorable. Over the last few years several studies reporting restored calf vessels by thrombolysis have been published. This may lead to more successful bypasses and improved limb salvage. Once the bypass is accomplished good long-term results are probable. Interestingly, vein grafts used for bypasses in patients with popliteal aneurysms appear to be wider and stay patent longer than for other patient groups.

ACUTE INTESTINAL ISCHEMIA

Mesenteric artery thrombosis has the highest mortality rate of all causes of mesenteric ischemia. First described in the late 15th century, little progress was made in its treatment before the 20th century.

In 1901, a patient with a long history of postprandial pain was found to have an atherosclerotic plaque with overlying thrombus of the superior mesenteric artery (SMA). The physician concluded that if a patient could develop pain of the lower extremities secondary to atherosclerosis, it would stand to reason that a patient could present with postprandial pain due to narrowing of the mesenteric vessels. An example of complete occlusion is illustrated in the image below. The pathophysiologic mechanism by which ischemia produces pain remains poorly understood.

The arterial circulation to the gut has extensive collaterals and arcades providing multiple sources of blood inflow. This explains why vascular occlusion is well tolerated as evidenced by the relative lack of clinical intestinal ischemia despite the high prevalence of atherosclerotic disease of the aorta and visceral arteries. Certain collateral patterns are recognized, depending on which artery is blocked. When either the celiac or superior mesenteric artery (SMA) is compromised, the main collateral circulation is by the gastroduodenal and pancreaticoduodenal arteries. The main collateral channels between the SMA and inferior mesenteric artery (IMA) occur in the region of the splenic flexure between the middle and left colic arteries. In the presence of either SMA or IMA occlusion, the marginal artery of Drummond and the arch of Riolan (an ascending branch of the left colic artery anastomosing with branches of the SMA) enlarge significantly. In the presence of an IMA occlusion, another important collateral circulation is between the internal iliac artery and the left colic artery via the superior hemorrhoidal arteries.

The SMA is the critically important vessel in maintaining visceral perfusion, as demonstrated by increased blood flow after eating. This is not seen in the celiac artery. In chronic ischemia, all patients have SMA stenosis or occlusion, in addition to celiac artery and/or IMA involvement.

Etiology

OCCLUSIVE DISEASE

Emboli. The SMA is the most common site of embolic occlusion although the celiac artery can be affected. There is classically an underlying cardiac problem giving rise to the organized thrombus that embolizes. This is usually atrial fibrillation or less commonly a mural thrombus from an acute myocardial infarction. A history of previous embolic events is not uncommon. Other causes of emboli include iatrogenic intra-aortic manipulations, paradoxical emboli through a septal defect, atrial myxoma or primary aortic tumors.

The history is of constant severe epigastric or periumbilical pain of sudden onset. It is frequently followed by copious vomiting and explosive diarrhea.

Typically the patient has been previously well and asymptomatic. The abdominal signs are often lacking or nonspecific, with distension in association with absent or normal bowel sounds without any signs of peritonism. This combination of severe abdominal pain out of proportion to the clinical findings is typical. Peritonism or blood in the stool or vomitus indicates severe advanced intestinal ischemia with likely infarction and is generally a late clinical feature.

The presence of proximal SMA pulsation and the distribution of intestinal ischemia are intra-operative clues for an embolus. The occlusion in embolism is usually distal to the origin of the pancreaticoduodenal and middle colic branches, which allows some blood flow to the small intestine to be maintained. The stomach, duodenum, and proximal jejunum are normal with ischemia extending to the mid transverse colon.

Thrombosis.

Thrombosis of the superior mesenteric or celiac arteries is most often associated with a preexisting atherosclerotic lesion that already compromises flow. The most common preexisting pathology found in patients with acute mesenteric thrombosis is atherosclerosis.

Many patients present with histories consistent with chronic mesenteric ischemia. Wasting, postprandial pain, and phagophobia (fear of eating) are all common.

Typically, the atherosclerotic lesion gradually compromises flow to the gut, causing a progressive worsening of symptoms. During a period of low flow, the artery thromboses, and flow to the gut is compromised.

Unlike embolic events that occur in arterial branches and result in limited bowel

ischemia, thrombosis occurs at the vessel origin, resulting in extensive bowel involvement.

Superior mesenteric arterial thrombosis may occur as the result of progression of SMA stenosis that had not previously been diagnosed or treated. There is often a history of intestinal or food fear with severe weight loss, the hallmark of chronic intestinal ischemia in about 65% of patients. The typical patient is female and a heavy smoker, often with evidence of widespread arterial disease including previous myocardial infarction or claudication. As with embolic occlusion, the combination of severe abdominal pain out of proportion to the clinical findings is typical. The thrombosis of the SMA occurs at the origin of the artery.

In contrast to embolic disease, the proximal SMA pulse is absent and the distribution of intestinal ischemia is more extensive. Only the stomach, duodenum and distal colon are spared.

In the young patients, fibromuscular dysplasia can cause mesenteric arterial thrombosis with equally devastating results. Intravenous cocaine abuse is another increasing problem accounting for intestinal ischemia in the young patients. The extent of intestinal ischemia and infarction tends to be focal and less than that seen with atherosclerotic thrombosis. The mechanism of ischemia appears to be occlusive rather than due to vasospasm. Mesenteric ischemia should be considered in the differential diagnosis when evaluating a young patient with a history of cocaine abuse presenting with an acute abdomen.

Some prothrombotic states such as hyperhomocysteinemia or the 20210 A prothrombin gene mutation have resulted in primary arterial thrombosis.

Mesenteric venous thrombosis (MVT) is rare and accounts for 5% to 15% of all acute mesenteric ischemia. It is classified as primary (where no cause is recognized) or secondary. Secondary MVT may follow hypercoagulable states, portal venous stasis and hypertension, intra-abdominal infection and inflammation or malignancy, use of oral contraceptives and splenectomy. Long-term anticoagulation is required for MVT, because of the high recurrence rates. The clinical presentation is usually less acute than that of arterial occlusion.

Severe but vague abdominal pain that tends to be colicky and slowly progressive is usually present. Few abdominal signs are present except tenderness, distension and decreased bowel sounds. The pain is out of proportion to the physical findings. Fecal occult blood is present in the majority of patients.

There is a pyrexia of greater than 38 °C in 25% to 50% of patients, and 20% have a tachycardia. Leucocytosis ranges from 12000 to 29000.

Frank peritonitis is seen only when transmural infarction or perforation has occurred.

Surgical findings include blood-stained free peritoneal fluid at laparotomy. The affected bowel is cyanotic and edematous with a rubbery texture.

Mesenteric arterial pulsations are present but the veins contain fresh thrombus that extrude when the veins are cut. Infarction is most common in the mid small bowel.

FIG. A - Schematic representation of the collateral circulation of the

intestine. B - Angiographic appearance of arch of Riolan from superior mesenteric artery (stented at its origin). C - Angiographic appearance of marginal artery of Drummond. D - Initial angiogram demonstrates occluded IMA. The delayed film shows the colonic supply.

Diagnosis

Acute intestinal ischemia is a life-threatening surgical emergency, yet can be a difficult diagnosis to make, with delay contributing directly to infarction.

The majority of cases are diagnosed more than 12 hours after the onset of symptoms. Delayed diagnosis accounts for the majority of malpractice claims involving acute mesenteric ischemia in the United States. Diagnosis depends on a high index of suspicion. The main presenting feature is the combination of severe abdominal pain out of proportion to the clinical findings, as discussed above.

Serum levels of lactate and leucocytes are elevated in the majority (65% to 90%) of patients to greater than 50 U/L and 15000/mL, respectively.

Hyperamylasemia is seen in just under half the patients with acute mesenteric ischemia. Elevation of serum inorganic phosphate levels have been proposed as a marker of mesenteric ischemia, as it is extensively found in gut, but this only occurs in 15% to 33% of such patients.

However, in those patients who did have elevated phosphate levels, it predicted extensive injury and poor prognosis. The fibrinolytic marker D-dimer is elevated in thrombo-embolic occlusion of the SMA, although levels are also raised in other conditions of acute bowel ischemia such as strangulation or ruptured aortic aneurysm.

Animal studies have suggested intestinal fatty acid binding protein (I-FABP) as a serum marker reflecting bowel ischemia. Early human studies show promise, as patients with ischemic bowel disease demonstrate significantly higher I-FABP levels than either healthy subjects or patients with acute abdominal pain. Patients with mesenteric infarction had the highest serum I-FABP levels.

Plain radiographs of the abdomen may reveal nonspecific bowel dilatation or, in MVT, wall edema (thumbprinting); or gas in the bowel wall or portal vein. Unfortunately they are not

helpful in most cases.

Mesenteric angiography will confirm the diagnosis of arterial occlusion but at the cost of delay in treatment. If there are clear abdominal signs of peritonitism, urgent laparotomy without angiography is the best course of action. In the remainder of patients suspected of acute intestinal ischemia with-out abdominal signs, angiography is indicated with lateral views of the visceral aorta and its branches.

In acute SMA thrombosis, there is usually no visualization of the entire artery because of the ostial nature of the disease, although delayed views may show slow filling of the distal SMA. SMA embolization usually allows visualization of the proximal artery to just beyond the level of the middle colic artery.

Treatment

Nonsurgical

In all cases, the patient should be initially resuscitated, given broadspectrum intravenous antibiotics and fully heparinized. As yet, the twin goals of mesenteric revascularization and resection of nonviable bowel can only be achieved by surgical means.

Surgery is indicated in all patients with peritonitis. Angiography in patients without peritonitis may demonstrate NOMI or MVT. In NOMI, treatment is nonoperative and depends on optimizing cardiac output and treating underlying conditions such as sepsis. Intramesenteric arterial infusion of papaverine at a dose of 30 to 60 mg/lr may be beneficial.

Up to 65% of patients who have undergone cardiac surgery have had symptomatic improvement within hours when diagnosed early.

If MVT is diagnosed at angiography, intra-arterial thrombolytic therapy has been given successfully. Nonoperative management by full anticoagulation for acute MVT is feasible when the initial diagnosis is certain and when the bowel infarction has not led to transmural necrosis and bowel perforation. The morbidity, mortality, and survival rates are similar in cases of surgical and nonoperative management.

Other reported endovascular procedures for acute intestinal ischemia include fenestration and stent placement in aortic dissection, angioplasty and stenting in an acute occlusion in a patient with chronic mesenteric insufficiency, and angioplasty alone . This

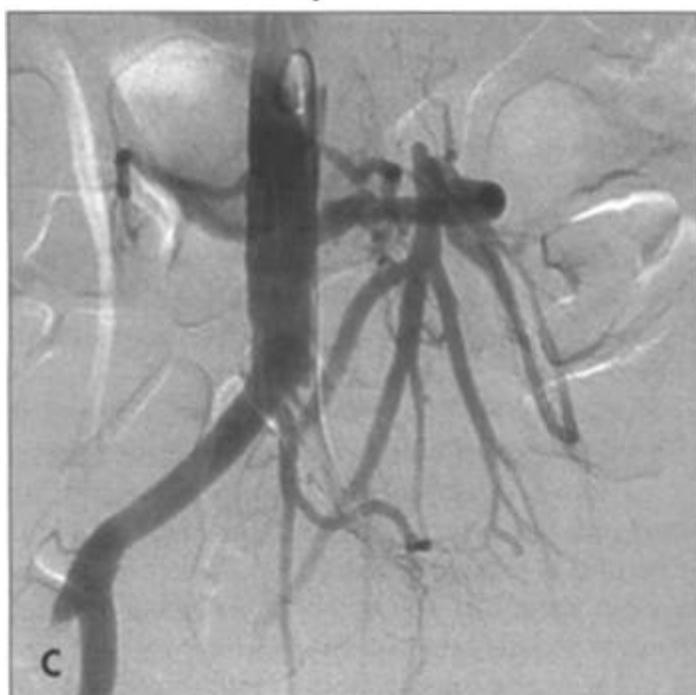

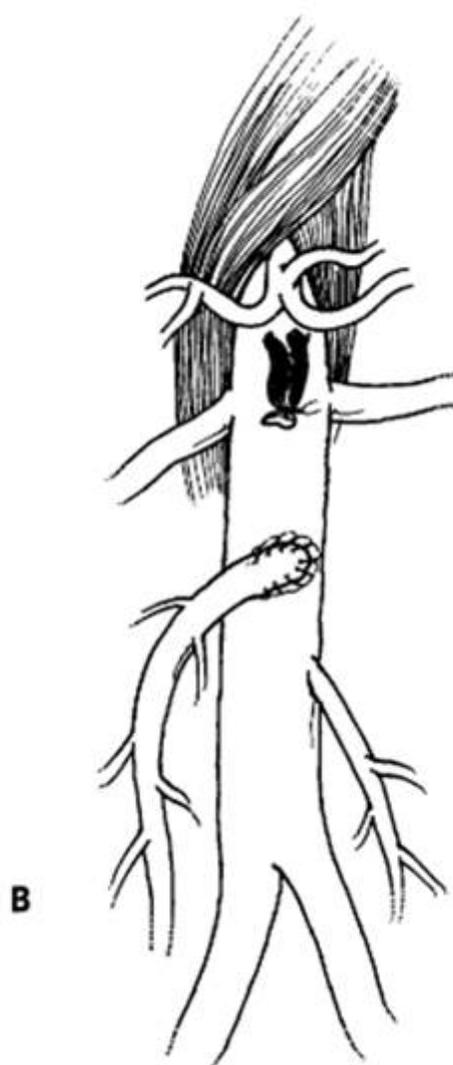

contrasts with an increasing use of angioplasty for chronic mesenteric ischemia.

SURGICAL

Laparotomy is indicated in patients with peritonitis after rapid resuscitation. The first step is to assess the degree and extent of bowel viability. Free, foul smelling peritoneal fluid is a sign of advanced necrosis even if perforation has not occurred. Ischemic bowel has a characteristic appearance with loss of its normal sheen. It is dull, gray in color and flabby in tone without any peristalsis. Infarcted bowel is purplish black in color, often friable and perforated. In many cases the bowel ischemia will be so extensive and advanced that no further surgical treatment is undertaken and palliative care given. Where there is hope of sufficient bowel viability, revascularization should be performed before any bowel resection is considered. After successful revascularization, previously precarious segments of intestine may recover and resection of clearly ischemic bowel can then take place.

SMA embolectomy. The proximal portion of the SMA is dissected free from the surrounding fat and lymphatic tissue just as it emerges from the pancreatic neck into the base of the mesentery. Approximately 3 to 4 centimeters of artery is cleared, with care taken not to damage the branches. Heparin (5000 units) is given intravenously. A transverse arteriotomy is made and a 3F or 4F embolectomy catheter is passed proximally and distally to clear the embolus and reestablish vigorous pulsatile flow. If proximal flow cannot be established, SMA thrombosis is likely and reconstructive surgery will be required.

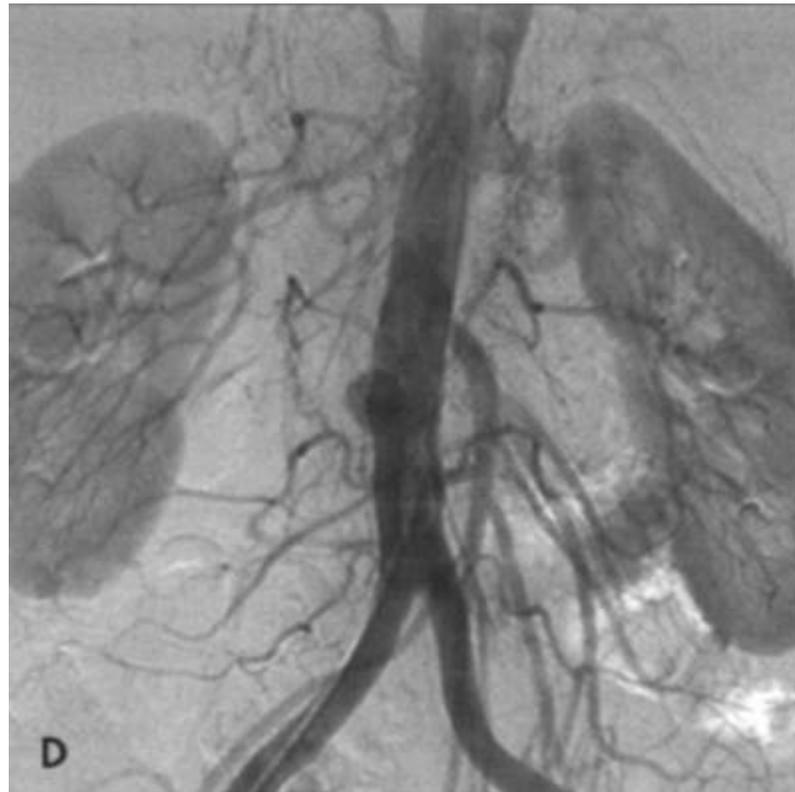

FIG. A - Schematic representation of revascularization of the SMA with: bypass taking care to avoid kinking and obstruction B - Or re-implantation of SMA into the aorta. C - Angiographic appearance of aorto-SMA bypass with vein graft. There is co-existing left common iliac occlusion. TOPIC № 17. AORTIC ARCH SYNDROME. CAUSES OF AORTIC ARCH SYNDROME. CLINICAL CHARACTERISTICS. CLASSIFICATION.

Carotid Artery Disease

Atherosclerotic occlusive plaque is by far the most common pathology seen in the carotid artery bifurcation. Thirty to 60% of all ischemic strokes are related to atherosclerotic carotid bifurcation occlusive disease. In the following section, discussion will be focused on clinical presentation, diagnosis, and management, including medical therapy, surgical carotid endarterectomy, and stenting of atherosclerotic carotid occlusive disease. In the second part of the section, a brief review will be focused on other less common non-atherosclerotic diseases involving the extracranial carotid artery, including kink and coil, fibromuscular dysplasia (FMD), arterial dissection, aneurysm, radiation arteritis, Takayasu's arteritis, and carotid body tumor.

Epidemiology and Etiology of Carotid Occlusive Disease

Approximately 700,000 Americans suffer a new or recurrent stroke each year. Eighty-five percent of all strokes are ischemic and 15% are hemorrhagic. Hemorrhagic strokes are caused by head trauma or spontaneous disruption of intracerebral blood vessels. Ischemic strokes are due to hypoperfusion from arterial occlusion, or less commonly due to decreased flow resulting from proximal arterial stenosis and poor collateral network. Common causes of ischemic strokes are cardiogenic emboli (35%), carotid artery disease (30%), lacunar (10%), miscellaneous (10%), and idiopathic (15%). The term *cerebrovascular accident* (CVA) often is used interchangeably to refer to an ischemic stroke. A *transient ischemic attack* (TIA) is defined as a temporary focal cerebral or retinal hypoperfusion state that resolves spontaneously within 24 hours after its onset. However, the majority of TIAs resolve within minutes, and longer lasting neurologic deficits more likely represent a stroke. Recently, the term *brain attack* has been coined to refer to an acute stroke or TIA, denoting the condition as a medical emergency requiring immediate attention, similar to a heart attack.

Stroke due to carotid bifurcation occlusive disease usually is caused by atheroemboli (Fig. 1). The carotid bifurcation is an area of low-flow velocity and low-shear stress. As the blood circulates through the carotid bifurcation, there is separation of flow into the low-resistance ICA, and the high-resistance external carotid artery. Characteristically,

atherosclerotic plaque forms in the outer wall opposite to the flow divider (Fig. 2). Atherosclerotic plaque formation is complex, beginning with intimal injury, platelet deposition, smooth muscle cell proliferation, and fibroplasia, and leading to subsequent luminal narrowing. With increasing degree of stenosis in the ICA, flow becomes more turbulent, and the risk of atheroembolization escalates. The severity of stenosis is commonly divided into three categories according to the luminal diameter reduction: mild (less than 50%), moderate (50 to 69%), and severe (70 to 99%). Severe carotid stenosis is a strong predictor for stroke. In turn, a prior history of neurologic symptoms (TIA or stroke) is an important determinant for recurrent ipsilateral stroke. The risk factors for the development of carotid artery bifurcation disease are similar to those causing atherosclerotic occlusive disease in other vascular beds. Increasing age, male gender, hypertension, tobacco smoking, diabetes mellitus, homocysteinemia, and hyperlipidemia are well-known predisposing factors for the development of atherosclerotic occlusive disease.

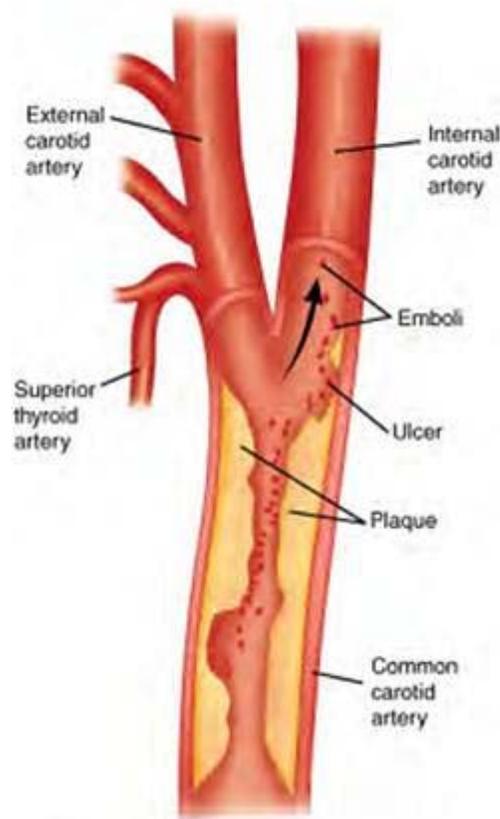

Fig. 1. Stroke due to carotid bifurcation occlusive disease is usually caused by atheroemboli arising from the internal carotid artery, which provides the majority of blood flow to the cerebral hemisphere

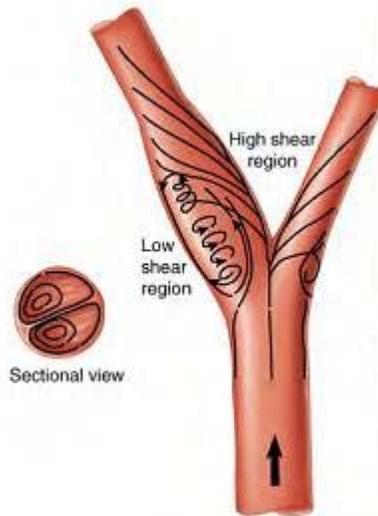

Fig.2 A. The carotid bifurcation is an area of low-flow velocity and low-shear stress. As the blood circulates through the carotid bifurcation, there is separation of flow into the low-resistance internal carotid artery and the high-resistance external carotid artery

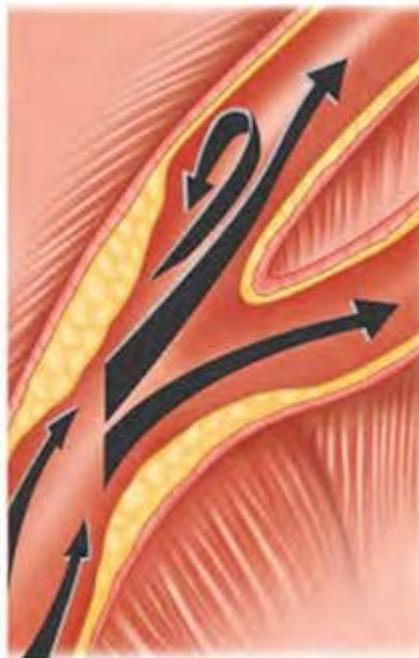

Fig. 2 B. The carotid atherosclerotic plaque typically forms in the outer wall opposite to the flow divider due in part to the effect of the low-shear stress region, which also creates a transient reversal of flow during cardiac cycle.

Clinical Manifestations of Cerebral Ischemia

TIA is a focal loss of neurologic function, lasting for <24 hours. *Crescendo TIAs* refer to a syndrome comprising repeated TIAs within a short period of time that is characterized by

complete neurologic recovery in between. At a minimum the term should probably be reserved either for those with daily events or multiple resolving attacks within 24 hours. Hemodynamic TIAs represent focal cerebral events that are aggravated by exercise or hemodynamic stress and typically occur after short bursts of physical activity, postprandially or after getting out of a hot bath. It is implied that these are due to severe extracranial disease and poor intracranial collateral recruitment. *Reversible ischemic neurologic deficits* refer to ischemic focal neurologic symptoms lasting longer than 24 hours but resolving within 3 weeks. When a neurologic deficit lasts longer than 3 weeks, it is considered a *completed stroke*. *Stroke in evolution* refers to progressive worsening of the neurologic deficit, either linearly over a 24-hour period, or interspersed with transient periods of stabilization and/or partial clinical improvement.

The patients who suffer CVAs typically present with three categories of symptoms, including ocular symptoms, sensory/motor deficit, and/or higher cortical dysfunction. The common ocular symptoms associated with extracranial carotid artery occlusive disease include amaurosis fugax and presence of Hollenhorst plaques. Amaurosis fugax, commonly referred to as *transient monocular blindness*, is a temporary loss of vision in one eye that patients typically describe as a window shutter coming down or gray shedding of the vision. This partial blindness usually lasts for a few minutes and then resolves. Most of these phenomena (>90%) are due to embolic occlusion of the main artery or the upper or lower divisions. Monocular blindness progressing over a 20-minute period suggests a migrainous etiology. Occasionally, the patient will recall no visual symptoms while the optician notes a yellowish plaque within the retinal vessels, which is also known as the *Hollenhorst plaque*. These are frequently derived from cholesterol embolization from the carotid bifurcation and warrant further investigation. Additionally, several ocular symptoms may be caused by microembolization from the extracranial carotid diseases, including monocular vision loss due to retinal artery or optic nerve ischemia, the ocular ischemia syndrome, and visual field deficits secondary to cortical infarction and ischemia of the optic tracts. Typical motor and/or sensory symptoms associated with CVAs are located in either an ipsilateral or contralateral neurologic deficit. Ischemic events tend to have an abrupt onset, with the severity of the insult being apparent from the onset and not usually associated with seizures or paraesthesia. In contrast, they represent loss or diminution of neurologic function. Furthermore, motor or sensory deficits can be unilateral or bilateral, with the upper and lower limbs being variably affected depending on the site of the cerebral lesion.

The combination of a motor and sensory deficit in the same body territory is suggestive

of a cortical thromboembolic event as opposed to lacunar lesions secondary to small vessel disease of the penetrating arterioles. However, a small proportion of the latter may present with a sensorimotor stroke secondary to small vessel occlusion within the posterior limb of the internal capsule. Pure sensory and pure motor strokes and those strokes where the weakness affects one limb only or does not involve the face are more typically seen with lacunar as opposed to cortical infarction. A number of higher cortical functions, including speech and language disturbances, can be affected by thromboembolic phenomena from the carotid artery with the most important clinical example for the dominant hemisphere being dysphasia or aphasia, and visuospatial neglect being an example of nondominant hemisphere injury.

Diagnostic Evaluation

Duplex ultrasonography is the most widely used screening tool to evaluate for atherosclerotic plaque and stenosis of the extracranial carotid artery. It is also commonly used to monitor patients serially for progression of disease, or after intervention (carotid endarterectomy or angioplasty). Duplex ultrasound of the carotid artery combines B-mode gray-scale imaging and Doppler waveform analysis. Characterization of the carotid plaque on gray-scale imaging provides useful information about its composition. However, there are currently no universal recommendations that can be made based solely on the sonographic appearance of the plaque. On the other hand, criteria have been developed and well refined for grading the degree of carotid stenosis based primarily on Doppler-derived velocity waveforms.

The external carotid artery has a high-resistance flow pattern with a sharp systolic peak and a small amount of flow in diastole. In contrast, a normal ICA will have a low-resistance flow pattern with a broad systolic peak and a large amount of flow during diastole. The flow pattern in the common carotid artery (CCA) resembles that in the ICA, as 80% of the flow is directed to the ICA, with waveforms that have broad systolic peaks and a moderate amount of flow during diastole. Conventionally, velocity measurements are recorded in the common, external carotid bulb, and the proximal, mid-, and distal portions of the ICA. Characteristically, the peak systolic velocity is increased at the site of the vessel stenosis. The end-diastolic velocity is increased with a greater degree of stenosis. In addition, stenosis of the ICA can lead to color shifts with color mosaics indicating a poststenotic turbulence. Dampening of the Doppler velocity waveforms are typically seen in areas distal to severe carotid stenosis where blood flow is reduced. It is well known that occlusion of the ipsilateral ICA can lead to a "falsely" elevated velocity on the contralateral side due to an increase in compensatory blood

flow. In the presence of a high-grade stenosis or occlusion of the ICA, the ipsilateral CCA displays high flow resistance waveforms, similar to that seen in the external carotid artery. If there is a significant stenosis in the proximal CCA, its waveforms may be dampened with low velocities.

The Doppler grading systems of carotid stenosis were initially established by comparison to angiographic findings of disease. Studies have shown variability in the measurements of the duplex properties by different laboratories, as well as heterogeneity in the patient population, study design, and techniques. One of the most commonly used classifications was established at the University of Washington School of Medicine in Seattle. Diameter reduction of 50 to 79% is defined by peak systolic velocity >125 cm/sec with extensive spectral broadening. For stenosis in the range of 80 to 99%, the peak systolic velocity is >125 cm/sec and peak diastolic velocity is >140 cm/sec. The ratio of internal carotid to common carotid artery (ICA/CCA) peak systolic velocity has also been part of various ultrasound diagnostic classifications. A ratio >4 is a great predictor of angiographic stenosis of 70 to 99%. A multispecialty consensus panel has developed a set of criteria for grading carotid stenosis by duplex examination (Table 1).

Table 1. Carotid Duplex Ultrasound Criteria for Grading Internal Carotid Artery Stenosis

Degree of Stenosis (%)	ICA PSV (cm/s)	ICA/CCA PSV Ratio	ICA EDV (cm/s)	Plaque Estimate (%)*
Normal	<125	<2.0	<40	None
<50	<125	<2.0	<40	<50
50–69	125–230	2.0–4.0	40–100	≥ 50
≥ 70 to less than near occlusion	>230	>4.0	>100	≥ 50
Near occlusion	High, low, or not detected	Variable	Variable	Visible
Total occlusion	Not detected	Not applicable	Not detected	Visible, no lumen

MRA is increasingly being used to evaluate for atherosclerotic carotid occlusive disease and intracranial circulation. MRA is noninvasive and does not require iodinated contrast agents. MRA uses phase contrast or time-of-flight, with either two-dimensional or three-dimensional data sets for greater accuracy. Three-dimensional, contrast-enhanced MRA allows data to be obtained in coronal and sagittal planes with improved image qualities due to shorter study time. In addition, the new MRA techniques allow for better reformation of images in various planes to allow better grading of stenosis. There have been numerous studies comparing the sensitivity and specificity of MRA imaging for carotid disease to duplex and selective contrast angiography. Magnetic resonance imaging (MRI) of the brain is essential in

the assessment of acute stroke patients. MRI with diffusion-weighted imaging can differentiate areas of acute ischemia, areas still at risk for ischemia (penumbra), and chronic cerebral ischemic changes. However, computed tomographic (CT) imaging remains the most expeditious test in the evaluation of acute stroke patients to rule out intracerebral hemorrhage. Recently, multidetector CTA has gained increasing popularity in the evaluation of carotid disease. This imaging modality can provide volume rendering, which allows rotation of the object with accurate anatomic structures from all angles (Fig. 3). The advantages of CTA over MRA include faster data acquisition time and better spatial resolution. However, grading of carotid stenosis by CTA requires further validation at the time of this writing before it can be widely applied.

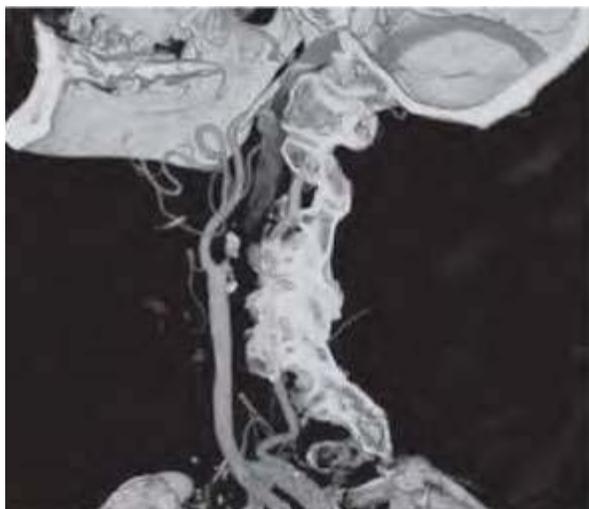

Fig. 3 A. Carotid computed tomography angiography is a valuable imaging modality that can provide a three-dimensional image reconstruction with high image resolution. A carotid artery occlusion is noted in the internal carotid artery.

Fig.3

B. The entire segment of extracranial carotid artery is visualized from the thoracic compartment to the base of skull.

Historically, DSA has been the gold standard test to evaluate the extra- and intracranial circulation (Fig. 4). This is an invasive procedure, typically performed via a transfemoral puncture, and involves selective imaging of the carotid and vertebral arteries using iodinated contrast. The risk of stroke during cerebral angiography is generally reported at approximately 1%, and is typically due to atheroembolization related to wire and catheter manipulation in the arch aorta or proximal branch vessels. Over the past decades, however, the incidence of neurologic complications following angiography has been reduced, due to the use of improved guidewires and catheters, better resolution digital imaging, and increased experience. Local access complications of angiography are infrequent and include development of hematoma, pseudoaneurysm, distal embolization, or acute vessel thrombosis. Currently, selective angiography is particularly used for patients with suspected intracranial disease and for patients in whom percutaneous revascularization is considered. The techniques of carotid angioplasty and stenting for carotid bifurcation occlusive disease are described in the "Techniques of Carotid Angioplasty and Stenting" section. Preoperative CTA or MRA is routinely utilized to get information about the aortic arch anatomy and presence of concomitant intracranial disease and collateral pathway in planning our strategy for carotid stenting or endarterectomy.

Fig. 4. A carotid angiogram reveals an ulcerated carotid plaque (*arrow*) in the proximal internal carotid artery, which also resulted in a high-grade, internal, carotid artery stenosis

Treatment of Carotid Occlusive Disease

Conventionally, patients with carotid bifurcation occlusive disease are divided into two broad categories: patients without prior history of ipsilateral stroke or TIA (asymptomatic) and those with prior or current ipsilateral neurologic symptoms (symptomatic). It is estimated that 15% of all strokes are preceded by a TIA. The 90-day risk of a stroke in a patient presenting with a TIA is 3 to 17%. According to the Cardiovascular Health Study, a longitudinal, population-based study of CAD and stroke in men and women, the prevalence of TIA in men was 2.7% between the ages of 65 to 69 and 3.6% for ages 75 to 79; the prevalence in women was 1.4% and 4.1%, respectively. There have been several studies reporting on the effectiveness of stroke prevention with medical treatment and carotid endarterectomy for symptomatic patients with moderate to severe carotid stenosis. Early and chronic aspirin therapy has been shown to reduce stroke recurrence rate in several large clinical trials.

Symptomatic Carotid Stenosis

Currently, most stroke neurologists prescribe both aspirin and clopidogrel for secondary stroke prevention in patients who had experienced a TIA or stroke. In patients with symptomatic carotid stenosis, the degree of stenosis appears to be the most important predictor in determining risk for an ipsilateral stroke. The risk of a recurrent ipsilateral stroke in patients with severe carotid stenosis approaches 40%. Two large multicenter randomized clinical trials, the European Carotid Surgery Trial and the North American Symptomatic Carotid Endarterectomy Trial, have both shown a significant risk reduction in stroke for patients with symptomatic high-grade stenosis (70 to 99%) undergoing carotid endarterectomy when compared to medical therapy alone. There has been much discussion regarding the different methodology used in the measurement of carotid stenosis and calculation of the life-table data between the two studies, which still led to similar results. Findings of these two landmark trials have also been reanalyzed in many subsequent publications. The main conclusions of the trials remain validated and widely acknowledged. Briefly, the North American Symptomatic Carotid

Endarterectomy Trial study showed that, for high-grade carotid stenosis, the cumulative risk of ipsilateral stroke was 26% in the medically treated group and 9% in the surgically treated group at 2 years. For patients with moderate carotid artery stenosis (50 to 69%), the benefit of carotid endarterectomy is less but still favorable when compared to medical treatment alone; the 5-year fatal or nonfatal ipsilateral stroke rate was 16% in the surgically treated group vs. 22% in the medically treated group. The risk of stroke was similar for the remaining group of symptomatic patients with less than 50% carotid stenosis, whether they had endarterectomy or medical treatment alone. The European Carotid Surgery Trial reported similar stroke risk reduction for patients with severe symptomatic carotid stenosis and no benefit in patients with mild stenosis, when carotid endarterectomy was performed vs. medical therapy.

The optimal timing of carotid intervention after acute stroke, however, remains debatable. Earlier studies showed an increased rate of postoperative stroke exacerbation and conversion of a bland to hemorrhagic infarction when carotid endarterectomy was carried out within 5 to 6 weeks after acute stroke. The dismal outcome reported in the early experience was likely related to poor patient selection. The rate of stroke recurrence is not insignificant during the interval period and may be reduced with early intervention for symptomatic carotid stenosis. Contemporary series have demonstrated acceptable low rates of perioperative complications in patients undergoing carotid endarterectomy within 4 weeks after acute stroke. In a recent retrospective series, carotid artery stenting, when performed early (<2 weeks) after the acute stroke, was associated with higher mortality than when delayed (>2 weeks).

Asymptomatic Carotid Stenosis

Whereas there is universal agreement that carotid revascularization (endarterectomy or stenting) is effective in secondary stroke prevention for patients with symptomatic moderate and severe carotid stenosis, the management of asymptomatic patients remains an important controversy to be resolved. Generally, the detection of carotid stenosis in asymptomatic patients is related to the presence of a cervical bruit or based on screening duplex ultrasound findings. In one of the earlier observational studies, the authors showed that the annual rate of occurrence of neurologic symptoms was 4% in a cohort of 167 patients with asymptomatic cervical bruits followed prospectively by serial carotid duplex scan. The mean annual rate of carotid stenosis progression to a greater than 50% stenosis was 8%. The presence of or progression to a greater than 80% stenosis correlated highly with either the development of a

total occlusion of the ICA or new symptoms. The major risk factors associated with disease progression were cigarette smoking, diabetes mellitus, and age. This study supported the contention that it is prudent to follow a conservative course in the management of asymptomatic patients presenting with a cervical bruit.

One of the first randomized clinical trials on the treatment of asymptomatic carotid artery stenosis was the Asymptomatic Carotid Atherosclerosis Study, which evaluated the benefits of medical management with antiplatelet therapy vs. carotid endarterectomy. Over a 5-year period, the risk of ipsilateral stroke in individuals with a carotid artery stenosis greater than 60% was 5.1% in the surgical arm. On the other hand, the risk of ipsilateral stroke in patients treated with medical management was 11%. Carotid endarterectomy produced a relative risk reduction of 53% over medical management alone. The results of a larger randomized trial from Europe, The Asymptomatic Carotid Surgery Trial, confirmed similar beneficial stroke risk reduction for patients with asymptomatic greater than 70% carotid stenosis undergoing endarterectomy compared to medical therapy. An important point derived from this latter trial was that even with improved medical therapy, including the addition of statin drugs and clopidogrel, medical therapy was still inferior to endarterectomy in the primary stroke prevention for patients with high-grade carotid artery stenosis. It is generally agreed that asymptomatic patients with severe carotid stenosis (80 to 99%) are at significantly increased risk for stroke and stand to benefit from either surgical or endovascular revascularization. However, revascularization for asymptomatic patients with a less severe degree of stenosis (60 to 79%) remains controversial.

Carotid Endarterectomy vs. Angioplasty and Stenting

Currently, the argument is no longer that medical therapy alone is inferior to surgical endarterectomy in stroke prevention for severe carotid stenosis. Rather, the debate now revolves around whether carotid angioplasty and stenting produces the same benefit that has been demonstrated by carotid endarterectomy. Since carotid artery stenting was approved by the FDA in 2004 for clinical application, this percutaneous procedure has become a treatment alternative in patients who are deemed "high-risk" for endarterectomy (Table 2). In contrast to many endovascular peripheral arterial interventions, percutaneous carotid stenting represents a much greater challenging procedure, because it requires complex, catheter-based skills using the 0.014-in guidewire system and distal protection device. Moreover, current carotid stent devices predominantly use the monorail guidewire system that requires more technical agility,

in contrast to the over-the-wire catheter system that is routinely used in peripheral interventions. This percutaneous intervention often requires balloon angioplasty and stent placement through a long carotid guiding sheath via a groin approach. Poor technical skills can result in devastating treatment complications such as stroke, which can occur due in part to plaque embolization during the balloon angioplasty and stenting of the carotid artery. Because of these various procedural components that require high technical proficiency, many early clinical investigations of carotid artery stenting, which included physicians with little or no carotid stenting experience, resulted in alarmingly poor clinical outcomes. A recent Cochrane review noted that, before 2006, a total of 1269 patients had been studied in five randomized controlled trials comparing percutaneous carotid intervention and surgical carotid reconstruction.³² Taken together, these trials revealed that carotid artery stenting had a greater procedural risk of stroke and death when compared to carotid endarterectomy (odds ratio 1.33; 95% CI 0.86–2.04). Additionally, greater incidence of carotid restenosis was noted in the stenting group than the endarterectomy cohorts. However, the constant improvement of endovascular devices, procedural techniques, and adjunctive pharmacologic therapy will likely improve the treatment success of percutaneous carotid intervention. Critical appraisals of these trials comparing the efficacy of carotid stenting vs. endarterectomy are available for review.³³ Several ongoing clinical trials will undoubtedly provide more insights on the efficacy of carotid stenting in the near future.

Table 2. Conditions Qualifying Patients as "High Surgical Risk" for Carotid Endarterectomy

Anatomical Factors	Physiological Factors
• High carotid bifurcation (above C2 vertebral body)	• Age ≥80 y
• Low common carotid artery (below clavicle)	• Left ventricular ejection fraction ≤30%
• Contralateral carotid occlusion	• New York Heart Association Class III/IV congestive heart failure
• Restenosis of ipsilateral prior carotid endarterectomy	• Unstable angina: Canadian Cardiovascular Society Class III/IV angina pectoris
• Previous neck irradiation	
• Prior radical neck dissection	• Recent myocardial infarction
• Contralateral laryngeal nerve palsy	• Clinically significant cardiac disease (congestive heart failure, abnormal stress test, or need for coronary revascularization)
• Presence of tracheostomy	
	• Severe chronic obstructive pulmonary disease
	• End-stage renal disease on dialysis

Surgical Techniques of Carotid Endarterectomy

Although carotid endarterectomy is one of the earliest vascular operations ever described and its techniques have been perfected in the last two decades, surgeons continue to debate

many aspects of this procedure. For instance, there is no universal agreement with regard to the best anesthetic of choice, the best intraoperative cerebral monitoring, whether to "routinely" shunt, open vs. eversion endarterectomy, and patch vs. primary closure. Various anesthetic options are available for a patient undergoing carotid endarterectomy including general, local, and regional anesthesia. Typically, the anesthesia of choice depends on the preference of the surgeon, anesthesiologist, and patient. However, depending on the anesthetic given, the surgeon must decide whether intraoperative cerebral monitoring is necessary or intra-arterial carotid shunting will be used. In general, if the patient is awake, then his or her abilities to respond to commands during carotid clamp period determine the adequacy of collateral flow to the ipsilateral hemisphere. On the other hand, intraoperative electroencephalogram or transcranial power Doppler (TCD) has been used to monitor for adequacy of cerebral perfusion during the clamp period for patients undergoing surgery under general anesthesia. Focal ipsilateral decreases in amplitudes and slowing of electroencephalogram waves are indicative of cerebral ischemia. Similarly, a decrease to less than 50% of baseline velocity in the ipsilateral middle cerebral artery is a sign of cerebral ischemia. For patients with poor collateral flow exhibiting signs of cerebral ischemia, intra-arterial carotid shunting with removal of the clamp will restore cerebral flow for the remaining part of the surgery. Stump pressures have been used to determine the need for intra-arterial carotid shunting. Some surgeons prefer to shunt all patients on a routine basis and do not use intraoperative cerebral monitoring.

The patient's neck is slightly hyperextended and turned to the contralateral side, with a roll placed between the shoulder blades. An oblique incision is made along the anterior border of the sternocleidomastoid muscle centered on top of the carotid bifurcation (Fig. 5). The platysma is divided completely. Typically, tributaries of the anterior jugular vein are ligated and divided. The dissection is carried medial to the sternocleidomastoid. The superior belly of the omohyoid muscle is usually encountered just anterior to the CCA. This muscle can be divided. The carotid fascia is incised and the CCA is exposed. The CCA is mobilized cephalad toward the bifurcation. The dissection of the carotid bifurcation can cause reactive bradycardia related to stimulation of the carotid body. This reflex can be blunted with injection of lidocaine 1% into the carotid body or reversed with administration of IV atropine. A useful landmark in the dissection of the carotid bifurcation is the common facial vein. This vein can be ligated and divided. Frequently, the twelfth cranial nerve (hypoglossal nerve) traverses the carotid bifurcation just behind the common facial vein. The external carotid artery is mobilized just enough to get a clamp across. Often, a branch of the external carotid artery crossing to the sternocleidomastoid can be divided to allow further cephalad mobilization of the ICA. For high

bifurcation, division of the posterior belly of the digastric muscle is helpful in establishing distal exposure of the ICA.

Fig 5. To perform carotid endarterectomy, the patient's neck is slightly hyperextended and turned to the contralateral side. An oblique incision is made along the anterior border of the sternocleidomastoid muscle centered on top of the carotid bifurcation.

IV heparin sulfate (1 mg/kg) is routinely administered just before carotid clamping. The ICA is clamped first using a soft, noncrushing vascular clamp to prevent distal embolization. The external and common carotid arteries are clamped subsequently. A longitudinal arteriotomy is made in the distal CCA and extended into the bulb and past the occlusive plaque into the normal part of the ICA. Endarterectomy is carried out to remove the occlusive plaque (Fig. 6). If necessary, a temporary shunt can be inserted from the CCA to the ICA to maintain continuous antegrade cerebral blood flow (Fig. 7). Typically, a plane is teased out from the vessel wall, and the entire plaque is elevated and removed. The distal transition line in the ICA where the plaque had been removed must be examined carefully and should be smooth. Tacking sutures are placed when an intimal flap remains in this transition to ensure no obstruction to flow (Fig. 8). The occlusive plaque is usually removed from the origin of the external carotid artery using the eversion technique. The endarterectomized surface is then irrigated and any debris removed. A patch (autogenous saphenous vein, synthetic such as polyester, PTFE, or biologic material) is sewn to close the arteriotomy (Fig. 9). Whether patch closure is necessary in all patients and which patch is the best remain controversial. However, most surgeons agree

that patch closure is indicated particularly for the small vessel (<7 mm). The eversion technique also has been advocated for removing the plaque from the ICA. In the eversion technique, the ICA is transected at the bulb, the edges of the divided vessel are everted, and the occluding plaque is "peeled" off the vessel wall. The purported advantages of the eversion technique are no need for patch closure and a clear visualization of the distal transition area. Reported series have not shown a clear superiority of one technique over the others. Surgeons will likely continue to use the technique of their choice. Just before completion of the anastomosis to close the arteriotomy, it is prudent to flush the vessels of any potential debris. When the arteriotomy is closed, flow is restored to the external carotid artery first and to the ICA second. IV protamine sulfate can be given to reverse the effect of heparin anticoagulation following carotid endarterectomy. The wound is closed in layers. After surgery, the patient's neurologic condition is assessed in the operating room (OR) before transfer to the recovery area.

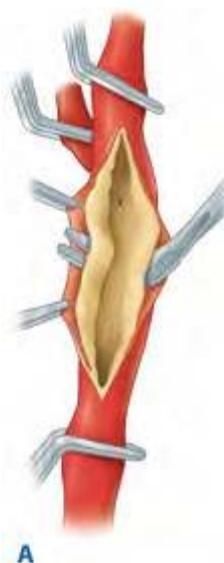

Fig. 6 A. During carotid endarterectomy, vascular clamps are applied in common carotid, external carotid, and internal carotid arteries. Carotid plaque is elevated from the carotid lumen

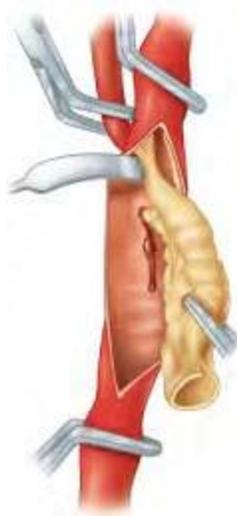

Fig. 6 B. Carotid plaque is removed and the arteriotomy is closed either primarily or with a patch angioplasty

Fig. 7. A temporary carotid shunt is inserted from the common carotid artery (*long arrow*) to the internal carotid artery (*short arrow*) during carotid endarterectomy to provide continuous antegrade cerebral blood flow.

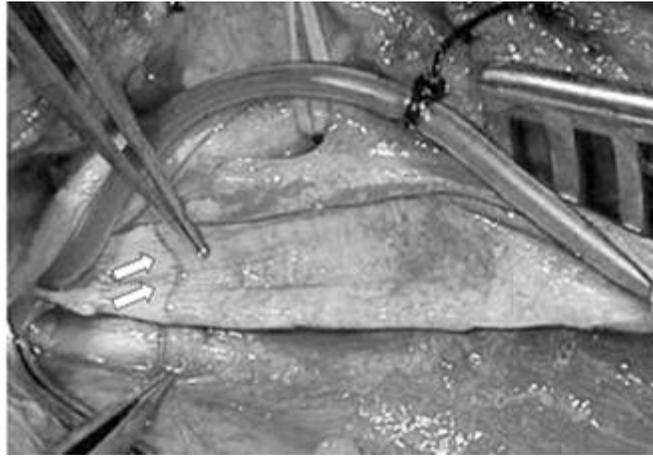

Fig. 8. The distal transition line (left side of the picture) in the internal carotid artery where the plaque had been removed must be examined carefully and should be smooth. Tacking sutures (*arrows*) are placed when an intimal flap remains in this transition to ensure no obstruction to flow.

Fig. 9 A. An autologous or synthetic patch can be used to close the carotid arteriotomy incision, which maintains the luminal patency

Fig 9 B. A completion closure of carotid endarterectomy incision using a synthetic patch.

Complications of Carotid Endarterectomy

Most patients tolerate carotid endarterectomy very well and typically are discharged home within 24 hours after surgery. Complications after endarterectomy are infrequent but can be potentially life threatening or disabling. Acute ipsilateral stroke is a dreaded complication following carotid endarterectomy. Cerebral ischemia can be due to either intraoperative or postoperative events. Embolizations from the occlusive plaque or prolonged cerebral ischemia are potential causes of intraoperative stroke. The most common cause of postoperative stroke is due to embolization. Less frequently, acute carotid artery occlusion can cause acute postoperative stroke. This is usually due to carotid artery thrombosis related to closure of the arteriotomy, an occluding intimal flap, or distal carotid dissection. When patients experience acute symptoms of neurologic ischemia after endarterectomy, immediate intervention may be indicated. Carotid duplex scan can be done expeditiously to assess patency of the extracranial ICA. Re-exploration is mandated for acute carotid artery occlusion. Cerebral angiography can be useful if intracranial revascularization is considered.

Local complications related to surgery include excessive bleeding and cranial nerve palsies. Postoperative hematoma in the neck after carotid endarterectomy can lead to devastating airway compromise. Any expanding hematoma should be evacuated and active bleeding stopped. Securing an airway is critical and can be extremely difficult in patients with large postoperative neck hematomas. The reported incidence of postoperative cranial nerve palsies after carotid endarterectomy varies from 1 to 30%. Well-recognized injuries involve the

marginal mandibular, vagus, hypoglossal, superior laryngeal, and recurrent laryngeal nerves. Often these are traction injuries but can also be due to severance of the respective nerves.

Techniques of Carotid Angioplasty and Stenting

Percutaneous carotid artery stenting has become an accepted alternative treatment in the management of patients with carotid bifurcation disease (Fig. 10). The perceived advantages of percutaneous carotid revascularization are related to the minimal invasiveness of the procedure compared to surgery. There are anatomical conditions based on angiographic evaluation in which carotid artery stenting should be avoided due to increased procedural-related risks (Table 3). In preparation for carotid stenting, the patient should be given oral clopidogrel 3 days before the intervention if the patient was not already taking the drug. The procedure is done in either the OR with angiographic capabilities or in a dedicated angiography room. The patient is placed in the supine position. The patient's BP and cardiac rhythm are closely monitored.

Fig. 10 A. Carotid angiogram demonstrated a high-grade stenosis of the left internal carotid artery

Fig. 10 B. Completion angiogram demonstrating a satisfactory result following a carotid stent placement.

Table 3. Unfavorable Carotid Angiographic Appearance in Which Carotid Stenting Should Be Avoided

• Extensive carotid calcification
• Polyloid or globular carotid lesions
• Severe tortuosity of the common carotid artery
• Long segment stenoses (>2 cm in length)
• Carotid artery occlusion
• Severe intraluminal thrombus (angiographic defects)
• Extensive middle cerebral artery atherosclerosis

To gain access to the carotid artery, a retrograde transfemoral approach is most commonly used as the access site for carotid intervention. Using the Seldinger technique, a diagnostic 5F or 6F sheath is inserted in the CFA. A diagnostic arch aortogram is obtained. The carotid artery to be treated is then selected using a 5F diagnostic catheter, and contrast is injected to show the carotid anatomy. It is important to assess the contralateral carotid artery, vertebrobasilar, and intracranial circulation if these are not known based on the preoperative, noninvasive studies. Once the decision is made to proceed with carotid artery stenting, with the tip of the diagnostic catheter still in the CCA, a 0.035-in, 260-cm long stiff glide wire is placed

in the ipsilateral external carotid artery. Anticoagulation with IV bivalirudin bolus (0.75mg/kg) followed by an infusion rate of 2.5 mg/kg per hour for the remainder of the procedure is routinely administered. Next, the diagnostic catheter is withdrawn and a 90-cm 6F guiding sheath is advanced into the CCA over the stiff glide wire. It is critical not to advance the sheath beyond the occlusive plaque in the carotid bulb. The stiff wire is then removed and preparation is made to deploy the distal embolic protection device (EPD). Several distal EPDs are available (Table 4). The EPD device is carefully deployed beyond the target lesion. With regard to the carotid stents, there are several stents that have received approval from the FDA and are commercially available for carotid revascularization (Table 5). All current carotid stents use the rapid-exchange monorail 0.014-in platform. The size selection is typically based on the size of CCA. Predilatation using a 4-mm balloon may be necessary to allow passage of the stent delivery catheter. Once the stent is deployed across the occlusive plaque, postdilatation is usually performed using a 5.5-mm or less balloon. It's noteworthy that balloon dilation of the carotid bulb may lead to immediate bradycardia due to stimulation of the glossopharyngeal nerve. The EPD is then retrieved and the procedure is completed with removal of the sheath from the femoral artery. The puncture site is closed using an available closure device or with manual compression. Throughout the procedure, the patient's neurologic function is closely monitored. The bivalirudin infusion is stopped, and the patient is kept on clopidogrel (75 mg daily) for at least 1 month and aspirin indefinitely.

Table 4. Commonly Used Embolic Protection Devices (EPDs)

Mechanism	Name of EPD	Pore Size (micrometers)
Distal balloon occlusion	PercuSurge Guard Wire, Export catheter (Medtronic)	N/A
Distal filter	Angioguard (Cordis)	100
	AccUNET (Abbott)	150

Complications of Carotid Stenting

Although there have been no randomized trials comparing carotid stenting with and without EPD, the availability of EPDs appears to have reduced the risk of distal embolization and stroke. The results of the various clinical trials and registries of carotid stenting have been reported and compared. It is well known that distal embolization as detected by TCD is much more frequent with carotid stenting, even with EPD, when compared to carotid endarterectomy. However, the clinical significance of the distal embolization detected by TCD is not clear, as most are asymptomatic. Acute carotid stent thrombosis is rare. The incidence of in-stent carotid restenosis is not well known but is estimated at 10 to 30%. Duplex surveillance shows elevated peak systolic velocities within the stent after carotid stenting can occur frequently. However, velocity criteria are being formulated to determine the severity of in-stent restenosis after carotid stenting by ultrasound duplex. It appears that systolic velocities exceeding 300 to 400 cm/s would represent greater than 70 to 80% restenosis. Bradycardia and hypotension occurs in up to 20% of patients undergoing carotid stenting. Systemic administration of atropine is usually effective in reversing the bradycardia. Other technical complications of carotid stenting are infrequent and include carotid artery dissection, and access site complications such as groin hematoma, femoral artery pseudoaneurysm, distal embolization, and acute femoral artery thrombosis.

NON-ATHEROSCLEROTIC DISEASE OF THE CAROTID ARTERY

Carotid Coil and Kink

A carotid coil consists of an excessive elongation of the ICA producing tortuosity of the vessel (Fig. 11). Embryologically, the carotid artery is derived from the third aortic arch and

dorsal aortic root, and is uncoiled as the heart and great vessels descend into the mediastinum. In children, carotid coils appear to be congenital in origin. In contrast, elongation and kinking of the carotid artery in adults is associated with the loss of elasticity and an abrupt angulation of the vessel. Kinking is more common in women than men. Cerebral ischemic symptoms caused by kinks of the carotid artery are similar to those from atherosclerotic carotid lesions, but are more likely due to cerebral hypoperfusion than embolic episodes. Classically, sudden head rotation, flexion, or extension can accentuate the kink and provoke ischemic symptoms. Most carotid kinks and coils are found incidentally on carotid duplex scan. However, interpretation of the Doppler frequency shifts and spectral analysis in tortuous carotid arteries can be difficult because of the uncertain angle of insonation. Cerebral angiography, with multiple views taken in neck flexion, extension, and rotation, is useful in the determination of the clinical significance of kinks and coils.

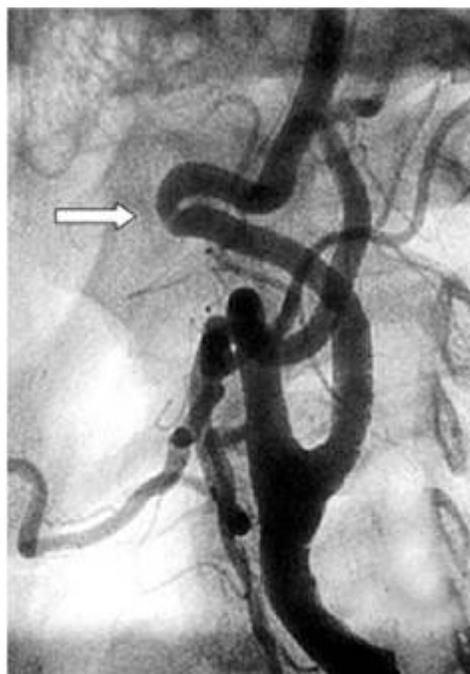

Fig. 11. Excessive elongation of the carotid artery can result in carotid kinking (*arrow*), which can compromise cerebral blood flow and lead to cerebral ischemia.

Fibromuscular Dysplasia

FMD usually involves medium-sized arteries that are long and have few branches (Fig. 12). Women in the fourth or fifth decade of life are more commonly affected than men. Hormonal effects on the vessel wall are thought to play a role in the pathogenesis of FMD.

FMD of the carotid artery is commonly bilateral, and in about 20% of patients, the vertebral artery also is involved. An intracranial saccular aneurysm of the carotid siphon or middle cerebral artery can be identified in up to 50% of the patients with FMD. Four histological types of FMD have been described in the literature. The most common type is medial fibroplasia, which may present as a focal stenosis or multiple lesions with intervening aneurysmal outpouchings. The disease involves the media with the smooth muscle being replaced by fibrous connective tissue. Commonly, mural dilations and microaneurysms can be seen with this type of FMD. Medial hyperplasia is a rare type of FMD, with the media demonstrating excessive amounts of smooth muscle. Intimal fibroplasia accounts for 5% of all cases and occurs equally in both sexes. The media and adventitia remain normal, and there is accumulation of subendothelial mesenchymal cells with a loose matrix of connective tissue causing a focal stenosis in adults. Finally, premedial dysplasia represents a type of FMD with elastic tissue accumulating between the media and adventitia. FMD also can involve the renal and the external iliac arteries. It is estimated that approximately 40% of patients with FMD present with a TIA due to embolization of platelet aggregates. DSA demonstrates the characteristic "string of beads" pattern, which represents alternating segments of stenosis and dilatation. The string of beads can also be shown noninvasively by CTA or MRA. FMD should be suspected when an increased velocity is detected across a stenotic segment without associated atherosclerotic changes on carotid duplex ultrasound. Antiplatelet medication is the generally accepted therapy for asymptomatic lesions. Endovascular treatment is recommended for patients with documented lateralizing symptoms. Surgical correction is rarely indicated.

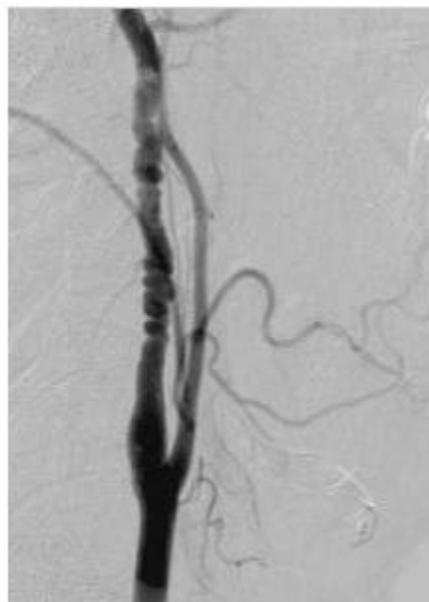

Fig. 12. A carotid fibromuscular dysplasia with typical characteristics of multiple stenosis with

intervening aneurysmal outpouching dilatations. The disease involves the media, with the smooth muscle being replaced by fibrous connective tissue

Carotid Artery Dissection

Dissection of the carotid artery accounts for approximately 20% of strokes in patients younger than 45 years of age. The etiology and pathogenesis of spontaneous carotid artery dissection remains incompletely understood. Arterial dissection involves hemorrhage within the media, which can extend into the subadventitial and subintimal layers. When the dissection extends into the subadventitial space, there is an increased risk of aneurysm formation. Subintimal dissections can lead to intramural clot or thrombosis. Traumatic dissection is typically a result of hyperextension of the neck during blunt trauma, neck manipulation, strangulation, or penetrating injuries to the neck. Even in supposedly spontaneous cases, a history of preceding unrecognized minor neck trauma is not uncommon. Connective disorders such as Ehlers-Danlos syndrome, Marfan syndrome, alpha1-antitrypsin deficiency, or FMD may predispose to carotid artery dissection. Iatrogenic dissections also can occur due to catheter manipulation or balloon angioplasty.

Typical clinical features of carotid artery dissection include unilateral neck pain, headache, and ipsilateral Horner's syndrome in up to 50% of patients, followed by manifestations of the cerebral or ocular ischemia and cranial nerve palsies. Neurologic deficits can result either because of hemodynamic failure (caused by luminal stenosis) or by an artery to artery thromboembolism. The ischemia may cause TIAs or infarctions, or both. Catheter angiography has been the method of choice to diagnose arterial dissections, but with the advent of duplex ultrasonography, MRI/MRA, and CTA, most dissections can now be diagnosed using noninvasive imaging modalities (Fig. 13). The dissection typically starts in the ICA distal to the bulb. Uncommonly, the dissection can start in the CCA, or is an extension of a more proximal aortic dissection. Medical therapy has been the accepted primary treatment of symptomatic carotid artery dissection. Anticoagulation (heparin and warfarin) and antiplatelet therapy have been commonly used, although there have not been any randomized studies to evaluate their effectiveness. The prognosis depends on the severity of neurologic deficit but is generally good in extracranial dissections. The recurrence rate is low. Therapeutic interventions have been reserved for recurrent TIAs or strokes, or failure of medical treatment. Endovascular options include intra-arterial stenting, coiling of associated pseudoaneurysms, or more recently, deployment of covered stents.

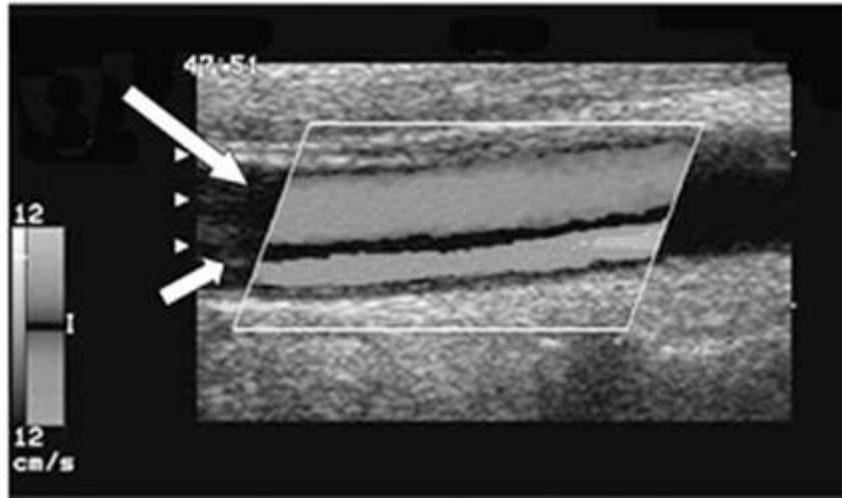

Fig. 13. Carotid ultrasound reveals a patient with a carotid artery dissection in which carotid flow is separated in the true flow lumen (*long arrow*) from the false lumen (*short arrow*).

Carotid Artery Aneurysms

Carotid artery aneurysms are rare, encountered in less than 1% of all carotid operations (Fig. 14). The true carotid artery aneurysm generally is due to atherosclerosis or medial degeneration. The carotid bulb is involved in most carotid aneurysms, and bilaterality is present in 12% of the patients. Patients typically present with a pulsatile neck mass. The available data suggest that, untreated, these aneurysms lead to neurologic symptoms from embolization. Thrombosis and rupture of the carotid aneurysm is rare. Pseudoaneurysms of the carotid artery can result from injury or infection. Mycotic aneurysms often involve syphilis in the past, but are now more commonly associated with peritonsillar abscesses caused by *Staphylococcus aureus* infection. FMD and spontaneous dissection of the carotid artery can lead to the formation of true aneurysms or pseudoaneurysms. Whereas conventional surgery has been the primary mode of treatment in the past, carotid aneurysms are currently being treated more commonly using endovascular approaches.

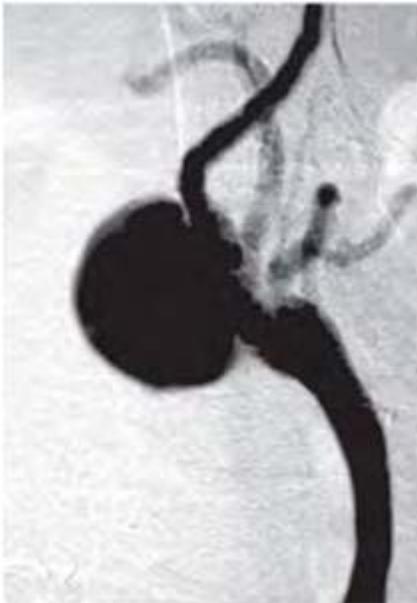

Fig. 14 B. A lateral projection of the carotid artery aneurysm

Fig. 14 C. Following endovascular placement, the carotid artery aneurysm is successfully excluded.

Carotid Body Tumor

The carotid body originates from the third branchial arch and from neuroectodermal-derived neural crest lineage. The normal carotid body is located in the adventitia or periadventitial tissue at the bifurcation of the CCA (Fig. 15). The gland is innervated by the glossopharyngeal nerve. Its blood supply is derived predominantly from the external carotid artery, but also can come from the vertebral artery. Carotid body tumor is a rare lesion of the neuroendocrine system. Other glands of neural crest origin are seen in the neck, parapharyngeal spaces, mediastinum, retroperitoneum, and adrenal medulla. Tumors involving these structures have been referred to as *paraganglioma*, *glomus tumor*, or *chemodectoma*. Approximately 5 to 7% of carotid body tumors are malignant. Although chronic hypoxemia has been invoked as a stimulus for hyperplasia of carotid body, approximately 35% of carotid body tumors are hereditary. The risk of malignancy is greatest in young patients with familial tumors.

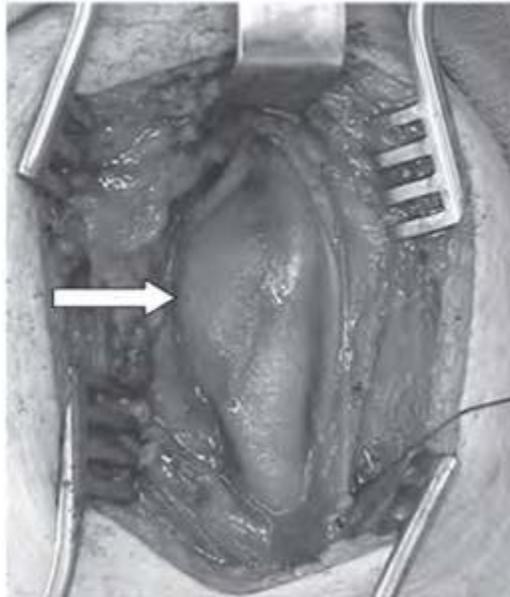

Fig. 15 A. A carotid body tumor (*arrow*) located adjacent to the carotid bulb

Fig. 15 B. Following periadventitial dissection, the carotid body tumor is removed

Symptoms related to the endocrine products of the carotid body tumor are rare. Patients usually present between the fifth and seventh decade of life with an asymptomatic lateral neck mass. The diagnosis of carotid body tumor requires confirmation on imaging studies. Carotid duplex scan can localize the tumor to the carotid bifurcation, but CT or MR imaging usually is required to further delineate the relationship of the tumor to the adjacent structures.

Classically, a carotid body tumor will widen the carotid bifurcation. The Shamblin classification describes the tumor extent: I. tumor is <5 cm and relatively free of vessel involvement; II. tumor is intimately involved but does not encase the vessel wall; and III. tumor is intramural and encases the carotid vessels and adjacent nerves. With good resolution CT and MR imaging, arteriography usually is not required. However, arteriography can provide an assessment of the vessel invasion and intracranial circulation, and allows for preoperative embolization of the feeder vessels, which has been reported to reduce intraoperative blood loss. Surgical resection is the recommended treatment for suspected carotid body tumor.

THORACIC AORTIC ANEURYSM

Introduction

Aneurysmal degeneration can occur anywhere in the human aorta. By definition, an aneurysm is a localized or diffuse dilation of an artery with a diameter at least 50% greater than the normal size of the artery.

A blood vessel has 3 layers: the intima (inner layer made of endothelial cells), media (contains muscular elastic fibers), and adventitia (outer connective tissue). Aneurysms are either true or false. The wall of a true aneurysm involves all 3 layers, and the aneurysm is contained inside the endothelium. The wall of a false or pseudoaneurysm only involves the outer layer and is contained by the adventitia. An aortic dissection is formed by an intimal tear and is contained by the media; hence, it has a true lumen and a false lumen.

Most aortic aneurysms (AA) occur in the abdominal aorta; these are termed abdominal aortic aneurysms (AAA). Although most abdominal aortic aneurysms are asymptomatic at the time of diagnosis, the most common complication remains life-threatening rupture with hemorrhage.

Aneurysmal degeneration that occurs in the thoracic aorta is termed a thoracic aneurysm (TA). Aneurysms that coexist in both segments of the aorta (thoracic and abdominal) are termed thoracoabdominal aneurysms (TAA). Thoracic aneurysms and thoracoabdominal aneurysms are also at risk for rupture. A recent population-based study suggests an increasing prevalence of thoracic aortic aneurysms. Thoracic aortic aneurysms are subdivided into 3 groups depending

on location: ascending aortic, aortic arch, and descending thoracic aneurysms or thoracoabdominal aneurysms. Aneurysms that involve the ascending aorta may extend as proximally as the aortic annulus and as distally as the innominate artery, whereas descending thoracic aneurysms begin beyond the left subclavian artery. Arch aneurysms are as the name implies.

Dissection is another condition that may affect the thoracic aorta. An intimal tear causes separation of the walls of the aorta. A false passage for blood develops between the layers of the aorta. This false lumen may extend into branches of the aorta in the chest or abdomen, causing malperfusion, ischemia, or occlusion with resultant complications. The dissection can also progress proximally, to involve the aortic sinus, aortic valve, and coronary arteries. Dissection can lead to aneurysmal change and early or late rupture. A chronic dissection is one that is diagnosed more than 2 weeks after the onset of symptoms. Dissection should not be termed dissecting aneurysm because it can occur with or without aneurysmal enlargement of the aorta.

The shape of an aortic aneurysm is either saccular or fusiform. A fusiform (or true) aneurysm has a uniform shape with a symmetrical dilatation that involves the entire circumference of the aortic wall. A saccular aneurysm is a localized outpouching of the aortic wall, and it is the shape of a pseudoaneurysm.

Treatment of abdominal aortic aneurysms, thoracoabdominal aneurysms, and thoracic aneurysms involves surgical repair in good-risk patients with aneurysms that have reached a size sufficient to warrant repair. Surgical repair may involve endovascular stent grafting (in suitable candidates) or traditional open surgical repair.

History of the Procedure

The development of treatment modalities for thoracic aneurysms followed successful treatment of abdominal aortic aneurysms. Estes' 1950 report revealed that the 3-y survival rate for patients with untreated abdominal aortic aneurysms was only 50%, with two thirds of deaths resulting from aneurysmal rupture. Since then, increased attempts were made to devise methods of durable repair.

Most of these initial successful repairs involved the use of preserved aortic allografts, thus triggering the establishment of numerous aortic allograft banks. Simultaneously, Gross and colleagues successfully used allografts to treat complex thoracic aortic coarctations, including those with aneurysmal involvement.

In 1951, Lam and Aram reported the resection of a descending thoracic aneurysm with allograft replacement.³ Ascending aortic replacement required the development of cardiopulmonary bypass and was first performed in 1956 by Cooley and DeBakey. They successfully replaced the ascending aorta with an aortic allograft. Successful replacement of the aortic arch, with its inherent risk of cerebral ischemia, was understandably more challenging and was not reported until 1957 by DeBakey et al.

Although the use of aortic allografts as aortic replacement was widely accepted in the early 1950s, the search for synthetic substitutes was well underway. Dacron was introduced by DeBakey. By 1955, Deterling and Bhonslay believed that Dacron was the best material for aortic substitution.⁶ Numerous types of intricately woven hemostatic grafts have since been developed and are now used much more extensively than their allograft counterparts. Such Dacron grafts are used to replace ascending, arch, thoracic, and thoracoabdominal aortic segments.

However, some patients required replacement of the aortic root, as well. Subsequently, combined operations that replaced the ascending aneurysm in conjunction with replacement of the aortic valve and reimplantation of the coronary arteries were performed by Bentall and De Bono in 1968, using a mechanical valve with a Dacron conduit. Ross, in 1962, and Barratt-Boyes, in 1964, successfully implanted the aortic homograft in the orthotopic position. In 1985, Sievers reported the use of stentless porcine aortic roots.

More recently, less invasive therapy for descending thoracic aortic aneurysm have been developed. Dake et al reported the first endovascular thoracic aortic repair in 1994.¹¹ In March 2005, the US Food and Drug Administration (FDA) approved the first thoracic aortic stent graft, the GORE TAG graft (W.L. Gore and Associates; Newark, Del).

Problem

Aneurysms are usually defined as a localized dilation of an arterial segment greater than 50% its normal diameter. Most aortic aneurysms occur in the infrarenal segment (95%). The average size for an infrarenal aorta is 2 cm; therefore, abdominal aortic aneurysms are usually defined by diameters greater than 3 cm.

The normal size for the thoracic and thoracoabdominal aorta is larger than that of the infrarenal aorta, and aneurysmal degeneration in these areas is defined accordingly. The average diameter of the mid-descending thoracic aorta is 26-28 mm, compared with 20-23 mm at the level of the celiac axis.

Frequency

Although findings from autopsy series vary widely, the prevalence of aortic aneurysms probably exceeds 3-4% in individuals older than 65 years.

Death from aneurysmal rupture is one of the 15 leading causes of death in most series. The estimated incidence of thoracic aortic aneurysms is 6 cases per 100,000 person-years. In addition, the overall prevalence of aortic aneurysms has increased significantly in the last 30 years. This is partly due to an increase in diagnosis based on the widespread use of imaging techniques. However, the prevalence of fatal and nonfatal rupture has also increased, suggesting a true increase in prevalence. Population-based studies suggest an incidence of acute aortic dissection of 3.5 per 100,000 persons; an incidence of thoracic aortic rupture of 3.5 per 100,000 persons; and an incidence of abdominal aortic rupture of 9 per 100,000 persons. An aging population probably plays a significant role.

Etiology

Aneurysmal degeneration occurs more commonly in the aging population. Aging results in changes in collagen and elastin, which lead to weakening of the aortic wall and aneurysmal dilation. According to the Laplace law, luminal dilation results in increased wall tension and the vicious cycle of progressive dilation and greater wall stress. Pathologic sequelae of the aging aorta include elastic fiber fragmentation and cystic medial necrosis. Arteriosclerotic (degenerative) disease is the most common cause of thoracic aneurysms.

A previous aortic dissection with a persistent false channel may produce aneurysmal dilation; such aneurysms are the second most common type. False aneurysms are more common in the descending aorta and arise from the extravasation of blood into a tenuous pocket contained by the aortic adventitia. Because of increasing wall stress, false aneurysms tend to enlarge over time.

Aneurysmal degeneration occurs more commonly in the aging population. Aging results in changes in collagen and elastin, which lead to weakening of the aortic wall and aneurysmal dilation. According to the law of Laplace, luminal dilation results in increased wall tension and the vicious cycle of progressive dilation and greater wall stress. Pathologic sequelae of the aging aorta include elastic fiber fragmentation and cystic medial necrosis. Arteriosclerotic (degenerative) disease is the most common cause of thoracic aneurysms.

A previous aortic dissection with a persistent false channel may produce aneurysmal dilation; such aneurysms are the second most common type. False aneurysms are more common in the descending aorta and arise from the extravasation of blood into a tenuous pocket contained by the aortic adventitia. Because of increasing wall stress, false aneurysms tend to enlarge over time.

Authorities strongly agree that genetics play a role in the formation of aortic aneurysms. Of first-degree relatives of patients with aortic aneurysms, 15% have an aneurysm. This appears especially true in first-degree relatives of female patients with aortic aneurysms. Thus, inherited disorders of connective tissue appear to contribute to the formation of aortic aneurysms.

Pathophysiology

The occurrence and expansion of an aneurysm in a given segment of the arterial tree probably involves local hemodynamic factors and factors intrinsic to the arterial segment itself.

The medial layer of the aorta is responsible for much of its tensile strength and elasticity. Multiple structural proteins comprise the normal medial layer of the human aorta. Of these, collagen and elastin are probably the most important. The elastin content of the ascending aorta is high and diminishes progressively in the descending thoracic and abdominal aorta. The infrarenal aorta has a relative paucity of elastin fibers in relation to collagen and compared with the thoracic aorta, possibly accounting for the increased frequency of aneurysms in this area. In

addition, the activity and amount of specific enzymes is increased, which leads to the degradation of these structural proteins. Elastic fiber fragmentation and loss with degeneration of the media result in weakening of the aortic wall, loss of elasticity, and consequent dilation.

Hemodynamic factors probably play a role in the formation of aortic aneurysms. The human aorta is a relatively low-resistance circuit for circulating blood. The lower extremities have higher arterial resistance, and the repeated trauma of a reflected arterial wave on the distal aorta may injure a weakened aortic wall and contribute to aneurysmal degeneration. Systemic hypertension compounds the injury, accelerates the expansion of known aneurysms, and may contribute to their formation.

Hemodynamically, the coupling of aneurysmal dilation and increased wall stress is defined by the law of Laplace. Specifically, the law of Laplace states that the (arterial) wall tension is proportional to the pressure times the radius of the arterial conduit ($T = P \times R$). As diameter increases, wall tension increases, which contributes to increasing diameter. As tension increases, risk of rupture increases. Increased pressure (systemic hypertension) and increased aneurysm size aggravate wall tension and therefore increase the risk of rupture.

Aneurysm formation is probably the result of multiple factors affecting that arterial segment and its local environment.

Presentation

Most patients with aortic aneurysms are asymptomatic at the time of discovery. Thoracic aneurysms are usually found incidentally after chest radiographs or other imaging studies. Abdominal aortic aneurysms may be discovered incidentally during imaging studies or a routine physical examination as a pulsatile abdominal mass.

The most common complication of abdominal aortic aneurysms is rupture with life-threatening hemorrhage manifesting as pain and hypotension. The triad of abdominal pain, hypotension, and a pulsatile abdominal mass is diagnostic of a ruptured abdominal aortic aneurysm, and emergent operation is warranted without delay for imaging studies.

Patients with a variant of abdominal aortic aneurysm may present with fever and a

painful aneurysm with or without an obstructive uropathy. These patients may have an inflammatory aneurysm that can be treated with surgical repair.

Other presentations of abdominal aortic aneurysm include lower extremity ischemia, duodenal obstruction, ureteral obstruction, erosion into adjacent vertebral bodies, aortoenteric fistula (ie, GI bleed), or aortocaval fistula (caused by spontaneous rupture of aneurysm into the adjacent inferior vena cava [IVC]). Patients with aortocaval fistula present with abdominal pain, venous hypertension (ie, leg edema), hematuria, and high output cardiac failure.

Patients with thoracic aneurysms are often asymptomatic. Most patients are hypertensive but remain relatively asymptomatic until the aneurysm expands. Their most common presenting symptom is pain. Pain may be acute, implying impending rupture or dissection, or chronic, from compression or distension. The location of pain may indicate the area of aortic involvement, but this is not always the case. Ascending aortic aneurysms tend to cause anterior chest pain, while arch aneurysms more likely cause pain radiating to the neck. Descending thoracic aneurysms more likely cause back pain localized between the scapulae. When located at the level of the diaphragmatic hiatus, the pain occurs in the mid back and epigastric region.

Large ascending aortic aneurysms may cause superior vena cava obstruction manifesting as distended neck veins. Ascending aortic aneurysms also may develop aortic insufficiency, with widened pulse pressure or a diastolic murmur, and heart failure. Arch aneurysms may cause hoarseness, which results from stretching of the recurrent laryngeal nerves. Descending thoracic aneurysms and thoracoabdominal aneurysms may compress the trachea or bronchus and cause dyspnea, stridor, wheezing, or cough. Compression of the esophagus results in dysphagia. Erosion into surrounding structures may result in hemoptysis, hematemesis, or gastrointestinal bleeding. Erosion into the spine may cause back pain or instability. Spinal cord compression or thrombosis of spinal arteries may result in neurologic symptoms of paraparesis or paraplegia. Descending thoracic aneurysms may thrombose or embolize clot and atheromatous debris distally to visceral, renal, or lower extremities.

Patients who present with ecchymoses and petechiae may be particularly challenging because these signs probably indicate disseminated intravascular coagulation (DIC). The risk of significant perioperative bleeding is extremely high, and large amounts of blood and blood products must be available for resuscitative transfusion.

The most common complications of thoracic aortic aneurysms are acute rupture or dissection. Some patients present with tender or painful nonruptured aneurysms. Although debate continues, these patients are thought to be at increased risk for rupture and should undergo surgical repair on an emergent basis.

Marfan syndrome is a potentially lethal connective-tissue disease characterized by skeletal, heart valve, and ocular abnormalities. Individuals with this disease are at risk for aneurysmal degeneration, especially in the thoracic aorta. Marfan syndrome is an autosomal dominant genetic condition that results in abnormal fibrillin, a structural protein found in the human aorta. Patients with Marfan syndrome may develop annuloaortic ectasia of the sinuses of Valsalva, commonly associated with aortic valvular insufficiency and aneurysmal dilation of the ascending aorta.

Type IV Ehlers-Danlos syndrome results in a deficiency in the production of type III collagen, and individuals with this disease may develop aneurysms in any portion of the aorta. Imbalances in the synthesis and degradation of structural proteins of the aorta have also been discovered, which may be inherited or spontaneous mutations.

Atherosclerosis may play a role. Whether atherosclerosis contributes to the formation of an aneurysm or whether they occur concomitantly is not established. Other causes of aortic aneurysms are infection (ie, bacterial [mycotic or syphilitic]), arteritis (ie, giant cell, Takayasu, Kawasaki, Behçet), and trauma. Aortitis due to granulomatous disease is rare, but it can lead to the formation of aortic and, on occasion, pulmonary artery aneurysms. Aortitis caused by syphilis may cause destruction of the aortic media followed by aneurysmal dilation.

Traumatic dissection is a result of shearing from deceleration injury due to high speed motor vehicle accidents (MVA) or a fall from heights. The dissection occurs at a point of fixation, usually at the aortic isthmus (ie, at the ligamentum arteriosum, distal to the origin of the left subclavian artery), the ascending aorta, the aortic root, and the diaphragmatic hiatus.

The true etiology of aortic aneurysms is probably multifactorial, and the condition occurs in individuals with multiple risk factors. Risk factors include smoking, chronic obstructive pulmonary disease (COPD), hypertension, atherosclerosis, male gender, older age, high BMI, bicuspid or unicuspid aortic valves, genetic disorders, and family history. Aortic

aneurysms are more common in men than in women and are more common in persons with COPD than in those without lung disease.

Indications

Indications for surgery of thoracic aortic aneurysms are based on size or growth rate and symptoms. Because the risk of rupture is proportional to the diameter of the aneurysm, aneurysmal size is the criterion for elective surgical repair. Elefteriades published the natural history of thoracic aortic aneurysms and recommends elective repair of ascending aneurysms at 5.5 cm and descending aneurysms at 6.5 cm for patients without any familial disorders such as Marfan syndrome. These recommendations are based on the finding that the incidence of complications (rupture and dissection) exponentially increased when the size of the ascending aorta reached 6.0 cm (31% risk of complications) or when the size of the descending aorta reached 7.0 cm (43% risk).^{15,14} Patients with Marfan syndrome or familial aneurysms should undergo earlier repair, when the ascending aorta grows to 5.0 cm or the descending aorta grows to 6.0 cm.

In addition, relative aortic aneurysm size in relation to body surface area may be more important than absolute aortic size in predicting complications.¹⁶ Using the aortic size index (ASI) of aortic diameter (in cm) divided by body surface area (m²), patients are stratified into 3 groups: ASI <2.75 cm/m² are at low risk for rupture (4%/y), ASI 2.75-4.25 cm/m² are at moderate risk (8%/y), and ASI >4.25cm/m² are at high risk (20-25%/y).

Rapid expansion is also a surgical indication. Growth rates average 0.07 cm/y in the ascending aorta and 0.19 cm/y in the descending aorta.¹⁴ A growth rate of 1 cm/y or faster is an indication for elective surgical repair.

Symptomatic patients should undergo aneurysm resection regardless of size. Acutely symptomatic patients require emergent operation. Emergent operation is indicated in the setting of acute rupture. Rupture of the ascending aorta may occur into the pericardium, resulting in acute tamponade. Rupture of the descending thoracic aorta may cause a left hemothorax.

Patients with acute aortic dissection of the ascending aorta require emergent operation. They may present with rupture, tamponade, acute aortic insufficiency, myocardial infarction, or

end-organ ischemia. Acute dissection of the descending aorta does not require surgical intervention, unless complicated by rupture, malperfusion (eg, visceral, renal, neurologic, leg ischemia), progressive dissection, persistent recurrent pain, or failure of medical management.

Patients who undergo surgery for symptomatic aortic insufficiency or stenosis with an associated enlarged aneurysmal aorta should have concomitant aortic replacement if the aorta reaches 5 cm in diameter. Concomitant aortic replacement should be considered for patients with bicuspid aortic valves with an aorta >4.5 cm in diameter.

Summary of indications

Aortic size

Ascending aortic diameter ≥ 5.5 cm or twice the diameter of the normal contiguous aorta

Descending aortic diameter ≥ 6.5 cm

Subtract 0.5 cm from the cutoff measurement in the presence of Marfan syndrome, family history of aneurysm or connective tissue disorder, bicuspid aortic valve, aortic stenosis, dissection, patient undergoing another cardiac operation

Growth rate ≥ 1 cm/y

Symptomatic aneurysm

Traumatic aortic rupture

Acute type B aortic dissection with associated rupture, leak, distal ischemia

Pseudoaneurysm

Large saccular aneurysm

Mycotic aneurysm

Aortic coarctation

Bronchial compression by aneurysm

Aortobronchial or aorto-esophageal fistula

Relevant Anatomy

Ascending aortic aneurysms occur as proximally as the aortic annulus and as distally as the innominate artery. They may compress or erode into the sternum and ribs, causing pain or fistula. They also may compress the superior vena cava or airway. When symptomatic by rupture or dissection, they may involve the pericardium, aortic valve, or coronary arteries. They

may rupture into the pericardium, causing tamponade. They may dissect into the aortic valve, causing aortic insufficiency, or into the coronary arteries, causing myocardial infarction.

Aortic arch aneurysms involve the aorta where the innominate artery, left carotid, and left subclavian originate. They may compress the innominate vein or airway. They may stretch the left recurrent laryngeal nerve, causing hoarseness.

Descending thoracic aneurysms originate beyond the left subclavian artery and may extend into the abdomen. Thoracoabdominal aneurysms are stratified based on the Crawford classification. Type I involves the descending thoracic aorta from the left subclavian artery down to the abdominal aorta above the renal arteries. Type II extends from the left subclavian artery to the renal arteries and may continue distally to the aortic bifurcation. Type III begins at the mid-to-distal descending thoracic aorta and involves most of the abdominal aorta as far distal as the aortic bifurcation. Type IV extends from the upper abdominal aorta and all or none of the infrarenal aorta. Descending thoracic aneurysms and thoracoabdominal aneurysms may compress or erode into surrounding structures, including the trachea, bronchus, esophagus, vertebral body, and spinal column.

Contraindications

Aneurysm surgery has no strict contraindications. The relative contraindications are individualized, based on the patient's ability to undergo extensive surgery (ie, the risk-to-benefit ratio). Patients at higher risk for morbidity and mortality include elderly persons and individuals with end-stage renal disease, respiratory insufficiency, cirrhosis, or other comorbid conditions. For descending thoracic aneurysms, endovascular stent grafting is less invasive and is an ideal alternative (with appropriate anatomic considerations) to open repair for patients at high risk for complications of open repair. Stent grafts are also a reasonable alternative (with the appropriate anatomy) to open repair in patients who are not at high risk for complications. Patients must understand that life-long follow-up is required and that long-term durability is unknown.

Laboratory Studies

CBC count

Electrolyte evaluation and BUN/creatinine value: Determining renal function is important for stratifying morbidity.

Prothrombin time, international normalized ratio, and activated partial thromboplastin time

Blood type and crossmatch

Liver function tests and amylase lactate values: These tests are indicated for patients with acute dissection or risk of distal embolization.

Imaging Studies

Chest radiograph

In the case of ascending aortic aneurysms, chest x-rays may reveal a widened mediastinum, a shadow to the right of the cardiac silhouette, and convexity of the right superior mediastinum. Lateral films demonstrate loss of the retrosternal air space. However, the aneurysms may also be completely obscured by the heart, and the chest x-ray appear normal.

Plain chest radiographs may show a shadow anteriorly and slightly to the left for arch aneurysms and posteriorly and to the left for descending thoracic aneurysms. Aortic calcification may outline the borders of the aneurysm in the anterior, posterior, and lateral views in both the chest and abdomen.

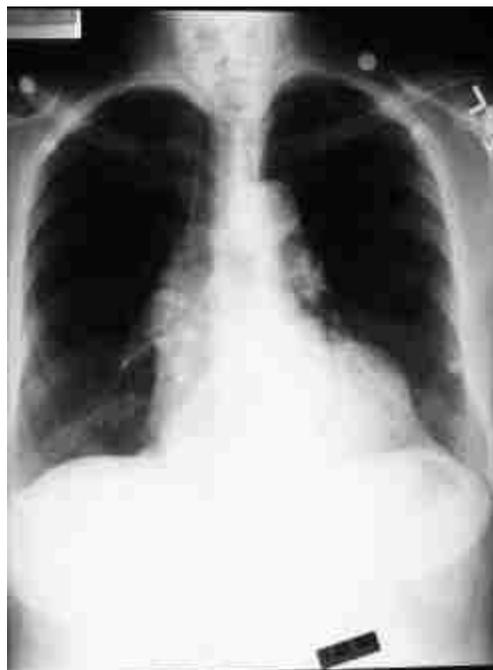

Fig. 16. Chest radiograph following aneurysm surgery

Echocardiography

Transthoracic echocardiography demonstrates the aortic valve and proximal aortic root. It may help detect aortic insufficiency and aneurysms of the sinus of Valsalva, but it is less sensitive and specific than transesophageal echocardiography.

Transesophageal echocardiography images show the aortic valve, ascending aorta, and descending thoracic aorta, but they are limited in the area of the distal ascending aorta, transverse aortic arch, and upper abdominal aorta. Transesophageal echocardiography can help accurately differentiate aneurysm and dissection, but the images must be obtained and interpreted by skilled personnel.

Ischemia may be evaluated using dipyridamole-thallium or dobutamine echocardiography scans.

Ultrasonography

Infrarenal abdominal aortic aneurysms may be visualized using ultrasonography, but these images do not help define the extent for thoracoabdominal aneurysms.

Carotid ultrasound may be needed for patients with carotid bruits, peripheral vascular disease, a history of transient ischemic attacks, or cerebrovascular accidents to evaluate for carotid disease.

Intraoperative intravascular ultrasound (IVUS) can also be used to provide additional anatomical information and guidance during placement of endovascular stents.

Intraoperative epiaortic ultrasound can be performed to scan the aorta for atherosclerotic disease or thrombus.

Aortography

Aortography images can delineate the aortic lumen, and they can help define the extent of the aneurysm, any branch vessel involvement, and the stenosis of branch vessels. It describes the takeoff of the coronary ostia.

For patients older than 40 years or those with a history suggestive of coronary artery disease, aortography helps evaluate coronary anatomy, ventricular function by ventriculography,

and aortic insufficiency. It does not help in defining the size of the aneurysm because the outer diameter is not measured, which may miss dissections.

Disadvantages include the use of nephrotoxic contrast and radiation. The risk of aortography includes embolization from laminated thrombus and carries a 1% stroke risk.

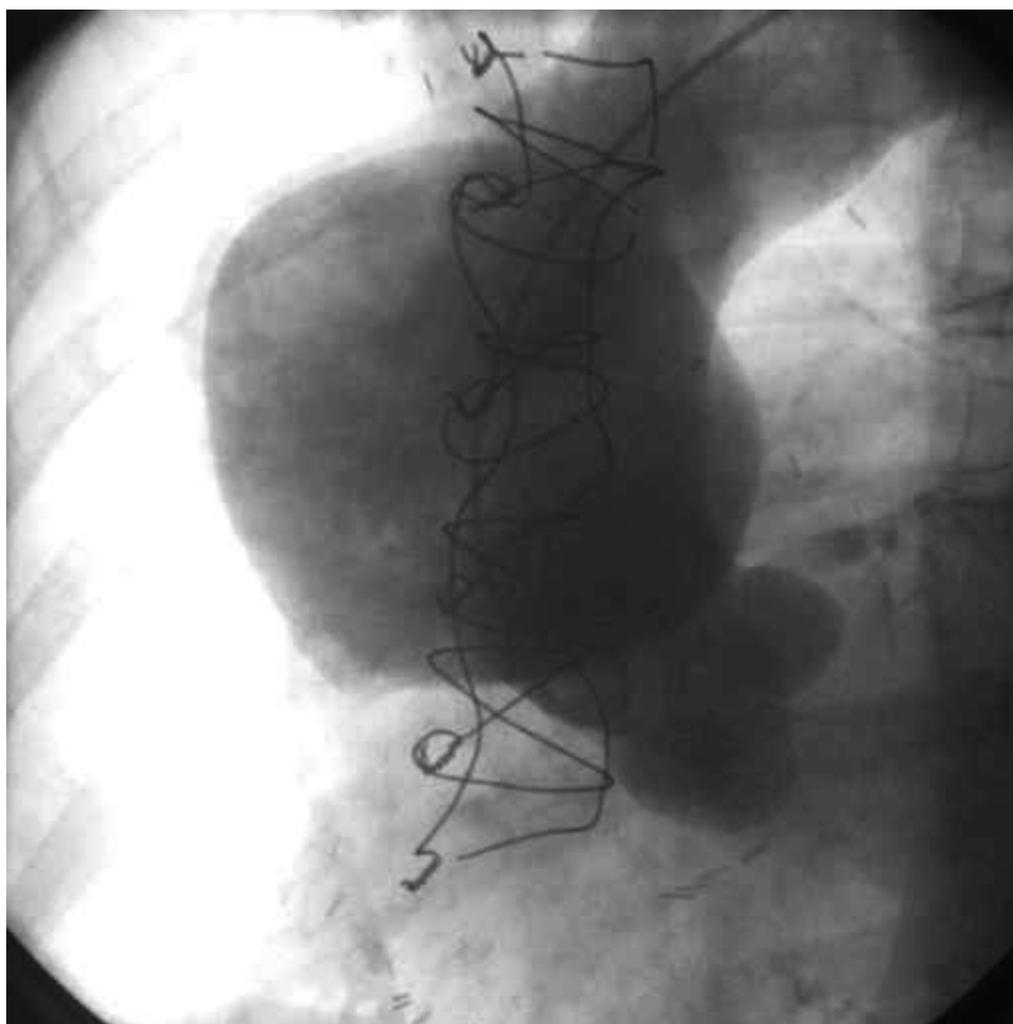

Fig.17. Ascending aortogram showing ascending aortic aneurysm
Computed tomography scan

CT scans with contrast have become the most widely used diagnostic tool. They rapidly and precisely evaluate the thoracic and abdominal aorta to determine the location and extent of the aneurysm and the relationship of the aneurysm to major branch vessels and surrounding structures. They can help accurately determine the size of the aneurysm and assesses dissection, mural thrombus, intramural hematoma, free rupture, and contained rupture with hematoma.

Sagittal, coronary, and axial images may be obtained with 3-dimensional reconstruction. Stent graft planning for endovascular descending thoracic aneurysm repairs requires fine-cut images from the neck through the pelvis to the level of the femoral heads. The takeoff of the arch vessels is critical to determine the adequacy of the proximal landing zone, as is assessing the patency of the vertebral arteries, if the left subclavian artery should be covered by the stent graft. Assessment of the common femoral artery access is essential to determine the feasibility of large-bore sheath access. A spiral CT scan with 1-mm cuts and 3-dimensional reconstruction with the ability to make centerline measurements is crucial to stent graft planning.

CT angiography may create multiplanar reconstructions and cines. This requires nephrotoxic contrast and radiation, but the procedure is noninvasive.

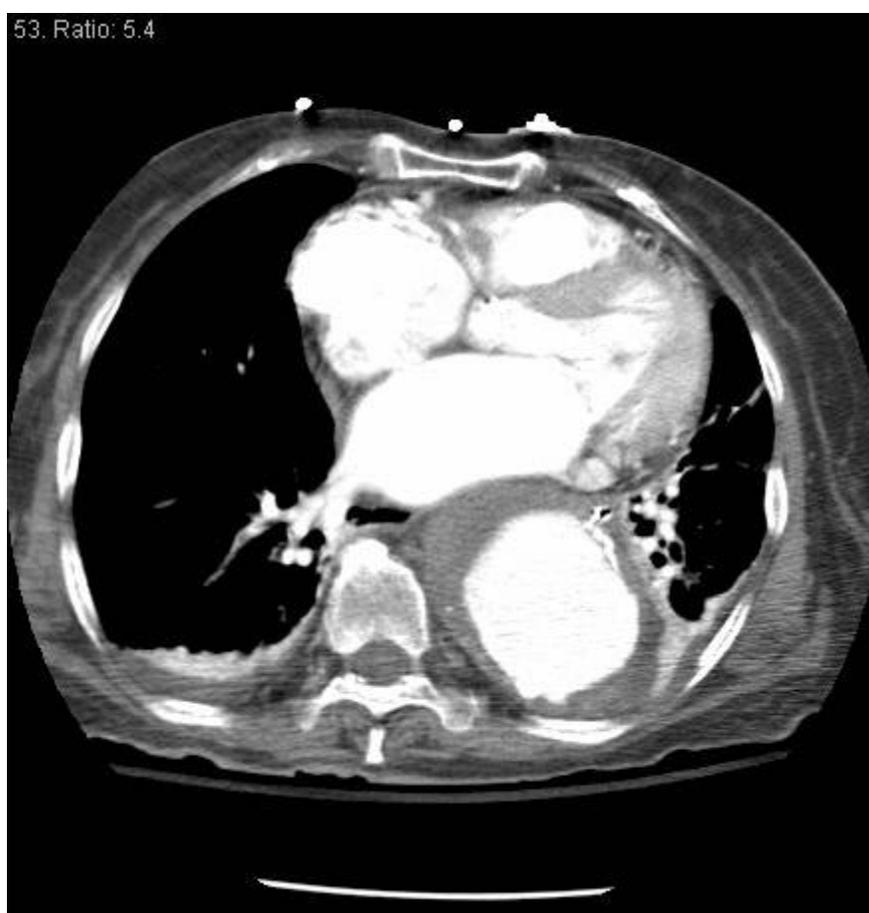

Fig.18. Descending thoracic aortic aneurysm with mural thrombus at the level of the left atrium

Magnetic resonance imaging

MRI and magnetic resonance angiography have the advantage of avoiding nephrotoxic

contrast and ionizing radiation compared with CT scans.

MRI and magnetic resonance angiography can also help accurately demonstrate the location, extent, and size of the aneurysm and its relationship to branch vessels and surrounding organs. These studies also precisely reveal aortic composition. However, they are more time consuming, less readily available, and more expensive than CT scans.

Other Tests

Electrocardiogram: Baseline ECG should be performed. Transthoracic echocardiograms noninvasively screen for valvular abnormalities and cardiac function.

Pulmonary function tests: Patients with a smoking history and COPD should be evaluated using pulmonary function tests with spirometry and room-air arterial blood gas determinations.

Diagnostic Procedures

Cardiac catheterization: Patients with a history of coronary artery disease or those older than 40 years should undergo cardiac catheterization.

Histologic Findings

Histologic findings may include elastic fiber fragmentation, loss of elastic fibers, loss of smooth muscle cells, cystic medial necrosis, intraluminal thrombus, and atherosclerotic plaque and ulceration.

Treatment

Medical Therapy

All aneurysms must be treated with risk-factor reduction. Systemic hypertension probably contributes to the formation of aneurysms and certainly contributes to expansion and rupture. This is especially true of thoracic aneurysms. Strict control of hypertension is implemented in all patients, regardless of aortic aneurysm size.

Tobacco use contributes to aneurysm formation, although the exact pathophysiology is not well understood. Cessation of smoking is recommended. Control of other risk factors for

peripheral arterial obstructive disease may be beneficial.

For acute aortic dissections, the first-line treatment of hypertension is with a short-acting beta-blocker (eg, esmolol). Beta blockade decreases the force of contraction, thus decreasing the dP/dt and shear force exerted on the dissection by minimizing the rate of rise of the aortic pressure. It also decreases the heart rate and the inotropic state of the myocardium, and reduces the likelihood of propagation of the dissection. A second-agent added is a vasodilator (eg, nitroprusside), which reduces the systolic blood pressure to, in turn, decrease the aortic wall stress and the possibility of rupture.

Surgical Therapy

Most aneurysm repairs involve aortic replacement with a Dacron tube graft. Dacron grafts allow ingrowth in the interstices to form a pseudoendothelial layer to minimize the risk of embolization. They may be knitted or woven. Knitted grafts are more porous and incorporate tissue well; however, they are prone to more bleeding. Woven grafts are more impervious and therefore are the most commonly used for aortic replacement. Grafts are typically impregnated with collagen to avoid preclotting the graft and to promote optimal healing.

Ascending aortic aneurysms

Surgical treatment of ascending aortic aneurysms depends on the extent of the aneurysm both proximally (eg, involvement of the aortic valve, annulus, sinuses of Valsalva, sinotubular junction, coronary orifices) and distally (eg, involvement to the level of the innominate artery). The choice of operation also depends on the underlying pathology of the disease, the patient's life expectancy, the desired anticoagulation status, and the surgeon's experience and preference.

Ascending aortic aneurysms with normal aortic valve leaflets, annulus, and sinuses of Valsalva are typically replaced with a simple supracoronary Dacron tube graft from the sinotubular junction to the origin of the innominate artery, with the patient under cardiopulmonary bypass.

If the aortic valve is diseased but the aortic sinuses and annulus are normal, the aortic valve is replaced separately and the ascending aortic aneurysm is replaced with a supracoronary

synthetic graft, leaving the coronary arteries intact (ie, Wheat procedure).

Sinus of Valsalva aneurysms with normal aortic valve leaflets and aortic insufficiency due to dilated sinuses may be repaired with a valve-sparing aortic root replacement. Two valve-sparing procedures have been developed: the remodeling method and the reimplantation method. The remodeling method involves resecting the aneurysmal sinus tissue while maintaining the tissue along the valve leaflets and scalloping the Dacron graft to form new sinuses to remodel the root. The reimplantation method involves reimplanting the scalloped native valve into the Dacron graft. Both require reimplantation of the coronary ostia into the Dacron graft.

Patients with an abnormal aortic valve and aortic root require aortic root replacement (ARR). In nonelderly patients who can undergo anticoagulation with reasonable safety, the aortic root may be replaced with a composite valve-graft consisting of a mechanical valve inserted into a Dacron graft coronary artery reimplantation (eg, classic or modified Bentall procedure, Cabrol procedure).

For elderly patients, young active patients who do not desire anticoagulation, women of childbearing age, and patients with contraindications to warfarin, the options include stentless porcine roots, aortic homografts, and pulmonary autografts (ie, Ross procedure). For elderly patients who cannot undergo a complex operation, another option is reduction aortoplasty (ie, wrapping of the ascending aorta with a prosthetic graft).

Patients with Marfan syndrome have abnormal aortas and cannot undergo tube graft replacement alone. They must have either a valve-sparing aortic root replacement or a complete aortic root replacement.

Aortic root replacement with a homograft is ideal in the setting of aortic root abscess from endocarditis.

Aortic arch aneurysms

Arch aneurysms pose a formidable technical challenge. Deep hypothermic circulatory arrest (DHCA) with or without antegrade or retrograde cerebral perfusion is usually used to

facilitate reanastomosis of the arch vessels. Aortic arch reconstruction techniques vary depending on the arch pathology.

In patients with proximal arch involvement extending from the ascending aorta, a hemiarch replacement may be performed. The ascending aorta is replaced with a Dacron graft beveled as a tongue along the undersurface of the arch. In patients whose conditions mandate replacement of the entire arch, the distal anastomosis is the Dacron graft to the descending thoracic aorta. The head vessels are reimplemented individually or as an island. Grafts have been developed with a trifurcated head-vessel attachment and with a fourth attachment for the cannula. In this case, the head vessels are attached individually to the trifurcated branches.

For patients in whom the arch replacement is part of a staged procedure, preceding the delayed repair of a concomitant descending thoracic aneurysm, an "elephant trunk" is used. That is, the Dacron graft used to reconstruct the transverse arch ends distally in an extended sleeve that is telescoped into the descending thoracic aorta, facilitating later replacement of the descending thoracic/abdominal aneurysm (2-stage procedure).

Descending thoracic aortic aneurysms and thoracoabdominal aneurysms

Descending thoracic aneurysms may be repaired with open surgery or, if appropriate, with endovascular stent grafting techniques. Stent graft repair of descending thoracic aortic aneurysms should be performed if the predicted operative risk is lower than that of an open repair. Patient age, comorbidities, symptoms, life expectancy, aortic diameter, characteristics and extent of the aneurysm, and landing zones, should also be taken into consideration.

Surgically, descending thoracic aneurysms may be repaired with or without the use of a bypass circuit from the left atrium to the femoral artery or femoral vein–femoral artery cardiopulmonary bypass, depending on the length of the anticipated ischemic cross-clamping and the experience of the surgeon. Discrete aneurysms with an anticipated clamp time of less than 30 minutes may be repaired without left heart or cardiopulmonary bypass (ie, "clamp and go" technique). More complex or larger aneurysms are probably safer to repair with the aid of either left heart, partial, or full cardiopulmonary bypass with hypothermic circulatory arrest. The use of left heart or cardiopulmonary bypass is favored to reduce hemodynamic instability and the risk of spinal cord paraplegia.

Descending thoracic aneurysms with the appropriate anatomy may now be repaired by endovascular stent grafts. The GORE TAG is an FDA-approved nitinol-based stent graft designed for descending thoracic aneurysm repair. An appropriate proximal neck of 2 cm prior to the aneurysm is required. Ideally, the proximal landing zone is beyond the left subclavian artery, though, in some circumstances, the stent may be placed proximal to the left subclavian artery. Distally, a sufficient landing zone of 2 cm prior to the celiac artery is required. The aortic inner neck diameters in the proximal and distal landing zones must fall within 23-37 mm. In addition, appropriately sized femoral and iliac arteries (typically >8 mm in diameter) that lack tortuosity and calcium are required for implantation.

The GORE TAG graft has been FDA-approved since March 2005. More recently, the Zenith TX2 endovascular graft (Cook Medical Inc.; Bloomington, Ind) was approved in March 2008, followed by the Talent Thoracic Stent Graft (Medtronic Inc.; Minneapolis, Minn) in June 2008.^{29,30} The Valiant Thoracic Stent Graft (Medtronic Inc.; Minneapolis, Minn) is approved for use outside the United States.

Thoracoabdominal aneurysms, comprising approximately 10% of thoracic aneurysms, may be repaired with the use of a partial bypass of the left atrium to the femoral artery. Crawford type I thoracoabdominal aneurysms involve Dacron graft replacement of the aorta from the left subclavian artery to the visceral and renal arteries as a beveled distal anastomosis, using sequential cross-clamping of the aorta. Crawford type II thoracoabdominal aneurysm repair requires a Dacron graft from the left subclavian to the aortic bifurcation with reattachment of the intercostal arteries, visceral arteries, and renal arteries. Crawford type III or IV thoracoabdominal aneurysm repairs, which begin lower along the thoracic aorta or upper abdominal aorta, may use either the partial bypass of the left atrial artery to the femoral artery or a modified atrio-visceral and/or renal bypass. Prevention of paraplegia is one of the principal concerns in the repair of descending and thoracoabdominal aneurysms.

Under investigational trials, Dr. Timothy Chuter at the University of California at San Francisco Medical Center and Dr. Roy Greenberg at the Cleveland Clinic have treated thoracoabdominal aneurysms using custom-built fenestrated and branched stent grafts. Such devices require precise anatomic tailoring of the grafts to the specific patient's anatomy for placement of the scallops (for visceral flow) or branches (for direct stenting into the visceral

vessels).

Preoperative Details

Ascending aortic aneurysm

Preoperative assessment of coronary artery disease is essential to determine the need for concomitant coronary artery bypass grafting. Transesophageal echocardiography is crucial preoperatively to examine the need for aortic valve replacement. Patients with aortic stenosis or aortic insufficiency in whom the valve leaflets are anatomically abnormal require replacement, whereas patients with aortic insufficiency and normal aortic valve leaflets may be candidates for valve-sparing procedures. Transesophageal echocardiography is valuable for accurate delineation of the aortic root at the sinuses of Valsalva and sinotubular junction.

Aortic arch aneurysm

The major morbidities from aortic arch aneurysm repair are neurologic, cardiac, and pulmonary in nature. All patients require preoperative assessment of cardiac function and evaluation for coronary artery disease. In the operating room, transesophageal echocardiography is used to monitor ventricular function and to assess for atherosclerosis of the aorta.

A major concern in arch surgery is neurologic injury, both transient neurologic dysfunction and permanent neurologic injury. Patients with a higher risk of stroke undergo preoperative noninvasive carotid ultrasound, and those with a history of stroke undergo a brain CT scan. In the operating room, steroids are often given at the onset of the procedure if hypothermic circulatory arrest is anticipated. Evidence suggests that steroids given preoperatively several hours before the operation may have benefit. Some institutions monitor electroencephalogram silence to assess for adequate duration and temperature of cerebral cooling for hypothermic circulatory arrest.

Descending thoracic aneurysms and thoracoabdominal aneurysms

A devastating complication of descending thoracic aneurysm and thoracoabdominal

aneurysm repair is spinal cord injury with paraparesis or paraplegia. Preoperatively, some groups perform spinal arteriograms to attempt to localize the artery of Adamkiewicz for reimplantation during surgery. Neurologic monitoring with somatosensory evoked potentials or motor evoked potentials is used by some to assess spinal cord ischemia and identify critical segmental arteries for spinal cord perfusion. Lastly, preoperative placement of catheters for cerebrospinal fluid drainage is performed to increase spinal cord perfusion pressure during aortic cross-clamping.

Spinal cord injury is less prevalent with endovascular stent grafting than with open repair but exists with both types of surgical treatment.^{24,25,27,28} For endovascular stent grafting, cerebrospinal fluid (CSF) drainage and avoidance of hypotension are the primary mechanisms used to prevent paraplegia. The use of CSF drainage is selective among most centers. For some discrete aneurysms, stent graft coverage may allow for preservation of spinal arteries. Others require coverage of the entire descending thoracic aorta. Indications for use of CSF drains include anticipated endograft coverage of T9-T12, coverage of the long segment of the thoracic aorta, compromised collateral pathways from prior infrarenal AAA repair, and symptomatic spinal ischemia.

Brain protection

Methods used for brain protection during deep hypothermic circulatory arrest (DHCA) include intraoperative EEG monitoring, evoked somatosensory potential monitoring, hypothermia (to temperatures <20°C), packing the patient's head in ice, Trendelenburg positioning (ie, head down), mannitol, CO₂ flooding, thiopental, steroids, and antegrade and retrograde cerebral perfusion.

Intraoperative Details

General monitoring and anesthesia

Venous access is obtained with 2 large-bore peripheral IVs and a central line. Filling pressures and cardiac output monitoring are performed with a pulmonary artery catheter. Continuous blood pressure monitoring is performed with a radial arterial line. Nasopharyngeal and bladder probes monitor systemic temperature. Intraoperative transesophageal

echocardiography is used to assess myocardial and valvular function.

Ascending aortic replacement

Cardiopulmonary bypass is established and the aorta is cross-clamped just below the innominate artery. The heart is arrested with cardioplegia. The aorta is transected at the sinotubular junction and sized for the appropriate Dacron tube graft. The tube graft is sutured to the proximal aorta with running 4-0 Prolene with a strip of felt. The tube graft is measured to length distally and sutured to the distal aorta using running 4-0 Prolene with a strip of felt.

Valve-sparing aortic root replacement

Once the aorta is transected at the sinotubular junction, the valve is inspected for normal anatomy. If sparing is feasible, the appropriate size tube graft is chosen to allow coaptation of the aortic valve leaflets without aortic insufficiency. In the remodeling technique, the tube graft is tailored to form aortic sinuses. The sinuses of Valsalva of the native aorta are removed, and the coronary ostia are mobilized. The neosinuses of the tube graft are sutured to the scalloped aortic valve with running 4-0 Prolene and a strip of felt.

In the reimplantation technique, Tycron sutures are placed along the subannular horizontal plane and passed through the tube graft. The scalloped aortic valve is placed within the tube graft, and the proximal suture line is secured. The scalloped aortic valve is positioned in the graft to achieve valve competence, and the subcoronary suture line along the scalloped valve is performed with running 4-0 Prolene. The valve is examined for competence within the graft. The coronary ostia are reimplanted in the graft. The graft is measured to length distally and sutured to the distal aorta.
